After all the threats and critical assets (and the consequences of their loss) were defined, the TA team began the process of determining the vulnerabilities of the security systems protecting those assets at NEIDL at each of the three locations to ultimately calculate the baseline risk at each of the three locations. In security assessments, vulnerabilities are defined as the measure of the likelihood of a specific adversary and its ability to cause damage to an identified asset or target. The method for determining vulnerabilities, therefore, involved developing specific scenarios that tested the ability of NEIDL security systems (which included hardware, software, procedures, and personnel) to prevent an adversary from accomplishing their mission against a specific target. The process involved using the threat spectrum developed for each of the three regions and the targeting analysis for the high-value, critical assets to evaluate the probability of success. The higher the vulnerability (i.e., the less effective the systems in place are at protecting a specific asset), the higher the risk to the facility.

The current NEIDLs' security system (which included both physical and operational elements) was used to simulate the vulnerabilities and calculate the risk of occurrence for a specified adversary, target, and consequence (i.e., for each identified scenario). The security system advantage of the security system in place allowed the team to quantify the vulnerabilities identified to provide the basis for mitigation strategies to reduce the risk to the facility. That evaluation identified two potential mitigations strategies:

- Vulnerabilities that must be mitigated with NEIDL at its actual location;
- Vulnerabilities that would need to be mitigated if the facility were at one of the other two comparable sites.

A *baseline* operational security environment (i.e., the security system in place at NEIDL) was defined to evaluate the threat-consequence scenarios and to identify necessary risk mitigation features on the basis of vulnerabilities identified during the analysis of the scenarios. The baseline conditions are outlined in the TA and provide the framework for measuring the effectiveness of NEIDL controls and barriers against the defined threats and the potential consequences related to the loss of critical assets. The same NEIDL-specific baseline security system components were used to model the conditions at the comparable sites.

The baseline model for developing the NEIDL TA defines the operational security configuration on the basis of existing features at the facility. The individual components of the baseline security system model are categorized by the physical protection system functions of deterrence, detection, delay, and response. The system effectiveness was determined for each scenario and then used to calculate a failure probability for each scenario.

The TA includes the analysis of threat-consequence scenarios against the identified high-consequence assets with site-specific responses to determine risk from the facility being at any one of the three sites. In addition, as vulnerabilities were identified that increased the risk, mitigation strategies were developed and additional risk calculations performed to demonstrate a lower mitigated risk.

6.6.1 Overview of Threat-Consequence Scenarios

The BRP concluded that additional studies were needed to adequately address judicial requests and concerns of the public and as a result made general and specific recommendations with regard to the agents and scenarios to be studied and the methodologies for risk assessment. The BRP also indicated that the scenarios evaluated should include the possibility of exposures resulting from malevolent actions. The following types of scenarios involving malevolent actions were recommended for study by the BRP:

- Internal breach of security, such as release/exposure due to malevolent actions;
- External breach of security, such as a terrorist attack.

The TA team developed realistic, reality-based scenarios keeping in mind the *worst-case* possibility, as required by the BRP as the framework for NIH BRP deliberations.

To identify vulnerabilities associated with the NEIDL security systems at the three comparable sites, adversary- and target-specific scenarios were developed to represent the theoretical risks associated with a site location and its physical and operation security systems. The number of site-specific, threat-consequence scenarios developed was based on the range of adversaries identified, the critical assets'

1 value, and the identified security system vulnerabilities. The vulnerability variable, V , in the security risk
2 equation was ultimately determined by specifically modeling the effectiveness of the in-place physical
3 and operational security systems and subsystems for specific threat-consequence scenarios. The identified
4 vulnerabilities then become the best estimate of the security system's effectiveness in terms of a
5 probability of an adversary attack being a success (Garcia 2006).

6
7 The adversary-consequence scenarios were reviewed by BU Police Department personnel and the BU
8 executive director of Public Safety and determined to be credible bounding scenarios. In addition,
9 developing NEIDL's baseline security system model (i.e., the description of the systems planned and in
10 place) was developed and based on on-site observations and research of the security systems' ability to
11 deter, detect, delay, and respond to a threat.

12
13 The potential for terrorists, extremists, criminals, malicious employees, and persons with psychopathic
14 tendencies were all considered in developing specific threat-consequence scenarios for analysis. The
15 evaluation of those scenarios was based on the site-specific adversaries in the three comparable
16 geographic areas. The intended target (i.e., the high-value, critical asset determined to be most attractive
17 to each specific adversary by the target attractiveness evaluation) was assigned to the scenarios with
18 regional relevance on the basis of the adversaries' capabilities in the region and the relative value of the
19 various targets for each adversary.

20
21 Tables 6-1 and 6-2 provide a general description of the scenarios that were developed for insider and
22 outsider threat analysis, respectively. Table 6-3 provides a general description of the scenarios that
23 involved insiders in collusion with an outsider. Those scenarios were reviewed by the BU executive
24 director of Public Safety and NIH security specialists within the Office of Research Services and were
25 determined to be *realistic and credible bounding*.

1

Table 6-1. Insider Scenarios Relative to BRP Requirements for Evaluation

Scenario	Adversary–Objective–Tactic
Scenario 1. Threatened or Actual Release of Pathogen into the Environment	Adversary: Disgruntled employee Objective: Intentional release of pathogen to cause harm Tactic: Surreptitious removal and release of pathogen
Scenario 2. Loss of Mission	Adversary: Disgruntled employee Objective: To cause financial harm or facility destruction Tactic: Sabotage the facility containment system(s) or lab work areas
Scenario 3. Simple Theft	Adversary: Employee (criminal) Objective: Monetary gain Tactic: Using deceit or stealth entry to gain access to the facility and steal a pathogen
Scenario 4. Loss of Laboratory Personnel	Adversary: Disgruntled employee (psychotic active shooter) Objective: Kill researchers at the NEIDL facility Tactic: Smuggle a weapon into the NEIDL facility
Scenario 5. Loss of Laboratory Personnel	Adversary: Disgruntled employee (psychotic insider) Objective: Cause maximum number of deaths Tactic: Introduce a weapon into the NEIDL facility

2

Table 6-2. Outsider Scenarios Relative to BRP Requirements for Evaluation

Scenario	Adversary–Objective–Tactic
Scenario 6. Extremist Attack	Adversary: External attack (extremist group) Objective: Rendering the NEIDL facility unusable and possible secondary release of pathogen Tactic: Use an improvised explosive device (IED) to attack the NEIDL
Scenario 7. Release of Pathogen into the Environment	Adversary: External attack (international terrorists) Objective: Panic and the disruption of the food chain Tactic: Acquire and release pathogen off-site
Scenario 8. Loss of Laboratory Personnel	Adversary: External attack (extremist group) Objective: Wound or kill key NEIDL personnel Tactic: Introduce an IED into the NEIDL facility

Table 6-3. Insider, in Collusion with Outsiders, Scenarios

Scenario	Adversary–Objective–Tactic
Scenario 9. Theft of a Select Agent from the Delivery Vehicle	Adversary: Outsider (insider assisted by means of mail delivery schedule) Objective: Intentional theft of Select Agent for the purpose of resale or release into the public Tactic: Theft of a Select Agent, by the takeover of a common carrier (e.g., mail service, FedEx) delivery vehicle
Scenario 10. Loss of Pathogen	Adversary: Employee (criminal) Objective: Obtain a pathogen for foreign entity Tactic: Foreign intelligence agency, using deceit or coercion, develops a relationship with an employee to remove a pathogen from the NEIDL facility
Scenario 11. Loss of Technology	Adversary: Employee (criminal in collusion with foreign intelligence agency) Objective: Theft of sensitive technology Tactic: Stealing sensitive technology for a foreign intelligence agency

6.6.2 Scenario Analyses

To evaluate each of these scenarios, the TA team, accompanied by NEIDL subject matter experts, toured the facility gathering information pertaining to effectiveness of the various components of the security system to the threat-consequence scenarios created. In addition, the TA team evaluated system component specifications and performance data of various systems either in place at NEIDL or anticipated to be in place before beginning research with select agents. The security systems were then evaluated against each adversary-consequence scenario on the basis of their ability to deter, detect and assess, delay and respond in a timely and effective manner to each malevolent act. The analyses provided data in each of those categories that were ultimately used to determine the success or failure of the combined systems to interdict an adversary before they could successful accomplish their mission. The following paragraphs define and describe each of those features of a security system that were evaluated.

Deterrence is customarily viewed as an implementable measure that is perceived by potential adversaries as an indication that it would be too difficult to defeat the security system either from the perception of detection, the difficulty of defeat, or the timeliness of a robust and interdicting response (Garcia 2001). Deterrence afforded by a physical security system is generally recognized as a difficult function to measure or observe. However, deterrence features (e.g., visible guards, a substantial fence delineating the plant boundary) are generally credited with defining the controlled areas in and around a site. The basis for deterring any incursion into NEIDL begins with discouraging and preventing unauthorized personnel

1 from gaining access to the facility site. To that end, the facility's visible guard presence, signage,
2 landscaping, and lighting were evaluated.

3
4 **Detection** is typically defined as a system's (or a component of a system's) ability to discover an
5 adversary's presence or unauthorized actions. To initiate a response, detection must also include an
6 assessment that validates the incursion as a potentially malevolent act. Therefore, as used in the context of
7 the TA, assessment was defined as the ability to detect and receive the intrusion information, to determine
8 what actions are required, to determine if those actions are within the capabilities of the response
9 resources, and to communicate the information in near real-time (Garcia 2001). Each of the components
10 of NEIDL's security system that contributed to the detection of a malevolent act was evaluated to
11 determine its effectiveness relative to each scenario evaluated.

12
13 To determine a system component's ability to detect and assess the initiation of a malevolent act, all the
14 systems and subsystems in place were evaluated on the basis of each of NEIDL-specific scenarios. Each
15 of the system components with detection and assessment capabilities were included along with their
16 respective effectiveness for the calculation of risk for each scenario. The highest effectiveness value was
17 chosen for each scenario as representative of the point of most probable detection because that would be
18 indicative of the point with the highest probability the malevolent action or intent would be detected.

19
20 **Delay**, as used to describe a component of a security system, is the slowing of an adversary's progress.
21 The design of an effective security system requires that the delay features incorporated into the system are
22 sufficient to allow the response force appropriate time to interdict the adversary (Garcia 2001). Delay is
23 accomplished at NEIDL by using physical techniques and processes such as fencing, locks, reinforced
24 walls, clear zones (i.e., open areas on both sides of the perimeter barrier to provide an unobstructed view
25 of the barrier and the ground adjacent to it), and procedures. Each element of the NEIDL security system
26 (i.e., physical techniques and processes) was evaluated to determine the total delay afforded by the system
27 relative to each scenario evaluated.

28
29 Until detected, an adversary would have an infinite amount of time to accomplish the mission; however,
30 once an adversary is detected, the amount of time available to accomplish the mission becomes an amount
31 bounded by the time required for a response force to interrupt or stop the activity. To evaluate delay for
32 each threat-consequence scenario as it relates to the calculation of risk, it must first be recognized that,
33 only those system components in place that would be capable of providing delay after the most probable

point of detection along the path to the objective being reached were evaluated on the basis of each NEIDL scenario.

The delay values for security system features were derived from the tabulated values for the effectiveness of security system components in the Vulnerability and Assessment Methodology (January 2005). In addition to the delay afforded by specific security system components, there is also a quantifiable delay associated with the distances an adversary must traverse to reach a target. To determine the delay time associated with an adversary traversing a defined distance, the TA team developed average walking and running speeds [i.e., average walking and running rates expressed in feet per second (ft/sec)] using literature values to determine the time it would take for the adversary to traverse the total distance from the point of most probable detection to the targeted critical asset for each scenario. The total delay, (total time associated with security features and distances traversed) were then compared to the times from responding forces to reach and interdict an adversary.

Response, in the security arena, is defined by two components: (1) the ability for suitably trained personnel to arrive at the scene of an unauthorized action (i.e., incident) in time to challenge the person(s) attempting the unauthorized activity; and (2) the capabilities and effectiveness of a responding force.

Those two components were evaluated in each of the three regions to determine the effectiveness of a response to each specific threat-consequence scenario. The response time was evaluated by comparing the time between receipt of a detection and assessment of an adversary action and the mobilization and interruption of that action by a responding entity. The effectiveness of the response was determined using a combination of on-site and off-site response forces according to their level of training, equipment, and other specialized capabilities that could be required against a scenario (e.g., explosive ordinance disposal, SWAT).

6.7 Evaluating Security System Vulnerabilities

To determine the overall effectiveness for the security systems in place at each location, the TA team determined the most ineffective component of the security systems ability to detect, delay, and respond to a scenario as being representative of the overall effectiveness of the security system. That approach is appropriate because the lowest of those elements represents lowest effectiveness (i.e., the highest vulnerable) of the security system components associated with each scenario. That value was then used in the risk equation as a numerical representation of the overall vulnerability of the protectiveness of the

security system and the likelihood of success of the adversary. Where those results were determined to be unacceptable, system improvements (i.e., mitigations) were recommended.

Table 6-4 presents an example of a complete analysis of an adversary-consequence scenario and demonstrates the relationship between the probabilities of failure of the security system to the risk. In other words, as the probability of a security system (or component) failure decreases, so does the risk from a scenario. In the example of the baseline condition, the extremist group would be successful 421 times out of every 1,000 attempts it made to wound or kill key personnel. After mitigations were implemented (i.e., features, personnel or additional procedures) to address the identified vulnerabilities, their success rate would decrease to only being successful 3.5 times out of every 1,000 attempts.

Table 6-4. Example Scenario Analysis

Scenario: Extremist group Objective: Wound or kill key personnel Tactic: Use deceit to introduce and detonate an IED	T	C	V	Risk per 1,000
Baseline analysis results based on site-specific threat spectrum, and vulnerabilities associated with the security systems' ability to deter, detect, delay, and respond to a malevolent act	0.78	0.90	0.6	421
Mitigated analysis results based on site-specific threat spectrum, and vulnerabilities associated with the security systems' ability to deter, detect, delay, and respond to a malevolent act <i>after incorporating mitigation strategies</i>	0.78	0.90	0.005	3.5

6.8 Threat Assessment Results in Relation to the RA

The Threat Assessment identifies 11 scenarios that are described in detail, but it does not provide an analysis of potential consequences of those scenarios. DOE NEPA Guidance (DOE 2002) acknowledges the difficulty of analyzing malevolent acts and suggests that the consequences could be compared to consequences of severe accidents because the forces resulting in releases of hazardous materials could be similar. The scenarios evaluated as part of the TA were assigned a probability and a determination was made as to whether a release of a pathogen could be reasonably expected to occur if the adversary was successful in accomplishing their mission.

Section 4.2.6 of Chapter 4 identifies accidents that are similar to a malevolent act scenario and provides a discussion of the potential similarities and differences in consequences. It was concluded that the consequences resulting from the malevolent act scenarios associated with a pathogen release from NEIDL are bounded by the MRF earthquake consequences. Therefore, consequences were not calculated specifically for malevolent acts.

1 The consequences of malevolent acts could be highly variable depending on the intent and success of the
2 adversary. Malevolent acts that attempt to disperse the pathogen to members of the public can be grouped
3 into two types: (1) those that attempt to release directly from the building; and (2) those that attempt to
4 remove the pathogen from the facility for release at a later time in the location of their choosing. Each of
5 those types is discussed below.

6
7 Releases directly from the facility could be compared to accidental releases because the release locations
8 are the same, the inventory is limited, and the mechanism of release can be characterized. For example,
9 malevolent act scenarios of this type could involve the use of an improvised explosive device to damage
10 the containment boundary and the HVAC system, including the HEPA filters. The consequences of the
11 MRF earthquake are expected to exceed those of these malevolent scenarios the following reasons:

- 12 1. The viable pathogen inventory in the HEPA filters is expected to be much lower than the
13 maximum working volume, which is the inventory used for the earthquake analysis. Not only is
14 the pathogen inventory in the HEPA filter expected to be less, but the continual flow of dry air
15 through the filter could inactivate much of the pathogen inventory that might accumulate in a
16 filter.
- 17 2. Shock to a HEPA filter is approximately 2×10^{-6} (DOE 2000), which is less than the release
18 fraction for the MRF earthquake (i.e., 2.8×10^{-5} , as shown in Section F.8.3.4.4.3 of Appendix F).
- 19 3. If the HVAC blowers continue to operate, and/or there is a breach of containment and structure,
20 then the release would likely be through the stack or above ground level, rather than the ground-
21 level release assumed for the MRF earthquake. An above-ground-level release results in large
22 dilution of the pathogens, especially for people near the point of release, which results in low
23 exposure levels.

24
25 For those reasons, the consequences of the malevolent scenarios are expected to be much less than the
26 consequences of the MRF earthquake and could be closer to the consequences of the BDB earthquake.

27
28 Malevolent acts that attempt to remove the pathogen from the facility cannot be readily compared to
29 accidental releases because the locations are different and the release mechanisms could be different. For
30 example, if an adversary were successful and removed a pathogen from the facility, it might be possible
31 to use a nebulizer and fans in a highly populated area to deliver high exposure levels to a large number of
32 people. However, the release could be attempted at any location of the adversary's choosing. While the
33 likelihood of success of this type of scenario is low, the potential consequences of such a release, after the

fact at an unknown location, would be speculative and is beyond the scope of this RA to attempt to characterize the consequences of this type of scenario.

Table 6-5 addresses each malevolent scenario, identifies a similar accident scenario where one exists, and provides a discussion.

Table 6-5. Relationship of the Consequences of Threat Assessment Scenarios and Accident Scenarios

Malevolent Act Scenario	Accident Scenario	Discussion
1. Threatened or actual release of pathogen into the public	No similar events	As discussed, there are no similar events for scenarios involving the removal of pathogens from the laboratory. Also, the release location is an unknown.
2. Loss of mission	Bounded by the MRF earthquake	This malevolent scenario involves an explosive device. As discussed the consequences are bounded by the MRF earthquake
3. Simple theft	No similar events	See discussion for malevolent scenario 1.
4. Loss of laboratory personnel (first scenario)	No similar events	If successful, this malevolent act results in personnel death(s) from weapons and does not involve pathogens. The accident analyses addressed only pathogen exposures.
5. Loss of laboratory personnel (second scenario)	No similar events	See the discussion for malevolent scenario 4.
6. Extremist attack	Bounded by the MRF earthquake	See the discussion for malevolent scenario 2.
7. Release of pathogen into the environment	No similar events	See the discussion for malevolent scenario 1.
8. Loss of laboratory personnel (third scenario)	No similar events	See the discussion for malevolent scenario 4.
9. Theft of a Select Agent from the delivery vehicle	No similar events	See the discussion for malevolent scenario 1.
10. Loss of pathogen	No similar events	See the discussion for malevolent scenario 1.
11. Loss of technology	No similar events	There are no direct consequences from the loss of technology. Secondary consequences are speculative because they depend on the nature of the technology stolen and the foreign agency's or commercial entity's ability to use it.

As shown in Table 6-5, the consequence of each malevolent scenario that results in a release directly from the facility is bounded by the MRF earthquake. Malevolent scenarios involving personnel deaths are not addressed by the accident scenarios. It would be speculative to attempt to provide an estimate of the consequences of malevolent scenarios involving the removal of pathogens from the facility.

7. Potential for Released Pathogens to Become Established in the Environment

7.1 Introduction

One of the four hazard categories identified by the Advisory Committee to the Director of the NIH for evaluation in any subsequent risk analysis for the NEIDL (Chapter 3) is that of a “vector-borne pathogen that is relevant to the particular sites under evaluation” (Mahmoud et al. 2008). The intention of that category is to address whether, as a result of biocontainment operations at the NEIDL, a pathogen could find its way into the environment, either by a direct release route or indirectly in the form of an escaped infected vector or infected animal, and become established in the environment as a result. This chapter considers all 13 pathogens to decide whether any has potential to become established in the environments near the sites under evaluation, following a loss of biocontainment at the NEIDL.¹ Consideration is given to whether there is any basis to conclude that any of the pathogens could persist or replicate in air, soil, vegetation, water, or in an insect, other arthropod, or other animal species in the local environments outside the biocontainment space.

7.2 Approach

Each of the 13 pathogens was considered with regard to its potential to persist in the environment, using data compiled primarily from peer-reviewed scientific literature. The data were supplemented with additional information published by scientific authorities and leading scientific experts, information from documented personal communications, and data published by state and federal agencies. Information was collected on wildlife and livestock populations for the vicinities of the three proposed sites. The information was considered together with regional climatic factors associated with the three sites. For more complete information concerning data methodology and findings, see Chapter 3 and Appendix C of this document. One of the 13 pathogens, RVFV, previously was studied by a specially assembled working group. Summarized findings from that study are included in this chapter, and a complete copy of the working group’s report is presented in Appendix H.

Fundamental considerations in evaluating the potential for pathogens to become established in the environment of proposed NEIDL sites include the following:

- Could the pathogen exist in the natural environment in the absence of a permissive vector or a susceptible host?
- Is the pathogen known to require a vector to spread in the environment?
- If a vector is required for spread in the environment, does the vector exist in New England, and, in particular, in proximity to the sites under consideration for the NEIDL?

- Does the pathogen have a known animal host?
- If the pathogen has a known animal host, does the host exist in New England and, in particular, in proximity to the sites under consideration for NEIDL operation?

Each of the five preceding topics requires consideration of related follow-on questions. Examples of such questions include:

- *Could the pathogen exist in the natural environment in the absence of a permissive vector or a susceptible host?* If a pathogen were accidentally released to the exterior of the facility, could it be expected to survive in ambient atmospheric conditions, including temperature, relative humidity, solar irradiation, and open air factors such as ozone, and olefins? Could the pathogen be expected to survive after coming into contact with soil, vegetation, or water? If the pathogen would be expected to survive in the environment, could it be able to replicate independently (e.g., could it grow in soil or water) or would it require a host (as in the case of viruses)?
- *Is the pathogen known to require a vector to spread in the environment?* Some of the 13 pathogens are not known to spread in nature, except via an insect or arthropod vector. If it were possible for a given pathogen to survive its initial release from the facility, would it require a vector to spread, or is it possible for the pathogen to spread by another means?
- *If a vector is required for spread in the environment, does the vector exist in New England and the sites under consideration for the NEIDL?* In the case of tick-borne encephalitis virus, Far Eastern sub-type (TBEV-FE), formerly known as Russian spring-summer encephalitis virus in the tick-borne encephalitis complex, a vector is required for natural spread, and the vector species are not present in North America. However, a closely related vector species is present in North America. Is it possible for that species to serve as a vector for the virus?
- *Does the pathogen have a known animal host? [If so] does the host exist in New England and, in particular, in proximity to the sites under consideration for NEIDL operation?* In the case of Junín virus (JUNV), primary hosts are field mice species not found in North America. However, serologic testing of mice in areas where JUNV is endemic shows that other mouse species have been exposed to the virus. One of those species is common in the Americas, including the northeastern United States. Is it possible for that species to serve as a host for the virus?

Conclusions for each topic were developed by systematic consideration of data in Chapter 3 and Appendix C. Particular attention was given to data availability and relevance for the following parameters for each of the 13 pathogens:

- Pathogen stability (outside of host/vector, if any)

- Vectors (if any)
- Host species naturally (field) or experimentally (laboratory) susceptible to infection
- Infectivity of the pathogen (infectious doses and primary routes of infection)
- Transmissibility potential (secondary transmission in the environment)
- Reservoirs (in the environment)
- Other relevant epidemiological/ecological data

Key points and conclusions regarding whether any of the 13 pathogens has potential to become established in the environments near proposed NEIDL sites are presented below and in Tables 7-1 and 7-2. Pathogens are organized according to biosafety level.

7.3 BSL-3 Pathogens

7.3.1 Bacillus anthracis (B. anthracis)

B. anthracis is not vector-borne, although tabanid flies have been associated with rare cases of cutaneous disease (Turell and Knudson 1987). Human infection from B. anthracis is acquired by three main routes: cutaneous, inhalational, and gastrointestinal. Human anthrax is uncommon in the United States, but generally occurs as inhalational or cutaneous anthrax associated with contact with infected animals or contact with aerosols generated from contaminated hair, hides, and skins of infected animals; a singular case of gastrointestinal anthrax associated with this latter exposure source was reported in the United States in 2009 (Goodnough 2009; Brooks 2010; Centers for Disease Control and Prevention 2010). In contrast, anthrax infection in livestock is enzootic (i.e., affecting or peculiar to animals of a specific area) in some geographic regions in the United States. Ten states reported at least one epizootic (i.e., an event attacking a large number of animals simultaneously) of anthrax from January 1996 through October 2001 (Figure 7-1) (Johnson 2008). All states with epizootics are west of the Mississippi River, specifically in the Midwest, the Southwest, and the western United States. Reports of epizootics might not be complete because sporadic cases of anthrax might have gone undiagnosed, or were diagnosed but not reported. Livestock producers in enzootic areas generally recognize the signs of anthrax and respond by vaccinating their animals, without reporting the disease to appropriate authorities (Johnson 2008). Anthrax epizootics in livestock and wildlife are restricted to specific geographic regions, regardless of continent, country, or geopolitical unit within a country.

B. anthracis spores can remain viable in soil for decades under favorable conditions (Titball, Turnbull, and Hutson 1991). Accordingly, there has been speculation that locations of epizootics of anthrax that occur in the United States are geographically correlated to anthrax infections that occurred during the

historic movement of large numbers of cattle during cattle drives and the migration of pioneers and their livestock westward (Johnson 2008). Most outbreaks occur in grazing herbivores, especially cattle, sheep, goats, and horses; pigs are more resistant to infection with *B. anthracis*. The number of livestock deaths due to anthrax in any year is typically one per one million susceptible range animals.

Figure 7-1. States reporting at least one animal anthrax outbreak, January 1996 to October 2001 (Johnson 2008)

Numbers = Number of outbreaks, January 1996 to October 2001

Observations on the role of climatic factors such as season of the year, ambient temperature, and drought in promoting anthrax epizootics have been made for decades. The commonality of summer months, high ambient temperatures, and drought with anthrax epizootics has been documented. The role of environmental factors such as soil types and soil disturbances via excavation are poorly defined despite attempts to evaluate these potential factors. However evidence suggests that soils rich in organic matter, with high calcium levels and a pH above 6.1 foster spore survival (Hugh-Jones and Blackburn 2009). Two microenvironments of geographic regions have been described in which repeated outbreaks of anthrax have occurred (Van Ness 1971). Those microenvironments or incubator areas are characterized by (1) low-lying depressions, where standing water has collected and devitalized plant life remains, and (2) rocklands, which are dried watercourses or hillside seeps where organic matter accumulates during runoff. Anthrax epizootics occur during the summer months in which there are dry periods punctuated by prolonged periods of intense rain; the hot, dry summer months of June through September are usually preceded by a wet spring. A proposed role of water in anthrax epizootics is the collection (aggregation)

1 and concentration of spores in storage areas or incubator areas (Dragon and Rennie 1995). Prolonged
2 rainfall promotes runoff and pooling of standing water. The surface of *B. anthracis* spores is highly
3 hydrophobic. The spores are resistant to dissolution by water and might be transported in clumps of
4 organic matter by runoff to standing pools of water. Dry weather causes evaporation of standing water
5 and concentration of floating anthrax spores as the water pools shrink. The high buoyant density of *B.*
6 *anthracis* spores provides an opportunity for the spores to adhere to vegetation as the vegetation
7 resurfaces during evaporation. The effects of water on anthrax spores have been summarized in three
8 steps: (1) successive cycles of run-off and evaporation concentrates anthrax spores in storage areas, (2)
9 evaporation redistributes the spores from soil onto vegetation, and (3) susceptible herbivores consume the
10 contaminated vegetation (Dragon and Rennie 1995). On the basis of the foregoing geographical and
11 ecological data, as well as the absence in recent decades of *B. anthracis* in the area of the proposed sites,
12 it is concluded that *B. anthracis* is not likely to have an undetected current presence in the vicinities of the
13 three proposed NEIDL sites. That conclusion is supported by ecological niche modeling, which has been
14 conducted on the basis of known or suspected parameters that support survival of *B. anthracis* spores in
15 soil (Blackburn et al. 2007). Findings from this modeling do not predict a current distribution of *B.*
16 *anthracis* spores in any of the three regions of the proposed NEIDL laboratory sites (Blackburn et al.
17 2007).

18
19 Although livestock populations in the vicinity of the three proposed sites are low or negligible (U.S.
20 Department of Agriculture 2002), ruminants, including wild ruminants, are present in the vicinities of the
21 Tyngsborough and Peterborough sites. It also is possible that residents in metropolitan cities such as
22 Boston harbor ruminants as backyard livestock, and livestock might be present in zoos, or as free-ranging
23 wild ruminants in city parks, reserves, refuges, and woodlands (Rotenberk 2010). Approximately 15,169
24 deer (*Odocoileus virginianus*) are within a 40km (25-mile) radius of Peterborough, and if the New
25 Hampshire Fish and Game Department reaches its Wildlife Management Unit objectives, the deer
26 population would increase by 27 percent within 5 to 10 years (New Hampshire Fish and Game
27 Department 2005). Approximately 269 moose (*Alces alces*) are in the 2-county area within a 40km (25-
28 mile) radius of Peterborough. The Tyngsborough, Massachusetts, site in Upper Middlesex County is 3km
29 (2-mile) from the New Hampshire border, Hillsborough County. Approximately 9,702 deer and
30 approximately 173 moose populate this adjacent area in New Hampshire.

31
32 *B. anthracis* infection in an animal involves multiplication and dissemination of the vegetative bacterial
33 cells within the animal. Those vegetative cells are exposed to oxygen after the animal dies, thereby
34 stimulating the formation of spores that eventually are deposited near the carcass. That is the natural
35 mechanism by which *B. anthracis* can multiply and spread in the environment. Experience has shown that

1 it is possible for aerosolized anthrax spores from a laboratory release to be distributed to livestock or
2 wildlife populations and to cause fatal infections in those animals (Meselson et al. 1994; Coleman et al.
3 2008). That incident, however, involved a Russian military research complex where an estimated 10,000
4 times the number of spores proposed for work at the NEIDL were accidentally released in a highly
5 dispersable, presumably powdered form (Wilkening 2006). In contrast, calculations that were performed
6 as part of this RA, and that are specific to proposed operations of the NEIDL, indicate that it is beyond
7 reasonably foreseeable (category D, once in more than 1 million years) for aerosolized spores from a
8 maximum reasonably foreseeable release event at the NEIDL to cause infection in the human population
9 at any of the three proposed sites (Chapter 9, Table 3-5-14c). Those calculations also can be used to
10 characterize potential risk to animal populations.

11
12 The likelihood of an infection occurring in an animal population increases as the population size increases
13 (just as it does for humans). For a given species, the true number of animals that are present within 1 km
14 of a proposed site at a given time cannot be known. Nor are the infectious doses for the various animal
15 species known. However, if one assumes that the dose-response relationships derived in Appendix J are
16 adequate estimates for a given animal species, the derived initial infections estimates for humans can be
17 related to potential infections among animals by comparing population sizes. It was calculated that an
18 average of about 1,200 residents and 1,000 nonresidents would be in one 22.5-degree sector within 1 km
19 of the urban site and could be exposed to an aerosol release. The number of people potentially exposed at
20 the other sites would be less than 10 percent of the number at the urban site (Table G.4-3). The frequency
21 of a maximum reasonably foreseeable earthquake release leading to *B. anthracis* infection among these
22 people was estimated to be in category D (once in more than 1 million years) and is beyond reasonably
23 foreseeable. It was further calculated that for this estimated frequency to increase to category C (once in
24 10,000 to 1,000,000 years), the number of people in one 22.5-degree sector within the 1-km radius would
25 have to increase by about a factor of 2,000. By extension, on the basis of the stated assumption about
26 infectious doses in animal species, the population in one 22.5-degree sector within the 1-km radius (about
27 0.196 km² or about 48.5 acres) for a given animal species would have to be at least 4,400,000 (i.e., 2,000
28 x 2,200) for the frequency of infection in that population to be in category C (once in 10,000 to 1,000,000
29 years). In the case of natural hosts—ruminants, horses, and swine—such a concentration of animals is not
30 credible, and on the basis of the stated assumptions, it can be surmised that the frequency of at least one
31 anthrax infection occurring within the 1-km radius as a result of the maximum reasonably foreseeable
32 aerosol release would be in category D (once in more than 1 million years) and is beyond reasonably
33 foreseeable.
34

1 Consideration also was given to the potential for re-aerosolization of spores that might settle onto
2 environmental substrates following a possible laboratory release, and that might remain infectious for a
3 long period. Studies in conjunction with *B. anthracis* contamination of a U.S. Senate office building
4 demonstrated that there is potential for re-aerosolization of *B. anthracis* spores from contaminated
5 surfaces in an indoor environment (Weis et al. 2002). However, regarding the potential re-aerosolization
6 of spores from exterior environmental surfaces such as soil and vegetation, findings of the U.S.
7 Department of the Army that were reported in 1996 might have some relevance. As summarized by the
8 Working Group on Civilian Biodefense, the Army findings showed no significant threat to personnel
9 from re-aerosolization of settled spores in the out-of-doors setting (Inglesby et al. 1999). It is possible,
10 though, that these findings might have limited applicability to potential infection of animals subsequent to
11 an accidental release from a NEIDL facility. It might be significant that no data concerning the Russian
12 incident were found to suggest that spores persisted in the environment and caused an increase in the
13 number of animal anthrax cases in the months following the release.

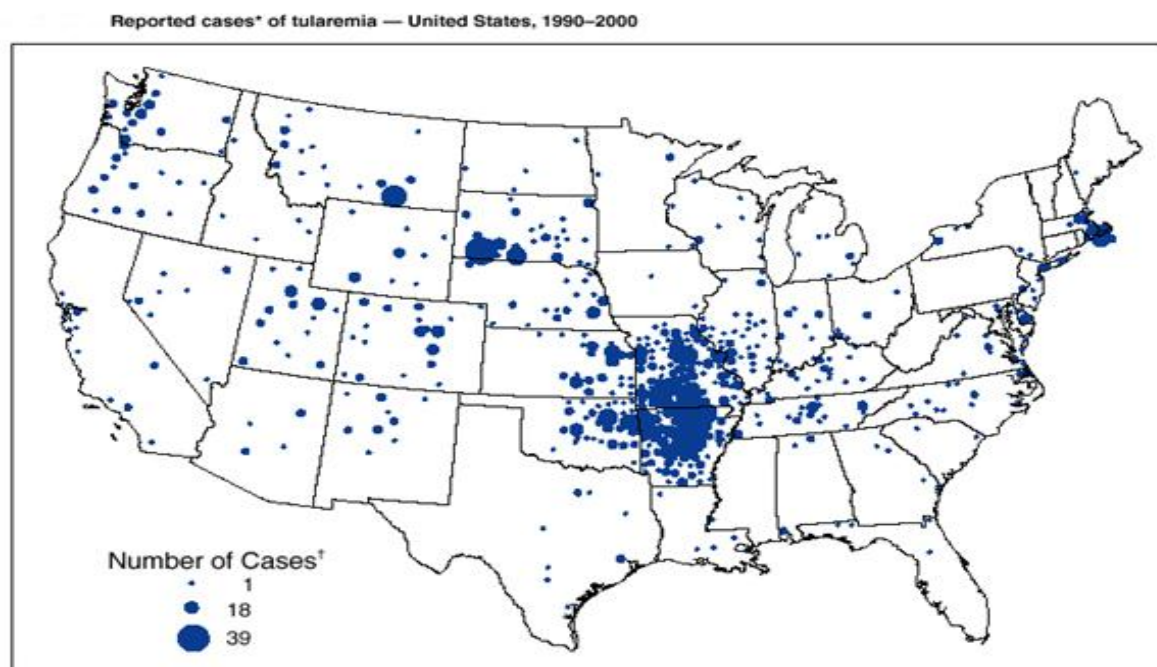

14
15 Because *B. anthracis* spores are resistant to adverse environmental conditions, it is possible that spores
16 released from the laboratory remain viable until deposited to a favorable environmental surface, where
17 they could germinate to form vegetative cells and subsequently increase in number by cellular division
18 (Saile and Koehler 2006). However, the available data suggest that the ability of vegetative cells to
19 survive outside an animal is low, particularly in areas other than the microenvironments previously
20 described (Titball, Turnbull, and Hutson 1991; Saile and Koehler 2006). The factors that allow prolonged
21 spore survival in those microenvironments are incompletely defined, but such environments are not found
22 in New England. The inability of *B. anthracis* to become established in New England is evidenced by the
23 cessation of animal and human anthrax in the decades following the demise of tanning and textile
24 industries that imported contaminated materials to the area (Van Ness 1971)(Blackburn, 2007).
25 Furthermore, this evidence is supported by results from ecological niche modeling, which do not predict
26 that *B. anthracis* spores would be capable of long-term survival in the environment of the regions at the
27 urban, suburban, or rural locations (Blackburn et al. 2007). On the basis of the foregoing information, it is
28 surmised that any foreseeable release of spores would not cause *B. anthracis* to become established in the
29 environments in the vicinities of the three proposed sites, either by shedding from the carcass of an
30 infected animal or by direct deposition to a favorable environmental substrate.

31 32 **7.3.2 *Francisella tularensis* (F. tularensis)**

33 Distribution of *F. tularensis* appears to be ubiquitous. Tularemia was first reported in the United States in
34 1911 and has been reported from all states but Hawaii. Except for a 6-year period from 1994 to 2000
35 when there was no federal requirement for reporting, cases of tularemia have required reporting to the

CDC (Centers for Disease Control and Prevention 2002). From 1990 to 2000, four states accounted for 56 percent of reported cases: Arkansas (315 cases [23 percent]), Missouri (265 cases [19 percent]), Oklahoma (90 cases [7 percent]), and South Dakota (96 cases [7 percent]). The county of residence was available for 1,357 reported cases. Among the 3,143 U.S. counties, 543 (17.3 percent) reported at least one case during 1990–2000. The counties with the highest numbers of reported cases were throughout Arkansas and Missouri, in the eastern parts of Oklahoma and Kansas, in southern South Dakota and Montana, and in Dukes County, Massachusetts (Martha’s Vineyard island) (Figure 8-3) (Centers for Disease Control and Prevention 2002). From 2001 through 2010, an additional 1,191 cases were reported nationally (Centers for Disease Control and Prevention 2011).

Figure 7-2

In the United States, most persons with tularemia acquired the infection from arthropod bites, particularly tick bites from the dog tick, *Dermacentor variabilis*, or from contact with infected mammals, particularly rabbits. Outbreaks of tularemia in the United States have been associated with tick bites, muskrat handling, deerfly bites, and lawn mowing or cutting brush (Centers for Disease Control and Prevention 2002). Outside the United States (in Italy, Turkey, Russia, and Scandinavia), infection also has been reported in association with contaminated water and mosquito bites (Greco et al. 1987; Willke et al. 2009; Meric et al. 2008; Sjostedt 2007).

Tularemia is endemic on Martha's Vineyard, Massachusetts, and *F. tularensis* is present there in mammalian hosts and in ticks (Matyas, Nieder, and Telford 2007; Goethert, Shani, and Telford 2004; Goethert and Telford 2009; Goethert, Saviat, and Telford 2009). Two outbreaks of pneumonic tularemia have been reported in the United States, and both occurred on Martha's Vineyard (1978 and 2000). Fifteen people were infected in these two outbreaks and 11 of those had pulmonary disease (Feldman et al. 2003). A survey conducted on the island to determine the exposure among landscapers (who have a higher risk of infection) found a seroprevalence (indicated by serologic testing) of 9.1 percent (12 of 132) as compared to a seroprevalence of 0.4 percent (1 of 263) among control groups (Feldman et al. 2003). On the basis of the foregoing geographical and ecological data, it is considered likely that *F. tularensis* is already present in wildlife populations, including arthropods, in the vicinities or surrounding areas of all three proposed NEIDL sites.

Animal populations in the vicinities of all three proposed sites include host species that can serve as vectors for, or be infected by, *F. tularensis*. In the case of dense urban areas such as Boston, those species are fewer in number. However, as noted by the Working Group on Civilian Biodefense, and others, tularemia can occur naturally in the urban areas (Dvorak 2005; Martone et al. 1979; Halsted and Kulasinghe 1978; Dennis et al. 2001). In addition to the many animal and arthropod host species, *F. tularensis* subspecies have been detected from water (Keim, Johansson, and Wagner 2007; Morner 1992) and implicated in non-chlorinated municipal water supplies (Greco et al. 1987), and an association with water-associated protozoans has been surmised (Keim, Johansson, and Wagner 2007). The half-life of the bacterium within artificially created aerosols reportedly ranged from about 12 to 45 minutes under experimental conditions (Hood 2009). On the basis of the foregoing information, it is concluded that it is possible for *F. tularensis* to persist in protozoa or become established in susceptible animals or arthropods following release by an aerosol route or by a liquid waste route, or accidental release of an infected vector(s) or escape of an experimentally infected animal(s).

7.3.3 *Yersinia pestis* (*Y. pestis*)

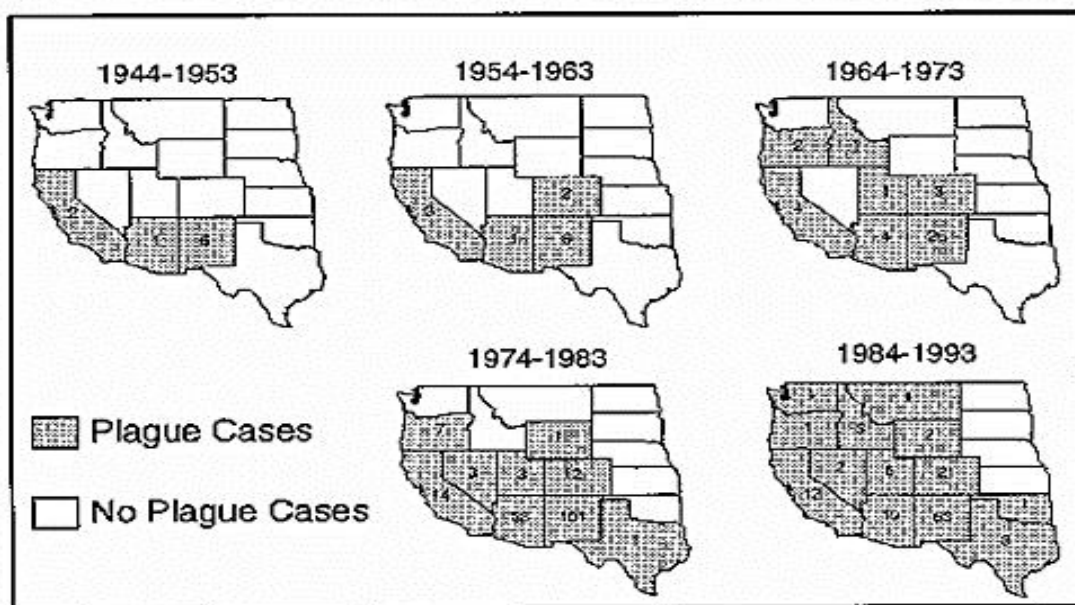

Human infection from *Y. pestis* usually is acquired through the bites of infected rodent fleas. Approximately 30 flea species have been documented as vectors of *Y. pestis*, but the primary species in the United States is *Oropsylla montanus* (the squirrel flea). Rodents are the most important hosts for the bacterium, and fleas become infected by taking blood meals from the infected host (Butler 1991; Gabastou et al. 2000; Dennis and Meier 1997; Gage 1998). Globally, natural infections have been reported in approximately 215 mammalian species from 73 genera. Although many mammals have high susceptibility and high case fatality ratios, others are more resistant (Christie 1980; Gage et al. 2000; Dennis and Meier 1997; Reed et al. 1970; von Reyn et al. 1976; Wild, Shenk, and Spraker 2006).

Carnivores appear to be highly resistant to infection (Salkeld et al. 2007; Boone, Kraft, and Stapp 2009). However, orally infected cats develop buboes (inflamed or enlarged lymph nodes) and bacteremia and transmit the infection via scratches, bites, and close contact (Gage et al. 2000).

From 1944 to 1993, 362 cases of human plague were reported in the United States. Approximately 90 percent of those occurred in Arizona, California, Colorado, and New Mexico, where disease is endemic in certain restricted environments that are associated with prairie dog (*Cynomys* spp.) habitats (Centers for Disease Control and Prevention). During each successive decade of that period, the number of states reporting cases increased from 3 during 1944–1953 to 13 during 1984–1993 (Figure 8-4), indicating the spread of human plague infection eastward to areas where cases previously had not been reported. In 1993 health departments in four states reported 10 confirmed cases of human plague to CDC. In addition, one case was confirmed during 1994, and five were confirmed in 1996. As of 2010, confirmed cases in the United States totaled 410 (Centers for Disease Control and Prevention 1994, 2011).

Figure 7-3

Number of human plague cases reported, by state and decade — United States, 1944–1993

As noted by the CDC, “the findings in this report (Centers for Disease Control and Prevention) emphasize the increasing importance of two related trends in the epidemiology of human plague in the U.S.: 1) increased peridomestic transmission [transmissions associated with animals living around human habitations (e.g., cats)] and 2) the role of domestic cats as sources of human infection. Peridomestic transmission is especially important in the most highly plague-endemic states of Arizona, Colorado, and

1 New Mexico, where rapid suburbanization has resulted in increasing numbers of persons living in or near
2 active plague foci. Domestic cats that are permitted to roam freely in areas where plague occurs in rodents
3 are at increased risk for infection and, therefore, increase the risk for peridomestic transmission to
4 humans.”

5
6 “Surveillance for plague in rodent and rodent-consuming carnivore populations during the 1990s
7 indicates that plague has spread eastward to counties in areas (e.g., eastern Montana, western Nebraska,
8 western North Dakota, and eastern Texas) believed to be free of this disease since widespread animal
9 surveillance began in the 1930s. The continued expansion of human plague in the U.S. (Figure 8-2)
10 underscores the need to enhance plague surveillance and to increase efforts to prevent, detect, and control
11 human plague”(Centers for Disease Control and Prevention 1994).

12
13 In this RA, one laboratory scenario entails release of the bacterium in aerosol form, as an unintended
14 consequence of routine research investigations. Aerosolized *Y. pestis* cells have been found to have a half-
15 life of 9 minutes under laboratory conditions (Won and Ross 1966). Bacterial cells, released by that route,
16 that do not come into contact with a susceptible host ultimately would be expected to be rendered inactive
17 by ambient environmental conditions (Won and Ross 1966; Rose et al. 2003). Furthermore, calculations
18 that were performed as part of this RA, and that are specific to proposed operations of the NEIDL,
19 indicate that aerosolized *Y. pestis* cells from a maximum reasonably foreseeable release event at the
20 NEIDL causing infection in the human population at any of the three proposed sites falls in category D
21 (once in more than 1 million years) and is beyond reasonably foreseeable (Chapter 9, Table 3-5-14c).
22 Those calculations also can be used to characterize potential risk to animal populations.

23
24 The likelihood of an infection occurring in an animal population increases as the population size increases
25 (just as it does for humans). For a given species, the true number of animals that are present within 1 km
26 of a proposed site at a given time cannot be known. Nor are the infectious doses for the various animal
27 species known. However, if one assumes that the dose-response relationships derived in Appendix J are
28 adequate estimates for an animal species, the derived initial infections estimates for humans can be related
29 to potential infections among animals by comparing population sizes. It was calculated that an average of
30 about 1,200 residents and 1,000 nonresidents would be in one 22.5-degree sector within 1 km of the urban
31 site and could be exposed to an aerosol release. The number of people potentially exposed at the other
32 sites would be less than 10 percent of the number at the urban site (Table G.4-3). The frequency of a
33 maximum reasonably foreseeable earthquake release leading to *Y. pestis* infection among those people
34 was estimated to be in category D (once in more than 1 million years) and is beyond reasonably
35 foreseeable. It was further calculated that for this estimated frequency to increase to category C (once in

10,000 to 1,000,000 years), the number of people in one 22.5-degree sector within the 1-km radius would have to increase by about a factor of 8,000. By extension, on the basis of the stated assumption about infectious doses in animal species, the population in one 22.5-degree sector within the 1-km radius (about 0.196 km² or about 48.5 acres) for an animal species would have to be at least 18,000,000 (i.e. 8,000 x 2,200) for the frequency of infection in that population to be in category C (once in 10,000 to 1,000,000 years). In the case of natural hosts such as mice, such a concentration is not credible, and on the basis of the stated assumptions, it can be surmised that the likelihood of at least one *Y. pestis* infection occurring within the 1-km radius as a result of the maximum reasonably foreseeable aerosol release would be in category D (once in more than 1 million years) and is beyond reasonably foreseeable.

A more plausible laboratory scenario for *Y. pestis* to become established in the environment is accidental release of an infected vector(s) or escape of an experimentally infected animal(s) that survives and then transmits the bacterium to others. On the basis of the foregoing information and the presence of rodents and rodent fleas in the vicinities of the proposed sites, the potential for *Y. pestis* to become established in susceptible animal populations present in the vicinities of the three proposed NEIDL sites cannot be ruled out.

7.3.4 1918 H1N1 Influenza Virus (1918 H1N1V)

1918 H1N1V is not known to be vector-borne. The origin of the 1918 strain of H1N1 virus is unknown (Taubenberger and Morens 2006). However, the available data suggest that natural infections occurred widely in swine during the 1918 pandemic, and the virus has been shown to replicate in experimentally infected pigs (Weingartl et al. 2009). The amount of inoculum used to experimentally infect the pigs was 10^{5.4} TCID₅₀ for each animal. Experimental infections also are possible in mice (*Mus musculus*), but the available data show that the virus does not spread from inoculated mice to uninfected cage mates, and there is no evidence that infection in mice can occur naturally (Lowen et al. 2006; Tumpey 2008; Tumpey et al. 2004; Kong et al. 2006). Ferrets (*Mustela putorius furo*) are better suited for the study of influenza virus transmission, and researchers have found that 1918 H1N1V transmits efficiently between ferrets by respiratory droplets (Tumpey et al. 2007). Wild ferrets, though, are not present in the three sites under consideration for the NEIDL and are not given further consideration here. Data concerning stability of influenza A virus (not 1918 H1N1 strain) in the environment indicate that the virus half-life can be as short as 18 minutes, but replication competence can be retained for as long as 1–2 days (Lytle and Sagripanti 2005; Sagripanti and Lytle 2007; Loosli et al. 1943; Bridges, Kuehnert, and Hall 2003). Isolation of avian strains of influenza virus from fresh waterbodies suggests that influenza A viruses have a measure of stability in water (Lebarbenchon, 2011 #16486).

Uncertainty calculations that were performed as part of this RA, and that are specific to proposed operations of the NEIDL, indicate that most (more than 90 percent) but not all estimates for the frequency of one or more infections from 1918 H1N1V occurring in the human population at the urban site as a result of a maximum reasonably foreseeable release event at the NEIDL fall in category D (once in more than 1 million years) and are beyond reasonably foreseeable (Chapter 9, Table 3-5-14C). All results for multiple (greater than or equal to 2) infections at the urban site, and any number of infections at the suburban and rural sites, fall in category D (once in more than 1 million years) and are beyond reasonably foreseeable. Those calculations also can be used to characterize potential risk to animal populations. The concentration of susceptible animal hosts at the rural site, and perhaps at the suburban site, could be greater than the concentration of humans. Also, the infectious dose and host susceptibility could vary between species. Assuming the same dose-response models apply for susceptible animal species near the three sites, a given animal species population would have to be comparable to or higher than the estimated urban population for any estimates of infection frequency to fall in category C (once in 10,000 to 1,000,000 years).

Wild birds are hosts to all known subtypes of influenza A virus (Centers for Disease Control and Prevention 2005), and starlings (*Sturnus vulgaris*)—a species that can flock in large numbers—appear to be naturally capable of carrying influenza virus (Qin et al. 2011). In addition, domestic birds can be infected with influenza viruses from wild birds. Recent experimentation has demonstrated that 1918 H1N1V has low pathogenicity in domestic birds (Babiuk et al. 2010). Data from that experiment indicate that 1918 H1N1V does not replicate efficiently in experimentally infected chickens and, although the virus does replicate in ducks (as shown by serological testing), the level of replication in most ducks was below the limit of detection (for nucleic acid-based detection tests). The amount of inoculum used in that experiment was 10^5 PFU per animal (Babiuk et al. 2010).

Potentially susceptible swine populations might be in the vicinity of the rural and suburban sites, and potentially susceptible avian populations are expected to be present in the vicinity of the three proposed NEIDL sites. On the basis of the foregoing information, the potential for released 1918 H1N1V to retain infectivity long enough to become established in susceptible animal populations present in the vicinities of the three proposed sites is low but cannot be ruled out.

7.3.5 SARS Corona Virus (SARS-CoV)

SARS-CoV is not known to be vector-borne. Genetic evidence has shown that initial infections in humans were acquired from non-domesticated animals (Wang and Eaton 2007). The reservoirs appear to be horseshoe bats of the genus *Rhinolophus*, and the secondary host appears mainly to be the palm civet (Shi

and Hu 2008; Wang and Eaton 2007). The virus was reported as being detected in raccoon dogs (*Nyctereutes* sp.), Chinese ferret badgers (*Melogale moschata*), and domestic cats (*Felis catus*) (Wang and Eaton 2007; Shi and Hu 2008). Of those natural hosts and reservoirs, only the domestic cat is native to North America. Experimental infections are possible in mice (*M. musculus*), hamsters (*Mesocricetus auratus*), and cats when using high concentrations of inocula ($10^{3.6}$ to 10^6 TCID₅₀), but the course of infection in those animals is abbreviated and the animals remain asymptomatic (Roberts et al. 2007; Martina et al. 2003). Experimental data show the virus can be transmitted between cats that are housed together. Naturally occurring infections in cats are believed to have resulted from prolonged contact with their infected owners. There is no evidence that the virus can be transmitted to humans by domestic animals. The available experimental data indicate that SARS-CoV is not able to survive in the environment outside a host for more than 2–3 weeks, so viruses accidentally released by an aerosol route, and that do not contact a susceptible host, ultimately would be expected to be rendered inactive by ambient environmental conditions (Lytle and Sagripanti 2005; Darnell et al. 2004; Wang et al. 2005; Rabenau et al. 2005; McKinney, Gong, and Lewis 2006; Wong and Yuen 2005). Calculations that were performed as part of this RA, and that are specific to proposed operations of the NEIDL, indicate that it is beyond reasonably foreseeable for aerosolized SARS-CoV from a maximum reasonably foreseeable release event at the NEIDL to cause infection in the human population at any of the three proposed sites (Chapter 9, Table 3-5-14c). Those calculations also can be used to characterize potential risk to animal populations.

The likelihood of an infection occurring in an animal population increases as the population size increases (just as it does for humans). For a given species, the true number of animals that are present within 1 km of a proposed site at a given time cannot be known. Nor are the infectious doses for the various animal species known. However, if one assumes that the dose-response relationships derived in Appendix J are adequate estimates for an animal species, the derived initial infections estimates for humans can be related to potential infections among animals by comparing population sizes. It was calculated that an average of about 1,200 residents and 1,000 nonresidents would be in one 22.5-degree sector within 1 km of the urban site and could be exposed to an aerosol release. The number of people potentially exposed at the other sites would be less than 10 percent of the number at the urban site (Table G.4-3). The frequency of a maximum reasonably foreseeable earthquake release leading to SARS-CoV infection among those people was estimated to be in category D (once in more than 1 million years) and is beyond reasonably foreseeable. It was further calculated that for this estimated frequency to increase to category C (once in 10,000 to 1,000,000 years), the number of people in one 22.5-degree sector within the 1-km radius would have to increase by about a factor of 200. By extension, on the basis of the stated assumption about

infectious doses in animal species, the population in one 22.5-degree sector within the 1-km radius (about 0.196 km² or about 48.5 acres) for an animal species would have to be at least 440,000 (i.e., 200 x 2,200) for the frequency of infection in that population to be in category C (once in 10,000 to 1,000,000 years). In the case of potential hosts such as mice or cats, such a concentration is not credible, and on the basis of the stated assumptions, it can be surmised that the likelihood of at least one SARS-CoV infection occurring within the 1-km radius as a result of the maximum reasonably foreseeable aerosol release would be in category D (once in more than 1 million years) and is beyond reasonably foreseeable.

Cats will not be used as experimental animals at the NEIDL, which should preclude a scenario in which an experimentally infected cat escapes and transmits the virus to other cats. On the basis of those observations, SARS-CoV is not considered able to survive or multiply in the vicinities of the three proposed NEIDL sites.

7.3.6 Rift Valley Fever Virus (RVFV)

The possibility that RVFV could become established in North America, and its potential environmental, economic, and public health effects, recently were considered by a panel of subject matter experts (Rift Valley Fever Virus Working Group 2004). When considering potential impact of the virus to public health, agriculture, and the environment in the United States, the Rift Valley Fever Virus Working Group (RVFVWG) found it useful to compare RVFV to West Nile virus (WNV). In brief, the working group concluded that endemic RVFV would constitute a much greater ecologic, economic, and public health threat to the United States than does WNV (see Appendix I of this RA). Their report envisioned a scenario of a malevolent deliberate release at three stockyards in the United States, with subsequent shipment of infected asymptomatic animals to multiple locations nationally, which would result in high numbers of initial infections and rapid geographic spread of the virus. That scenario is quite different from accidental release scenarios involving laboratory operations but, as the RVFVWG points out, if the virus were to become established in the environment, the effects would be the same regardless of how it had been introduced. The RVFVWG notes that spraying can be an effective strategy to control mosquito vectors in defined areas. Effective mosquito vector control, however, would require immediacy of detection, and there are no programs in place to support rapid detection of Rift Valley fever.

RVFV can be carried by at least 30 mosquito species in 5 genera, notably *Aedes* (Meegan and Bailey 1989). At least one *Aedes* species (*Aedes japonicus*) is known to exist in Massachusetts (Centers for Disease Control and Prevention 2010). A major characteristic in the epidemiology of RVF is that infected mosquitoes transmit the virus to their eggs, and mosquitoes that develop from the eggs become carriers of the virus. This phenomenon, known as transovarial vertical transmission, allows the mosquito to function

1 as a reservoir for the virus over years or decades and to propagate the virus over indefinite generations of
2 mosquitoes. Infected mosquitoes and their eggs are capable of surviving through winter conditions.
3 Overwintering of arbovirus-carrying mosquito species in northern climates has been documented in the
4 case of WNV (Nasci et al. 2001). In addition, significant mosquito populations have been known to occur
5 in large cities (New York City Department of Health and Mental Hygiene 2010).

6
7 In this RA, one laboratory scenario entails release of the virus in aerosol form, as an unintended
8 consequence of routine research investigations. Viruses released by an aerosol route, and that do not
9 contact a susceptible host, would be expected to have a half-life ranging from 7 to 77 minutes, and
10 ultimately would be rendered inactive by ambient environmental conditions (Brown, Dominik, and
11 Larson 1982; Miller et al. 1963). However, the possibility that a susceptible mammalian host could
12 become infected by exposure to accidentally released aerosolized RVFV cannot be ruled out. Calculations
13 that were performed as part of this RA, and that are specific to proposed operations of the NEIDL,
14 indicate that up to about five infections in the human population at the urban site might be expected in the
15 event of a maximum reasonably foreseeable release event at the NEIDL, which is estimated to occur in
16 category C (once in 10,000 to 1,000,000 years) (Chapter 9, Table 3-5-14C). At the suburban and rural
17 sites, most estimates suggest that a maximum reasonably foreseeable release resulting in any infections
18 would be placed in category D (once in more than 1 million years). However, some of the estimates place
19 the likelihood in the Low frequency category and, as a result, the possibility of an infection occurring in
20 an animal in the event of a maximum reasonably foreseeable release event cannot be excluded. If an
21 infected animal were to become viremic, it could be possible for indigenous mosquitoes to become
22 infected by feeding on the host, and subsequently spread the virus to other hosts in the area. Another,
23 perhaps more plausible, laboratory scenario for RVFV becoming established in the environment is
24 accidental release of an infected vector(s) or escape of an experimentally infected viremic mammal. In
25 that scenario, it is possible for the infected vector to transmit the infection to a susceptible animal(s), or
26 for the escaped mammal to transmit the virus to indigenous mosquitoes, thereby creating potential for the
27 virus to become established in the environment.

28
29 Ruminants such as cattle, sheep, and goats are the animals most often recognized in outbreaks of Rift
30 Valley fever in endemic areas. Although livestock populations in the vicinity of the three proposed sites
31 are low or negligible (U.S. Department of Agriculture 2002), ruminants, including wild ruminants, are
32 present in the vicinities of the Tyngsborough and Peterborough sites. It also is possible that residents in
33 metropolitan cities such as Boston harbor ruminants as backyard livestock, and livestock could be present
34 in zoos, or as free-ranging wild ruminants in city parks, reserves, refuges, and woodlands (Rotenberg
35 2010). The RVFVWG also expressed concern that white-tailed deer (*Odocoileus virginianus*) and bats

would be susceptible to infection. Approximately 15,169 deer are found within a 3km (2-mile) radius of Peterborough. If the New Hampshire Fish and Game Department is successful in reaching all the Wildlife Management Unit objectives identified in its plan, the deer population would increase by 27 percent in 5 to 10 years (New Hampshire Fish and Game Department 2005). Approximately 269 moose (*A. alces*) are in the 2-county area within a 3km (2-mile) radius of Peterborough. The Tyngsborough, Massachusetts, site in Upper Middlesex County is 3km (2-mile) from the New Hampshire border, Hillsborough County. Approximately 9,702 deer and approximately 173 moose populate this adjacent area in New Hampshire.

Importantly, and sometimes overlooked in discussion of permissive animal hosts for RVFV, is the fact that a range of non-ruminant mammals has been shown to become infected when experimentally challenged. Kittens and puppies reportedly are highly susceptible to experimental infection, and rodents such as mice, rats, and gray squirrels also are susceptible to the virus under experimental conditions (Shimshony and Barzilai 1983). Rodents are expected to be present in the vicinities of the three sites proposed for the NEIDL, and feral cats could be present as well. Accordingly, on the basis of the foregoing information, the potential for RVFV to become established in susceptible animal populations present in the vicinities of the three proposed NEIDL sites cannot be ruled out and, under favorable conditions, it is possible for the virus to become endemic in the United States as a result.

7.4 BSL-4 Pathogens

7.4.1 Andes Virus (ANDV)

ANDV is not known to be vector-borne. No aerosol stability data for this species were found, but predictions for a different hanta virus showed a half-life of about 28 minutes, which indicates that the virus ultimately would not be able to survive in the environment outside a host reservoir (Lytle and Sagripanti 2005). The main natural reservoirs for ANDV are rodents in the sub-family Sigmodontinae, namely, *Oligoryzomys longicaudatus* and other species of *Oligoryzomys* (Centers for Disease Control and Prevention 2008; Wells et al. 1997; McCaughey and Hart 2000; Padula et al. 2004). Experimental infections are possible in the Syrian hamster (*M. auratus*). Because none of those animals occur naturally in the United States, any escaped experimentally infected animal would not be able to transmit the virus to a known susceptible host species. Ecological studies to enumerate host species in the South American endemic area showed no infections among rodent species commonly found in New England (*R. rattus*, *R. norvegicus*, *M. musculus*) (Toro et al. 1998). As a result, ANDV is not considered able to survive or multiply in the environments in the vicinities of the three proposed NEIDL sites.

7.4.2 Ebola Virus (EBOV)

EBOV is not known to be vector-borne. The natural reservoirs are fruit bats, namely, *Hypsignathus monstrosus*, *Epomops franqueti*, and *Myonycteris torquata* (Leroy et al. 2005; Warfield, Deal, and Bavari 2009). Experimental infections are possible in the Syrian hamster (*M. auratus*) and in newborn and suckling mice (*M. musculus*) (Pattyn, Bowen, and Webb 2008). Because none of the natural reservoir species are found in the United States and because natural infections have not been found in mice, EBOV is not considered able to survive or multiply in the environments in the vicinities of the three proposed NEIDL sites.

7.4.3 Marburg Virus (MARV)

MARV is not known to be vector-borne. The reservoir appears to be a fruit bat, *Rousettus aegyptiacus*, and possibly insectivorous bats, *Miniopterus inflatus* and *Rhinolophus eloquens* (Swanepoel et al. 2007; Towner et al. 2007). Experimental infections are possible in newborn and weanling mice (*M. musculus*), guinea pigs (*Cavia porcellus*), and hamsters (*M. auratus*) (Siegert and Simpson 2008; Paragas and Geisbert 2006; Leffel and Reed 2004). Because none of the natural reservoir species are found in the United States and because natural infections have not been found in mice, MARV is not considered able to survive or multiply in the environments in the vicinity of the three proposed NEIDL sites.

7.4.4 Lassa Virus (LASV)

LASV is not known to be vector-borne. The natural host for LASV is the rodent *Mastomys natalensis* (Fisher-Hoch 2005). Reported associations with other species of *Mastomys* are unconfirmed, and are disputed because of the possibility of incorrect identifications (Demby et al. 2001). Species of *Mastomys* are not endemic to North America. Experimental infections are possible in guinea pigs (*C. porcellus*), and marmosets (*Callithrix jacchus*) and other NHPs (Carrion, Brasky, et al. 2007; Carrion, Patterson, et al. 2007; Peters et al. 1987). Because those host species are not endemic to North America, and because there is no reported evidence from endemic areas of infection in *M. musculus* (a common mouse in the New England region), LASV is not considered able to survive or multiply in the environments in the vicinity of the three proposed NEIDL sites.

7.4.5 Junín Virus (JUNV)

There is no field evidence of a vector for JUNV. Primary reservoirs and the source of most human infections with JUNV are vesper mice *Calomys musculus* and *C. laucha*, of the family Muridae, subfamily Sigmodontinae (Carballal, Videla, and Merani 1988; LeDuc 1989; Ambrosio et al. 2006; Parodi 2008). *M. musculus* (a common mouse in the New England region) has been reported as a less important natural host. On the basis of combined tests for antibody and antigen detection, the most recent

field data from the endemic area in Argentina showed a prevalence of JUNV in *C. musculus* of 11 percent (Mills et al. 1994). In contrast, the data showed no evidence, either by antibody or antigen detection, of JUNV in *M. musculus*. Earlier field studies from the endemic area reported antigen detection in 66 of 1,727 *C. musculus* (3.8 percent) versus only 2 of 503 *M. musculus* (0.39 percent) (Mills, Ellis, et al. 1991; Mills, Calderon, et al. 1991). Those data indicate that *M. musculus* is not a capable host species for JUNV. Host species for the arenaviruses are very specific. Presence of viral-specific antibodies in a given mammalian species indicates past exposure to and infection with the virus but does not necessarily indicate ability of that mammalian species to become viremic or to transmit the virus. That explains why antibody-based tests detect the virus at a higher rate than antigen-based tests. Presence of anti- JUNV antibodies in South American populations of *M. musculus* does not indicate that members of that species in North America could be successful hosts. (Lytle and Sagripanti 2005)

A prediction of viral stability for aerosols of this pathogen, on the basis of a model that was validated using experimental data from other viruses, estimates the half-life of aerosolized JUNV to be 30 minutes (Lytle and Sagripanti 2005). Because of the instability of aerosolized JUNV, and because *Calomys* species are not endemic to North America, and because available data indicate that *M. musculus* is not a capable host for the virus, JUNV is not considered able to survive or multiply in the environments in the vicinity of the three proposed NEIDL sites.

7.4.6 Tick-borne Encephalitis Virus, Far Eastern Sub-type (TBEV-FE), formerly known as Russian spring-summer encephalitis virus of the tick-borne encephalitis complex

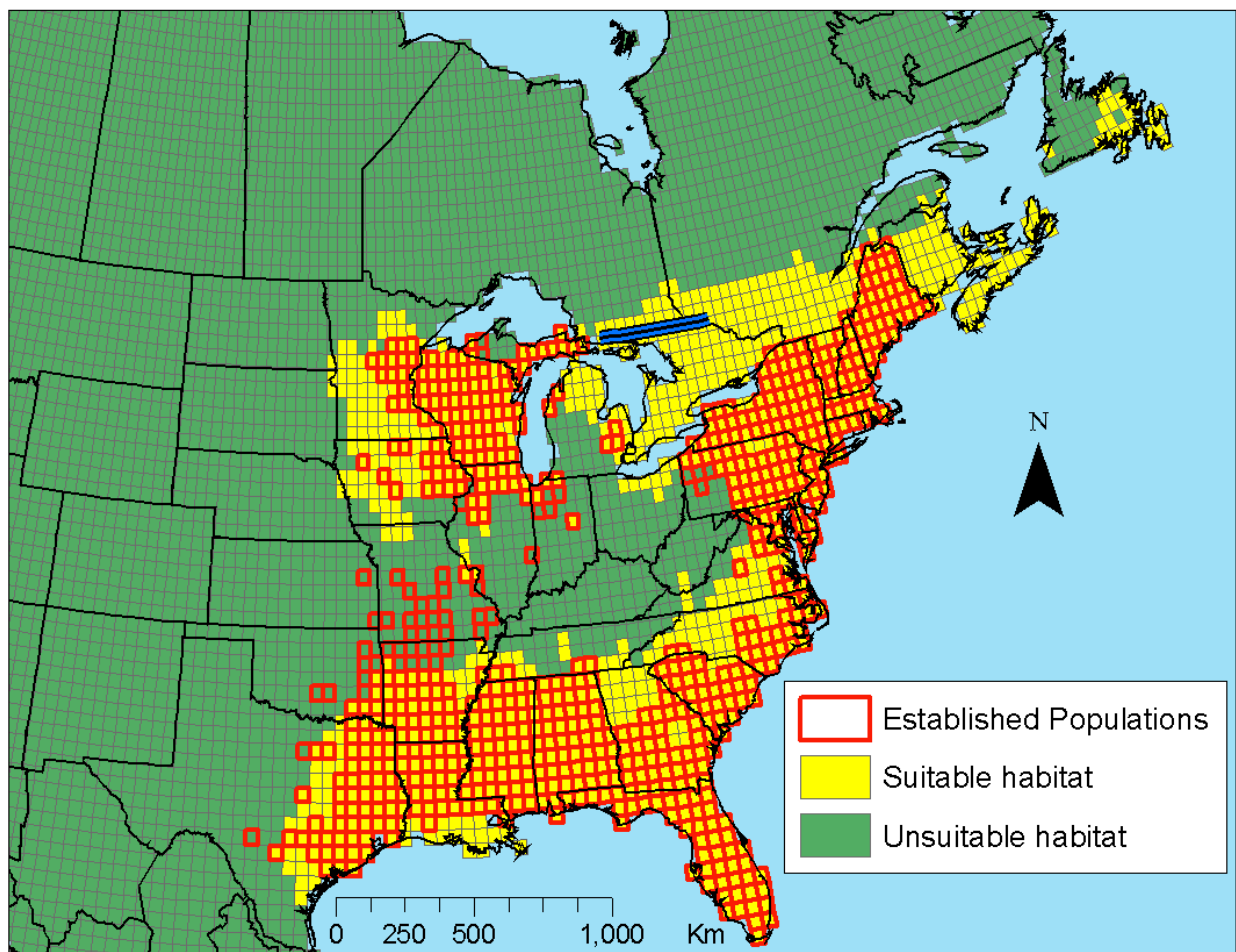

TBEV-FE is a highly infectious, zoonotic, tick-borne virus disease of humans (Gresikova 1989; Calisher 1988). *Ixodes persulcatus* ticks are the primary vectors and reservoirs for TBEV-FE (Gresikova 1989; Alciati et al. 2001; Chumakov 2008; Ruzek et al. 2008; Gritsun, Nuttall, and Gould 2003). The virus chronically infects ticks and is transmitted transstadially (passed from one life cycle stage to the next), transovarially (transmitted from one generation to the next), and between ticks during co-feeding on host mammals (Gritsun, Lashkevich, and Gould 2003; Suss 2003). In addition to passage of the virus between ticks as they co-feed on a host, an infected mammal such as a mouse can serve as a source of infection for ticks, but only over the very limited period during which it is viremic (Turell 2008). Mice do not serve as reservoirs and cannot transmit infection to humans. The tick is the reservoir and the vector. In endemic regions, the northern red-backed vole (*Myodes rutilus*) can serve as a reservoir and a host. The northern red-backed vole is endemic to Alaska but to no other U.S. states (U.S. Department of Agriculture Forest Service). Other major rodent hosts for TBEV-FE are not native to North America. However, goats,

1 cattle, and sheep can become infected, and goats can transmit the virus in their milk while viremic
2 (Gritsun, Nuttall, and Gould 2003; Heinz and Kunz 2004; Suss 2003).

3
4 Aerosolized virus reportedly is stable for at least 6 hours at room temperature (Gritsun, Lashkevich, and
5 Gould 2003). As a result, it can be surmised that aerosols released from the facility could have significant
6 stability. Historically, though, the aerosol route has not been satisfactory in initiating infection with this
7 virus in experimental animals, and the subcutaneous route of infection is preferred. Therefore, in this RA,
8 a more plausible scenario for the virus to become established in the environment would be accidental
9 release of an infected vector that could transmit the virus to a permissive host.

10
11 *I. persulcatus* is a tick that is not endemic to North America. However, the related species *Ixodes cookie*
12 and *I. scapularis* are the primary vectors of Powassan virus, which is closely “related” to viruses of the
13 TBE complex (Turell 2008). *I. scapularis* is the main vector of Lyme disease in North America and is
14 widespread along the eastern half of the United States (Figure 8-5) (Brownstein, Holford, and Fish 2005).
15 Although there is no known experimental work to assess whether the viruses of TBE complex can survive
16 in tick species indigenous to North America, it should be expected that ticks indigenous to New England
17 could be efficient reservoirs and vectors for the TBEV-FE and Central European virus (TBEV-CE)
18 members of the TBE complex (Turell 2008). Also, it is expected that indigenous mice would be suitable
19 hosts for amplification of TBE complex viruses (Turell 2008).

Figure 7-4. Established populations and suitable habitat for *I. scapularis* (Brownstein, Holford, and Fish 2005)

On the basis of the foregoing information, the potential for TBEV-FE to become established in susceptible animal populations present in the vicinities of the three proposed NEIDL sites cannot be ruled out.

7.4.7 Nipah Virus (NIPV)

There are no known arthropod vectors of NIPV. NIPV is able to infect a range of hosts, including swine, humans, and, to a minor extent, cats and dogs (Chua 2003; Eaton, Broder, and Wang 2005; Lo and Rota 2008; McEachern et al. 2008; Torres-Velez et al. 2008; Aljofan et al. 2009; Weingartl, Berhane, and Czub 2009). However, those are regarded as dead end hosts (considered to be non-transmitting and non-amplifying hosts) (Chua 2003; van der Poel, Lina, and Kramps 2006). The natural reservoir hosts for NIPV appear to be several species of fruit bats of the genus *Pteropus*, including *P. giganteus*, *P. vampyrus*, *P. hypomelanus*, *P. lylei*, and *P. poliocephalus* (Chua et al. 2002; Blum et al. 2009; Luby et al.

2009; Weingartl, Berhane, and Czub 2009). The half-life of NIPV under laboratory conditions (applied to a plastic substrate) was determined to be 1.5 minutes at 72 degrees Fahrenheit (Fogarty et al. 2008). Because the natural reservoir host species for NIPV are not endemic to the United States, NIPV is not considered able to survive or multiply in the environments in the vicinity of the three proposed NEIDL sites.

7.5 Summary

On the basis of the available evidence, it is concluded that five of the pathogens, *F. tularensis*, *Y. pestis*, 1918 H1N1V, RVFV, and TBEV-FE, are regarded as environmentally relevant to the sites under consideration for operation of the NEIDL. That means that those five pathogens all have potential, at least theoretically, to become established in the environments in the vicinity of the three proposed NEIDL sites (Tables 7-1 and 7-2). Four of those are vector-borne. On the basis of the available data, it is concluded that one of these pathogens, *F. tularensis*, might already be present in some areas in the vicinity of proposed NEIDL sites. Another of the pathogens, TBEV-FE, is regarded as environmentally relevant, even though its vectors and reservoirs are not endemic to North America, because it is thought that endemic arthropod species could be capable of serving as competent vectors and reservoirs if the virus were to become established in populations of those arthropods.

Theoretical potential exists for any of the five pathogens to become established in the environments associated with all three sites proposed for the NEIDL. The means by which this might occur involve animals (including arthropods) that could be present in those environments. It can be surmised that the intensively urbanized nature of the BioSquare Research Park site supports smaller populations of such animals and, as a result, would be expected to present a less favorable immediate environment for any such potential to be realized. However, although a quantitative difference regarding that potential can be surmised, no qualitative difference is found between the BioSquare Research Park site, the Tyngsborough site, and the New Hampshire site.

Table 7-1. BSL-3 pathogens* and their environmental relevance to proposed NEIDL sites

	Natural vector species	Vectors Species endemic to New England	Natural reservoirs	Reservoirs endemic to New England	Potential ^a to become established in environments surrounding proposed NEIDL sites
<i>B. anthracis</i>	none ^b	N/A	Soil (in endemic states)	No	No
<i>F. tularensis</i>	Ticks, deer flies, other arthropods	Yes	Rabbits (<i>Sylvilagus</i> or <i>Oryctolagus</i> spp.), hares (<i>Lepus</i> spp.)	Yes	Yes
<i>Y. pestis</i>	Fleas (<i>Oropsylla montanus</i>), ~ 30 other flea species	Yes	Mice (<i>Mus</i> spp.), water rats (<i>Scaptemomys</i> spp.), squirrels (<i>Sciurus</i> spp.), voles (<i>Microtus</i> spp.), rabbits (<i>Sylvilagus</i> or <i>Oryctolagus</i> spp.)	Yes	Yes
1918 H1N1V	None	N/A	Avian species, swine ^c	Yes ^c	Yes
SARS-CoV	None	N/A	Horseshoe bat (<i>Rhinolophus</i> spp.)	No	No
RVFV	Mosquitoes (~ 23 species), other hematophagous arthropods	Yes	Mosquitoes <i>Aedes</i> spp.	Yes	Yes
ANDV^d	None	N/A	Long-tailed pygmy rice rat <i>Oligoryzomys longicaudatus</i>	No	No

Notes:

* *Bacillus anthracis* (*B. anthracis*), *Francisella tularensis* (*F. tularensis*), *Yersinia pestis* (*Y. pestis*), 1918 H1N1 influenza virus (1918 H1N1V), SARS-associated coronavirus (SARS-CoV), Rift Valley fever virus (RVFV), Andes virus (ANDV)

a. Potential does not signify likelihood.

b. Tabanid flies have been reported infected rarely; these are endemic in New England.

c. Birds and swine are natural reservoirs for influenza A viruses. There currently is no reservoir for reconstructed 1918 H1N1V.

d. ANDV is a BSL-3 pathogen except when inoculated into a permissive host, which then requires BSL-4

N/A – not applicable

Table 7-2. BSL-4 pathogens* and their environmental relevance to proposed NEIDL sites

	Natural vector species	Vectors species endemic to New England	Natural reservoirs	Reservoirs endemic to New England	Potential ^a to become established in environments surrounding proposed NEIDL sites
ANDV^b	None	N/A	Long-tailed pygmy rice rat <i>Oligoryzomys longicaudatus</i>	No	No
EBOV	None	N/A	Fruit bats (<i>Hypsignathus monstrosus</i> , <i>Epomops franqueti</i> , <i>Myonycteris torquata</i>)	No	No

8. Health Effects – Initial Infection

8.1 Introduction

The goals of the event sequence analyses in Chapter 4 are to answer these questions: What could go wrong at NEIDL? How often would those events be expected to occur, and what would be the immediate consequences of those events? In other words, Chapter 4 estimates the effects of a loss of biocontainment in terms of the frequency of those events and the amount of pathogen an individual would be exposed to as a result of those events. In the next step of this RA, the goal is to answer the question, What would happen if an individual is exposed to a pathogen? This chapter examines the effects of exposure to a pathogen in terms of initial infections and deaths from that exposure. A distinction is made with regard to initial infection addressed in this chapter as that occurring after direct exposure to a pathogen as a result of a release from the laboratory and secondary infection that results from exposure to an already infected individual. Secondary infections are addressed in Chapter 9 and Appendix L.

This chapter is organized as follows. First, the dose-response section discusses probabilities or estimates of how likely it is for an infection to occur after exposure to different amounts of each pathogen through the respiratory route. Second, the event-specific initial infections sections describe how the dose-response estimates are linked with the exposure estimates from the event sequence analyses to provide estimates for the frequency or how often initial infections would be expected to occur as a result of loss of biocontainment at NEIDL. Those sections also include discussion of potential health effects, including deaths (mortalities) that might result in those who become infected. Finally, the potential implications of the presence of medically vulnerable sub-populations among members of the public are discussed in terms of how their vulnerability would affect their chances of infection after exposure to a pathogen. In this chapter, this is discussed in the context of a potential event that would directly expose members of the public to pathogen at the three alternate NEIDL sites.

8.2 Dose Response Assessment

8.2.1 Methodology – Introduction

Dose-response assessment is used to estimate the relationship between a dose, or amount of pathogen to which an individual is exposed, and a given response such as the establishment of infection, sickness (morbidity), or death (mortality). For this RA, dose-response assessment is an important component in converting estimates of the frequency and amount of exposure to a pathogen from the event sequence analysis to estimates of initial infection for the health effects analysis.

1 When an individual is exposed to a dose of viable pathogens, there is a likelihood that the pathogen will
2 replicate or multiply in the individual and cause an infection. The infection could lead to a disease in that
3 individual. There is also a probability that the pathogens will die off or be eliminated by the individual's
4 immune system before infection can be established. The outcome after a given exposure depends on
5 characteristics of both the pathogen and the individual. For each pathogen, this RA considers evidence for
6 the ability of doses of various sizes to infect humans, and, because a dose of a given size might affect one
7 human differently from another, this RA also considers differences in susceptibility to a pathogen among
8 different people.

9
10 Dose-response is assessed by estimating a functional relationship between the amount of exposure, or
11 dose, and the probability of that dose resulting in a response of interest in a randomly chosen individual
12 from a given population. This section describes the general methodology for assessing the relationship
13 between dose and response for each pathogen.

14
15 An exposure could result in no detectable response if the initial organisms to which the individual or host
16 is exposed die off, are eliminated from the host, cannot attach to host cells because of lack of or imperfect
17 receptor sites, or are inactivated by the host's immune system. Otherwise, the infection caused by a
18 pathogen in humans is the response of interest at this stage of the RA. Infection is a necessary first step
19 for disease and death to occur. Those are considered in subsequent sections as estimates of the percentage
20 of infections that eventually lead to symptomatic disease and death, respectively. Infection is an important
21 response to consider because it is also a necessary first step for potential secondary transmission. It is
22 important to note that for certain pathogens, the person transmitting the pathogen to another person might
23 not show symptoms of the disease at the time secondary transmission occurs.

24
25 Each pathogen has a natural route of infection that is dependent on the biology of the pathogen, natural
26 reservoirs, and typical modes of transmission. In a laboratory setting such as the NEIDL, some
27 experiments would attempt to simulate the natural route of infection, but it is possible that events
28 occurring during culturing, manipulating, transporting, and storing the pathogen could lead to potential
29 exposures that differ from those that would occur naturally. In such circumstances, it is possible that
30 exposure to a pathogen in a laboratory setting from a route different from its natural route of exposure
31 could result in an infection. For this RA, it is assumed that any route of exposure resulting from a NEIDL-
32 related event could potentially lead to infection in the exposed individual.

1 The probability of infection resulting from a given dose of a pathogen can vary according to the route of
2 exposure. The above routes of infection are considered on a pathogen-by-pathogen basis. Generally, the
3 bulk of the dose-response assessment focuses on the inhalation route of exposure, for the following
4 reasons. Some of the most important event sequences for this RA result in inhalational exposure, and
5 most of the relevant animal dose-response data for many of the pathogens were derived from inhalational
6 exposures. Other routes of exposure are considered, as appropriate, for each pathogen and compared with
7 the estimates generated for dose-response by the inhalational route.

8
9 The results of each event sequence analysis are provided in terms of exposures for one or more of the
10 following groups:

- 11 • Laboratory worker—People working in the biocontainment area where the event might be
12 initiated.
- 13 • Facility worker—People working in the NEIDL but not in the biocontainment area where the
14 event under consideration occurs. For example, they might work in other laboratories or in
15 administrative areas.
- 16 • Public—Any person outside the NEIDL-controlled perimeter, specifically referring to the
17 population in the surrounding communities.

18
19 For the dose-response assessment, estimates of the probabilities of human infection if exposure occurs are
20 assumed to be equal across all three groups, with the following exceptions.

- 21 • Vaccine status—As part of training and preparation for work in a high biocontainment laboratory,
22 it is possible that laboratory workers working with certain pathogens for which a vaccine is
23 available would have received that vaccine to prevent infection. Those vaccines might or might
24 not be available to facility workers or the general public. That possibility is considered on a
25 pathogen-by-pathogen basis.
- 26 • Post-exposure prophylaxis—The above three groups could have differential access to
27 prophylactic regimens, if available, after being exposed. The availability and effectiveness of
28 medication or vaccine prophylaxis are discussed on a pathogen-by-pathogen basis. Note that
29 many of the release scenarios examined in this RA assume that the incident leading to the release
30 is either undetected or unreported. In such situations, the issue of post-exposure prophylaxis
31 might not be applicable.
- 32 • Population susceptibility—The above three groups likely have different profiles of susceptibility
33 to disease because of differences in age, immune status, and preexisting health conditions. Those
34 differences might or might not be uniform between members of the public near the three sites

1 compared in this RA. In some cases, where relative susceptibility estimates for a specific
2 population are available, adjustments to dose-response estimates are made.

3 4 **8.2.2 Methodology – Quantitative Assessment**

5 The relationship between the dose received and the probability of infection can be quantified using
6 mathematical dose-response curves or assessment. For this RA, three different types of assessments
7 were considered (log-probit, exponential and Beta Poisson). The details pertaining to those three
8 types are described in Appendix J.

9
10 Two sets of dose-response assessments were derived for use in this RA, termed literature-based and
11 *expert-based* dose-response assessments.

- 12 • **Literature-based dose-response assessments**

13 The three candidate assessments described in Appendix J were evaluated in light of the dose-
14 response data and information available in the published literature for each of the pathogens.
15 The assessments found in the literature for each pathogen were evaluated, and, in some cases,
16 fit to published experimental data. The techniques are described in Appendix J.

- 17 • **Expert-based dose-response assessments**

18 The three candidate assessments described in Appendix J were also used to fit curves to the
19 information obtained from the expert panelists who were asked via the Delphi method to
20 provide estimates of infectious doses for the 13 pathogens (see the Delphi Panel Report). The
21 process for fitting curves to the expert-provided values is described in Appendix J. In this
22 context, the three candidate dose-response assessments were evaluated and compared with
23 each other in terms of their ability to match as closely as possible to the estimates provided by
24 each expert for each pathogen.

25
26 The results of the literature-based and expert-based dose-response assessment each consist of a
27 central estimate and an uncertainty range. The two alternate ranges of estimates were compared,
28 especially for low doses at which most of the exposure estimates for the event sequences occur. In
29 some cases, the literature-based range is more conservative (estimates higher risk) than the expert-
30 based range, and in other cases, the opposite is true. All results are presented and the differences
31 discussed in conjunction with each pathogen.

8.2.3 Results – BSL-3 Pathogens

This section documents the dose-response assessment for each of the seven BSL-3 pathogens. A detailed dose-response literature review and quantitative description and derivation of dose-response assessments for each pathogen are provided in Appendix J. This section provides a brief summary of dose-response information for each pathogen and the basis for the literature-based dose-response assessment, if applicable. The ranges of numerical infectious dose estimates to be used for this RA are provided in summary form in Section 8.2.5.

8.2.3.1 *Bacillus anthracis*

Bacillus anthracis (*B. anthracis*) is a bacterial organism that causes anthrax (Chapter 3 and Appendix C). No human experimental dose-response data are available for inhalational anthrax. However, quantitative studies have been performed using available information from historical inhalational exposures and infections that have occurred in human populations. In the absence of human data to further refine potential quantitative dose-response models, experimental studies involving NHPs provide the best available data from which to gain insights into potentially appropriate dose-response relationships for humans. Among the NHP data and models described in Appendix J, a model fit (Haas 2002) to data from cynomolgus monkeys (Brachman 1966) was selected as the literature-based dose-response assessment to be used in this RA.

8.2.3.2 *Francisella tularensis*

Francisella tularensis (*F. tularensis*) is a bacterial organism that causes tularemia (Chapter 3 and Appendix C). There is strong evidence that small inhaled doses of *F. tularensis* can result in human infections. It was determined that the human experimental data relevant to this RA (Saslaw 1961; McCrumb 1961) are not extensive or wide-ranging enough to serve as the sole basis for a statistically acceptable dose-response assessment. However, dose-response data from NHPs (Day 1972) are consistent with the human data (as confirmed by statistical tests described in Appendix J) and pooling these data with the human data results in a larger data set that serves as the literature-based dose-response assessment for use in this RA.

8.2.3.3 *Yersinia pestis*

Yersinia pestis (*Y. pestis*) is a bacterial organism that causes plague (Chapter 3 and Appendix C). No direct human dose-response data for *Y. pestis* are available in the literature. In the absence of human dose-response data for *Y. pestis*, experimental studies involving NHPs provide the best available data from which to gain insights into potentially appropriate dose-response relationships for humans. Results from

exposure of rhesus monkeys to aerosolized *Y. pestis* (Speck 1957) appear to be the only inhalational dose-response data that have been fit to dose response assessments (Huang 2010), and the method that was used deliver inhalational doses to the animals is more consistent with exposures that might occur as a result of releases studied in this RA than the dose delivery mechanisms of other studies, as described in Appendix J. Therefore, the best fit model (Huang 2010) to the rhesus monkey data (Speck 1957) was chosen as the literature-based assessment for this RA.

8.2.3.4 1918 H1N1 influenza virus

1918 H1N1 influenza virus (1918 H1N1V) is a particular strain of influenza A virus that caused a worldwide human influenza pandemic in 1918-1919 (Chapter 3 and Appendix C). No direct human dose-response data exist for 1918 H1N1V. Detailed review of the data sets available in the literature for other strains of influenza has determined that these data sets do not support quantitative dose-response estimates for 1918 H1N1V that would provide useful insight for this RA. Therefore, only the expert-based dose-response estimates were applied to exposure data from the event sequence analyses.

8.2.3.5 SARS-associated coronavirus

SARS-associated coronavirus (SARS-CoV) causes severe acute respiratory syndrome (SARS) (Chapter 3 and Appendix C). No direct human dose-response data exist for SARS-CoV. There was one dose-response assessment study of SARS-CoV found in the literature (Watanabe 2010), which consisted of an analysis of multiple data sets from the literature. Those are applied as the literature-based dose-response assessment for this RA. The estimates are based on data from experimental exposures of mice. The derived estimates appeared to be consistent with data from human volunteers exposed to various doses of a human coronavirus related to SARS-CoV.

8.2.3.6 Rift Valley fever virus

Rift Valley fever virus (RVFV) causes Rift Valley fever (Chapter 3 and Appendix C). No human dose-response data are available for RVFV. A dose response curve fit to a pooled data set from exposures of dogs and cats was chosen as the literature-based assessment for this RA.

8.2.3.7 Andes virus

Andes virus (ANDV) is a hantavirus that causes hantavirus pulmonary syndrome (HPS) (Chapter 3 and Appendix C). No human dose-response data are available for ANDV. A data set derived from ANDV exposures of Syrian hamsters (Hooper 2008) appears to be the only intranasal or inhalational dose-

response animal data available in the literature. Syrian hamsters had previously been shown to be an animal model that closely mimics human HPS (Hooper 2001). A dose-response curve fit to this data set is used as the literature-based dose-response assessment for this RA.

8.2.4 Results – BSL-4 Pathogens

This section documents the dose-response assessment for each of the six BSL-4 pathogens. A detailed dose-response literature review and quantitative description and derivation of dose-response assessments for each pathogen are provided in Appendix J. This section provides a brief summary of dose-response information for each pathogen and the basis for the literature-based dose-response assessment, if applicable. The ranges of numerical infectious dose estimates to be used for this RA are provided in summary form in Section 8.2.5.

8.2.4.1 Ebola virus

Ebola virus (EBOV) causes Ebola hemorrhagic fever (EHF) (Chapter 3 and Appendix C). No human dose-response data are available for EBOV. Unimmunized NHPs (*Macaca mulatta* or *M. fascicularis*) have been infected after inhalational exposure to EBOV in a number of studies, as reviewed in Appendix J. A 100 percent infection and death rate was observed across a range of doses in all studies except one (P'iankov 1995), in which a portion of monkeys survived exposure to the lower dose groups. A data set including results across all the relevant studies was amenable to dose-response curve fitting, and the best fit curve to this consolidated data set is used as the literature-based assessment for this RA

8.2.4.2 Marburg virus

Marburg virus (MARV) causes Marburg hemorrhagic fever (MHF) (Chapter 3 and Appendix C). No human dose-response data are available for MARV. Unimmunized NHPs (*M. mulatta* or *M. fascicularis*) have been infected after inhalational exposure to MARV in a number of studies, as reviewed in Appendix J. A 100 percent infection and death rate was observed across a range of doses in all studies except one (Bazjutin 1992), in which a portion of monkeys survived exposure in the lower dose group. However, the amounts of virus administered in this low dose group were reported imprecisely and in units that are difficult to reconcile with exposure estimates for this RA. Therefore, it was determined that dose-response curve fitting to the MARV data would not be appropriate.

EBOV is closely related to MARV, and a literature-based dose response curve for EBOV was described in the previous section. The estimates derived from that assessment were found to be consistent with the MARV dose-response data. In the absence of solid quantitative data for MARV and given the numerous

similarities between EBOV and MARV, it was decided to apply the EBOV literature-based dose-response curve to MARV for this RA.

8.2.4.3 Lassa virus

Lassa virus (LASV) causes Lassa fever (Chapter 3 and Appendix C). No human dose-response data are available for LASV. One dose-response curve (Tamrakar 2008) fit to data from guinea pigs exposed to inhalational doses of LASV (Stephenson 1984) was found in the literature. This curve is applied as the literature-based dose-response assessment in this RA.

8.2.4.4 Junin virus

Junin virus (JUNV) causes Argentine hemorrhagic fever (AHF) (Chapter 3 and Appendix C). No human dose-response data are available for JUNV. An NHP, the rhesus macaque (*M. mulatta*), was shown to be susceptible to infection with JUNV after inhalational exposure to a range of doses and developed disease symptoms similar to those observed in humans (Kenyon 1992). Because a 100 percent infection rate was observed, it is not possible to fit a dose-response curve to these data, so a literature-based dose-response assessment is not applied for JUNV in this RA. However, the NHP data are used to estimate upper bounds for various ID levels, for purposes of assessing whether the expert-based dose-response estimates are consistent with the NHP data. The median estimates from the expert-based estimates are close to the literature-based upper bounds estimated from NHP data, which means that about half the weight of the expert-based range is above that estimated upper bound. Those estimates above the median are not necessarily inaccurate because it is possible that humans are not as susceptible to infection from JUNV aerosols as are *M. mulatta*. The part of the distribution that lies below the literature-based upper bound can serve to represent the possibility that human susceptibility to JUNV is consistent with what was observed among NHPs.

8.2.4.5 Tick-borne encephalitis virus, Far Eastern subtype

[Formerly called Tick-borne encephalitis complex (Russian spring summer encephalitis virus)]

The Far Eastern subtype of tick-borne encephalitis virus (TBEV-FE) causes encephalitis (Chapter 3 and Appendix C). No human dose-response data are available for TBEV-FE. A review of the available literature determined that literature-based dose-response assessments were not appropriate for use for this RA. Hence expert-based dose-response estimates are applied.

8.2.4.6 Nipah virus

Nipah virus (NIPV) causes encephalitis and/or respiratory disease (Chapter 3 and Appendix C). No human dose-response data are available for NIPV. Bossart et al. (2009) exposed ferrets to oral-nasal doses of NIPV and generated a data set that is amenable to dose-response curve fitting. The best fit curve to this data set is applied as the literature-based assessment for this RA.

8.2.5 Results – Summary of quantitative estimates

The following tables summarize the range of infectious dose estimates used for this RA for each pathogen. Details are provided in Appendix J.

Table 8–1. Infectious dose (ID) estimates and associated ranges for BSL-3 pathogens

Pathogen	Dose-response assessment	ID ₅₀	ID ₁₀	ID ₁	ID _{0.1}	ID _{0.01}
<i>B. anthracis</i>	Literature-based	27,000 spores (15,000–47,000)	4,100 (2,200–7,100)	390 (210–680)	38 (21–68)	3.8 (2.1–6.8)
	Expert-based	8,600 org. (2,500–29,000)	690 (360–4,400)	73 (33–420)	10 (3.9–56)	2.4 (0.39–22)
<i>F. tularensis</i>	Literature-based	11 org. (6.1–18)	1.7 (0.93–2.7)	0.16 (0.089–0.25)		
	Expert-based	42 org. (12–460)	6.0 (1.9–120)	1.0 (0.18–46)		
<i>Y. pestis</i>	Literature-based	15,000 org. (8,200–36,000)	1400 (530–4,000)	120 (44–370)	12 (4.4–37)	1.2 (0.44–3.7)
	Expert-based	3,100 org. (530–27,000)	280 (80–4,100)	37 (5.0–390)	5.6 (0.32–39)	0.63 (0.034–10)
1918 H1N1V	Expert-based	700 org. (110–290,000)	42 (8.6–52,000)	3.3 (0.64–15,000)	0.52 (0.063–6,300)	0.11 (0.0063–3,000)
SARS-CoV	Literature-based	280 PFU (120–580)	43 (18–88)	4.1 (1.7–8.4)	0.41 (0.17–0.84)	0.041 (0.017–0.084)
	Expert-based	2900 org. (280–12,000)	200 (43–1,800)	17 (4.1–180)	3.9 (0.41–18)	0.67 (0.041–5.0)
RVFV	Literature-based	9.7 MICLD₅₀ (2.9–18)	1.5 (0.44–2.8)	0.14 (0.042–0.27)	0.014 (0.0042–0.026)	
	Expert-based	1000 org. (49–7,900)	100 (7.6–1,200)	15 (0.71–180)	3.9 (0.071–56)	
ANDV	Literature-based	63 PFU (24–140)	9.6 (3.6–21)	0.91 (0.35–2.0)	0.091 (0.034–0.20)	0.0091 (0.0034–0.020)
	Expert-based	520 org. (10–1,100)	44 (1.0–160)	7.1 (0.15–15)	0.79 (0.039–6.3)	0.079 (0.013–3.0)

Table 8–2. Infectious dose (ID) estimates and associated ranges for BSL-4 pathogens

Pathogen	Dose-response assessment	ID ₅₀	ID ₁₀	ID ₁	ID _{0.1}	ID _{0.01}
EBOV	Literature-based	4 PFU (1–10)	0.7 (0.2–2)	0.06 (0.02–0.2)		
	Expert-based	300 org. (120–1,000)	40 (19–100)	5.1 (1.8–31)		
MARV	Literature-based	4 PFU (1–10)	0.7 (0.2–2)	0.06 (0.02–0.2)		
	Expert-based	200 org. (100–1,000)	19 (10–100)	2.4 (0.74–15)		
LASV	Literature-based	18 PFU (6.7–40)	2.7 (1.0–6.1)	0.26 (0.098–0.58)		
	Expert-based	100 org. (18–30,000)	11 (2.8–300)	1.5 (0.27–7.0)		
JUNV	Expert-based	96 org. (14–1,000)	14 (2.1–100)	1.6 (0.20–15)	0.19 (0.020–3.9)

	Expert-based	1,000 org. (500–25,000)	100 (75–1,400)	15 (7.2–180)	3.9 (0.72–56)	

8.3 Initial Infections Resulting from Needlesticks in the Laboratory

8.3.1 Methodology

This section describes the methodology for generating estimates for initial infections resulting from Needlestick events described in Chapter 4 and Appendix F.

Chapter 4 described four distinct sub-events, depending on the setting of the event (BSL-3 or BSL-4 laboratories) and whether the event is detected and reported. The initial infections analyses are primarily concerned with consequences from potential LAI without prompt detection and reporting, because those events pose potential risk to the public through secondary transmission.

As described in Chapter 4 and further detailed in Appendix F, it is conservatively assumed that every needlestick would deliver a sufficiently high dose to cause an infection in the laboratory worker. It is important to note that, on the basis of a review of existing literature on needlestick injuries in the laboratory, not every needlestick results in an infection. However, without data to show how much

pathogen is introduced through the needlestick, the most conservative approach would be to assume that every needlestick will result in an infection. That likely overestimates the risk of needlestick injuries.

The results section for Needlestick events (Section 8.4.2) includes descriptions of potential health consequences for a laboratory worker infected via needlestick for each pathogen. This section also includes estimates for the frequency of mortalities among laboratory workers infected via needlestick without prompt detection and reporting.

8.3.2 Results

The health consequences resulting from exposure to a pathogen via needlestick are dependent on several pathogen characteristics and host factors. This RA assumes that the infectious dose of the pathogen delivered via needlestick is sufficient to cause disease (Chapter 4), so no probabilistic calculations for initial infections are performed. Further, the RA assumes that the pathogen is viable in the needle at the time of the needlestick. An important characteristic is the pathogen's ability to cause infection by this route. As with all infections, the health consequences are also dependent on the immune status and general health of the host. For this RA, for needlestick injuries involving laboratory workers, the assumption is that the laboratory worker is a healthy young adult. For needlestick events without prompt detection and reporting, the health consequences are also based on the assumption that post-exposure prophylaxis (if available), quarantine, and supportive measures are not instituted until the laboratory worker exhibits symptoms and seeks medical attention.

Table 8–3 summarizes the potential health consequences in the laboratory worker and subsequent risk to the public. In the setting of illness caused by needlestick, the presentation and disease course could be different from that of the natural disease, especially for pathogens that are not normally known to cause disease by direct introduction into the host through the skin such as 1918 H1N1V, SARS-CoV and NIPV. However, in the absence of data to suggest otherwise, this RA makes the conservative assumption that the illness caused by needlestick would mimic the natural disease with respect to the course, the organ systems affected, the morbidity and mortality caused and potential for secondary transmission.

The issues of preexisting immunity and potentially available vaccines for each pathogen are further discussed in Appendix J. Full descriptions of the clinical diseases caused by the pathogens are provided in Chapter 3 and Appendix C. The estimates for the case fatality rate (CFR) provided here are summarized in Chapter 3, Appendix C and Mahmoud et al. (2008) and are presumed to apply to heterogeneous

populations containing individuals from medically vulnerable groups. The CFR estimates are assumed to represent the probability that an infected laboratory worker would die from the resulting illness. Applying these CFR estimates to laboratory workers may be conservative, as it is presumed that laboratory workers are healthy adults as discussed further in Appendix I. Potential risk to the public from laboratory workers infected with transmissible pathogens is further discussed in Chapter 9 and Appendix L.

Table 8–3. Summary of health consequences in laboratory worker from needlestick

Pathogen	Pre-existing immunity to pathogen in laboratory worker	Resulting illness via needlestick route	CFR Estimate	Potential for secondary transmission to members of the public if initial infection is undetected and/or unreported
Biosafety Level 3 Pathogens				
<i>B. anthracis</i>	Possible, as vaccine is available	Bacteremia and sepsis with <i>B. anthracis</i>	45%	No
<i>F. tularensis</i>	Possible, as vaccine is available	Bacteremia, sepsis and pneumonic form of tularemia	< 2%	No
<i>Y. pestis</i>	No	Bacteremia, primary septicemic plague and pneumonic plague	15%	Yes, if pneumonic plague is present
1918 H1N1V	Possible, due to cross-protection from past influenza vaccines or infections	Influenza	2.5%	Yes, if respiratory symptoms are present
SARS-CoV	No	SARS	10%	Yes, if respiratory symptoms are present
RVFV	Possible, as vaccine is available	Rift Valley fever	0.5–2%	No
ANDV	No	Viremia and Hantavirus pulmonary syndrome	50%	Yes, if respiratory symptoms are present

Pathogen	Pre-existing immunity to pathogen in laboratory worker	Resulting illness via needlestick route	CFR Estimate	Potential for secondary transmission to members of the public if initial infection is undetected and/or unreported
Biosafety Level 4 Pathogens				
EBOV	No	Ebola hemorrhagic fever	40–90%	Yes
MARV	No	Hemorrhagic fever	100%	Yes
LASV	No	Lassa fever (hemorrhagic fever)	1–2%	Yes
JUNV	No	Argentine hemorrhagic fever	< 1%	Yes
TBEV-FE	No	Encephalitis	20–40%	No
NIPV	No	Viremia, encephalitis and/or pneumonia	40–70%	Yes, if respiratory symptoms are present

1

2 The CFR estimates in Table 8–3 can be combined with the frequency category for a needlestick incident

3 to estimate the frequency with which deaths would occur among laboratory workers because of infections

4 via needlestick. These CFR estimates are presumably most applicable to needlestick events without

5 prompt detection and reporting, in which treatment of the infection would likely not begin until after

6 symptoms appear, which is likely most often the case during natural disease outbreaks from which the

7 CFR estimates were derived. The frequency of needlestick events without prompt detection and reporting

8 was assigned to the B (0.01 per year to 0.0001 per year) frequency category. This was estimated as the

9 workforce risk for each BSL-3 pathogen as well as each BSL-4 pathogen (see Chapter 4). Frequencies

10 within the category range were multiplied with CFR estimates, with the results shown in Table 8–4.

Table 8—4. Frequency of death (mortality) among laboratory workers for needlestick event without prompt detection and reporting.

BSL-3 Pathogens			
Pathogen	Assumed CFR	Frequency range of laboratory worker mortalities	Frequency category
<i>B. anthracis</i>	0.45	≈ 1 in 200 to 20,000 yrs	B or C
<i>F. tularensis</i>	0.02	≈ 1 in 5,000 to 500,000 yrs	B or C
<i>Y. pestis</i>	0.15	≈ 1 in 700 to 70,000 yrs	B or C
1918 H1N1V	0.025	≈ 1 in 4,000 to 400,000 yrs	B or C
SARS-CoV	0.1	≈ 1 in 1,000 to 100,000 yrs	B or C
RVFV	0.02	≈ 1 in 5,000 to 500,000 yrs	B or C
ANDV	0.5	≈ 1 in 200 to 20,000 yrs	B or C
BSL-4 Pathogens			
Pathogen	Assumed probability of mortality per infection	Frequency range of laboratory worker mortalities	Frequency category
EBOV	0.9	≈ 1 in 100 to 10,000 yrs	B
MARV	1	≈ 1 in 100 to 10,000 yrs	B
LASV	0.02	≈ 1 in 5,000 to 500,000 yrs	B or C
JUNV	0.01	≈ 1 in 10,000 to 1 million yrs	C
TBEV-FE	0.4	≈ 1 in 200 to 20,000 yrs	B or C
NIPV	0.7	≈ 1 in 100 to 10,000 yrs	B

Frequency categories: A = 1 in 1 to 100 years; B = 1 in 100 to 10,000 years

C = 1 in 10,000 to 1 million years; D = 1 in > 1 million years

8.4 Initial Infections Resulting from Centrifuge Release

8.4.1 Methodology

This section introduces the methodology for generating estimates for initial infections resulting from BSL-3 Centrifuge Infectious Aerosol Release events described in Chapter 4 and Appendix F. A detailed description of the quantitative methodology is presented in Appendix K.

This event involves only those pathogens that can be studied under BSL-3 laboratory conditions (7 of the 13 pathogens). Centrifuge release scenarios involving BSL-4 pathogens are not carried forward to the initial infection analyses because the analysis described in Chapter 4 and Appendix F determined that it would not be credible for an aerosol exposure to go undetected in a BSL-4 laboratory.

1 All potentially exposed individuals from a centrifuge aerosol release are laboratory workers. The potential
2 route of exposure for laboratory workers during or after a centrifuge release is assumed to be through
3 direct contact, ingestion, or inhalation. Therefore, the dose-response information generated in Appendix J,
4 which focuses primarily on inhalational exposure, can be applied. The centrifuge release information
5 provided in Chapter 4 and the dose-response information provided in Appendix J are synthesized for each
6 of the seven BSL-3 pathogens.

7
8 *As this RA specifically considers centrifuge release scenarios that are undetected or unreported, the*
9 *initial infections results also serve as estimates for the frequency of infected laboratory workers leaving*
10 *the facility after a centrifuge incident, with potential to transmit to the public.*

11
12 Two types of calculations and results are presented for each pathogen: a *central estimate* and *uncertainty*
13 *results around that central estimate*. Uncertainty refers to the lack of knowledge of the true value of
14 parameters. Variability refers to the effect of chance and inherent unpredictability of the way events may
15 occur (stochasticity). In the estimation of initial infections, the effect of uncertainty for some key
16 unknown values was assessed by systematically comparing results under different assumptions for their
17 values, and the effect of variability was assessed by performing probabilistic calculations under each
18 tested scenario. The details of these analyses are presented in Appendix K.

19 20 **8.4.2 Results – Infection frequency**

21 This section summarizes the overall results for the centrifuge aerosol release event. Table 8–5 compiles
22 the central estimate results and Table 8–6 compiles the uncertainty results for all seven BSL-3 pathogens.

Table 8–5. Central estimates for infections from BSL-3 centrifuge infectious aerosol release (with full or partial respiratory protection)

Pathogen	Number of initial infections	Probability of initial infections given release	Average return period for release leading to initial infections	Frequency category
<i>B. anthracis</i>	1 or more	0.0065%	800,000 years	C
<i>F. tularensis</i>	1 or more	12%	400 years	B
	2 or more	0.38%	10,000 years	B/C
<i>Y. pestis</i>	1 or more	0.00091%	5 million years	D
1918 H1N1V	1 or more	0.23%	20,000 years	C
SARS-CoV	1 or more	0.028%	200,000 years	C
RVFV	1 or more	38%	100 years	A/B
	2 or more	6.7%	800 years	B
ANDV	1 or more	0.012%	400,000 years	C

Frequency categories: A = 1 in 1 to 100 years; B = 1 in 100 to 10,000 years
C = 1 in 10,000 to 1 million years; D = 1 in > 1 million years

For the central estimate example, the results show that *F. tularensis* and RVFV are estimated to result in the highest probability of infections occurring among one or two laboratory workers as a result of a centrifuge aerosol release, with the estimated frequency of those events falling in or near the borders of the B frequency category. For the other pathogens, the frequency of one or more infections falls in the C frequency category, except for *Y. pestis* (D category).

For each pathogen, a single dose-response estimate from Table 8–1 was applied as part of the calculations to arrive at the central estimate results. The literature-based dose-response estimate was applied in all cases except for 1918 H1N1V, for which estimates based on expert opinion were used.

Table 8–6: Summary of uncertainty results: number of 10,000 input combinations that resulted in the frequency of centrifuge releases leading to the given number of initial infections (among workers with full or partial protection) falling into each frequency category.

Pathogen	Dose-response estimate	Number of initial infections	Frequency category A	Frequency category B	Frequency category C	Frequency category D
<i>B. anthracis</i>	Literature-based	1 or more	0	20 (< 1%)	7606 (76%)	2374 (24%)
		2 or more	0	0	0	10000 (100%)
	Expert-based	1 or more	0	217 (2%)	7484 (75%)	2299 (23%)
		2 or more	0	0	0	10000 (100%)
<i>F. tularensis</i>	Literature-based	1 or more	1513 (15%)	8487 (85%)	0	0
		2 or more	56 (1%)	7036 (70%)	2908 (29%)	0
		3 or more	0	451 (5%)	7854 (79%)	1695 (17%)
		4 or more	0	2 (< 0.1%)	929 (9%)	9069 (91%)
	Expert-based	1 or more	348 (3%)	7557 (76%)	2095 (21%)	0
		2 or more	5 (< 0.1%)	1380 (14%)	5123 (51%)	3492 (35%)
		3 or more	0	23 (< 1%)	1806 (18%)	8171 (82%)
		4 or more	0	0	32 (< 1%)	9968 (> 99%)
<i>Y. pestis</i>	Literature-based	1 or more	0	0	1156 (12%)	8844 (88%)
		2 or more	0	0	0	10000 (100%)
	Expert-based	1 or more	0	24 (< 1%)	3281 (33%)	6695 (67%)
		2 or more	0	0	0	10000 (100%)
1918 H1N1V	Expert-based	1 or more	28 (< 1%)	3916 (39%)	4467 (45%)	1589 (16%)
		2 or more	0	21 (< 1%)	2524 (25%)	7455 (75%)
		3 or more	0	0	7 (0.1%)	9993 (99.9%)
SARS-CoV	Literature-based	1 or more	0	282 (3%)	9694 (97%)	24 (< 1%)
		2 or more	0	0	1 (< 0.1%)	9999 (> 99.9%)
	Expert-based	1 or more	0	28 (< 1%)	2792 (28%)	7180 (72%)
		2 or more	0	0	0	10000 (100%)
RVFV	Literature-based	1 or more	5400 (54%)	4600 (46%)	0	0
		2 or more	1679 (17%)	8313 (83%)	8 (0.1%)	0
		3 or more	310 (3%)	7608 (76%)	2080 (21%)	2 (< 0.1%)
		4 or more	31 (< 1%)	2517 (25%)	4068 (41%)	3384 (34%)
	Expert-based	1 or more	10 (0.1%)	2222 (22%)	7361 (74%)	407 (4%)
		2 or more	0	8 (0.1%)	1091 (11%)	8901 (89%)
		3 or more	0	0	2 (< 0.1%)	9998 (> 99.9%)
		4 or more	0	0	0	10000 (100%)
ANDV	Literature-based	1 or more	0	92 (1%)	9211 (92%)	697 (7%)
		2 or more	0	0	0	10000 (100%)
	Expert-based	1 or more	0	25 (< 1%)	2332 (23%)	7643 (76%)
		2 or more	0	0	0	10000 (100%)

Frequency categories: A = 1 in 1 to 100 years; B = 1 in 100 to 10,000 years
C = 1 in 10,000 to 1 million years; D = 1 in > 1 million years

1 The uncertainty results reveal how changing the input values across credible ranges affects changes in the
2 central estimate results. The following summarizes key aspects of results in this table for each pathogen.

3
4 *B. anthracis* infection frequency is placed mostly in the C frequency category, with a significant
5 percentage (> 20 percent) of results placed in D frequency category, and a small number (< 3 percent) in
6 B.

7
8 *F. tularensis* infection frequency is placed mostly in B, with uncertainty shifted mostly toward C. The
9 frequency of release resulting in multiple infections is estimated in B or C, with a wide uncertainty range
10 spanning all four categories.

11
12 *Y. pestis* infection frequency is placed mostly in D frequency category, with 12 percent or 33 percent in C
13 and less than 1 percent in B.

14
15 1918 H1N1V infection frequency estimates span all four categories, with most estimates (84 percent) in B
16 or C and < 1 percent in A. Releases resulting in multiple infections are placed in the C category for 25
17 percent of estimates, in B for < 1 percent, and the remainder in D frequency category.

18
19 SARS-CoV infection frequency was placed mostly in C under the literature-based dose-response
20 estimates and mostly in D frequency category under the expert-based estimates. Small percentages
21 (< 3 percent) were placed in B in both cases.

22
23 RVFV infection frequency was split more or less evenly between A and B under the literature-based
24 dose-response models and mostly in C under the expert-based models. Frequency of multiple-infection
25 releases displays a wide uncertainty range spanning all four categories across the two sets of estimates.

26
27 ANDV infection frequency was placed mostly in C under the literature-based dose-response models and
28 mostly in D frequency category under the expert-based models, with small percentages (< 1 percent) in B
29 in both cases.

30 31 **8.4.3 Results – Health Consequences**

32 The results described above estimate a non-zero risk of a laboratory worker developing an infection after
33 exposure to any of the BSL-3 pathogens as a result of loss of bio-containment after an event involving a
34 centrifuge. The route of exposure considered is via inhalation. As it is assumed that the exposure from the

centrifuge event is undetected and/or unreported, the health consequences are based on the assumption that post-exposure prophylaxis (if available), quarantine and supportive measures are not instituted unless and until the laboratory worker exhibits symptoms and seeks medical attention. Table 8–7 summarizes the potential health consequences in the laboratory worker and subsequent risk to the public, in the event of an inhalational infection occurring in the laboratory worker.

The issues of pre-existing immunity and potentially available vaccines for each pathogen are further discussed in Appendix J. Full descriptions of the clinical diseases caused by the pathogens are provided in Chapter 3 and Appendix C. The CFR estimates provided here are summarized in Chapter 3, Appendix C and Mahmoud et al. (2008) and are presumed to apply to heterogeneous populations containing individuals from medically vulnerable groups. Applying these CFR estimates to laboratory workers may be conservative, as it is presumed that laboratory workers are healthy adults as discussed further in Appendix I. Potential risk to the public from laboratory workers infected with transmissible pathogens is further discussed in Chapter 9 and Appendix L.

Table 8–7. Summary of Health Consequences in Laboratory Worker from Centrifuge Event

Pathogen	Preexisting immunity to pathogen in laboratory worker	Resulting illness via inhalation route	CFR estimates	Potential for secondary transmission to members of the public if initial infection is undetected and/or unreported
<i>B. anthracis</i>	Possible, as vaccine is available	Inhalational anthrax	45%	No
<i>F. tularensis</i>	Possible, as vaccine is available	Pneumonic form of tularemia	< 2%	No
<i>Y. pestis</i>	No	Pneumonic plague	15%	Yes, if pneumonic plague is present
1918 H1N1V	Possible, due to cross-protection from past influenza vaccines or infections	Influenza	2.5%	Yes
SARS-CoV	No	SARS	10%	Yes
RVFV	Possible, as vaccine is available	Rift Valley fever	0.5%–2%	No
ANDV	No	Hantavirus pulmonary syndrome	50%	Yes, if pulmonary syndrome is present

Finally, the CFR estimates in Table 8–7 were integrated into the initial infections calculations to compute estimates for the frequency of centrifuge releases leading to mortalities among laboratory workers. For *F. tularensis* and RVFV, the conservative value of 2 percent mortality was applied. The results under the central estimate example inputs are shown in Table 8–8.

Table 8–8. Central estimates for BSL-3 centrifuge release fatalities among laboratory workers (with full or partial respiratory protection)

Pathogen	Number of deaths among laboratory workers	Probability of deaths among laboratory workers from a release	Average return period of release leading to deaths among laboratory workers	Frequency category
<i>B. anthracis</i>	1 or more	0.0029%	2 million years	D
<i>F. tularensis</i>	1 or more	0.25%	20,000 years	C
	2 or more	0.00015%	> 10 million years	D
<i>Y. pestis</i>	1 or more	0.00014%	> 10 million years	D
1918 H1N1V	1 or more	0.0058%	900,000 years	C
SARS-CoV	1 or more	0.0028%	2 million years	D
RVFV	1 or more	1.0%	5,000 years	B
	2 or more	0.0027%	2 million years	D
ANDV	1 or more	0.0062%	800,000 years	C

Frequency categories: A = 1 in 1 to 100 years; B = 1 in 100 to 10,000 years
C = 1 in 10,000 to 1 million years; D = 1 in > 1 million years

Under the central estimate inputs, centrifuge releases leading to one or more deaths among laboratory workers would be placed in the B frequency category for RVFV, the C frequency category for *F. tularensis*, 1918 H1N1V, and ANDV, and the D frequency category for *B. anthracis*, *Y. pestis*, and SARS-CoV. Centrifuge releases leading to two or more deaths among laboratory workers would be placed in the D frequency category for all pathogens. As described under Table 8–5, these results were calculated using literature-based dose-response estimates except for the 1918 H1N1V results, which were calculated using dose-response estimates derived from expert opinion.

Uncertainty results pertaining to these mortality estimates are presented in Appendix K.

8.5 Initial Infections Resulting from Earthquake Event

8.5.1 Methodology

This section describes the methodology for generating estimates for initial infections resulting from earthquake release events described in Chapter 4 and Appendix F.

This event is relevant to all 13 pathogens analyzed in this RA. All potentially exposed individuals are assumed to be members of the public. This section discusses only initial infections, that is, members of the public directly exposed to an aerosol released from NEIDL. Chapter 9 and Appendix L discuss the potential consequences of initially infected individuals interacting with contacts.

The potential route of exposure for members of the public from this event is assumed to be through inhalation. Therefore, the dose-response information generated in Appendix J, which focuses primarily on inhalational exposure, can be applied. The earthquake release information provided in Appendix F and the dose-response information provided in Appendix J are synthesized for each of the 13 pathogens.

The methodology for generating quantitative estimates of the frequency of earthquake release events that lead to one or more initial infections or mortalities from each pathogen, as well as the uncertainty in the estimations and the sensitivity of the estimations to uncertainties in the input values, are described in detail in Appendix K. Two types of calculations and results are presented for each pathogen: a *central estimate* and *uncertainty* results around that central estimate.

8.5.2 Results—Beyond Design Basis Release

The earthquake initial infections calculations were performed using the exposure estimates from the Beyond Design Basis (BDB) Release scenario described in Chapter 4 and Appendix F. The BDB release represents a scenario in which an earthquake causes partial damage to the facility, enough to cause a partial loss of biocontainment but not a total collapse. As the calculations resulted in very low risk estimates for every pathogen under every population scenario, the results are displayed here only in summary form. A more detailed discussion of aspects of each pathogen relevant to potential initial infections in the public is reserved for Section 8.5.3.

Table 8–9. Central estimates for urban site BDB earthquake release

Pathogen	Number of initial infections overall	Probability of initial infections from release	Average return period of release leading to initial infections
<i>B. anthracis</i>	1 or more	1.4×10^{-9}	> 10 million years
<i>F. tularensis</i>	1 or more	5.7×10^{-7}	> 10 million years
<i>Y. pestis</i>	1 or more	3.7×10^{-11}	> 10 million years
1918 H1N1V	1 or more	7.6×10^{-18}	> 10 million years
SARS-CoV	1 or more	5.5×10^{-8}	> 10 million years
RVFV	1 or more	1.6×10^{-4}	> 10 million years
ANDV	1 or more	2.5×10^{-8}	> 10 million years
EBOV	1 or more	4.5×10^{-9}	> 10 million years
MARV	1 or more	9.0×10^{-10}	> 10 million years
LASV	1 or more	2.6×10^{-9}	> 10 million years
JUNV	1 or more	4.7×10^{-10}	> 10 million years
TBEV-FE	1 or more	1.5×10^{-47}	> 10 million years
NIPV	1 or more	1.7×10^{-10}	> 10 million years

For the central estimate example, all pathogens are estimated to produce a low probability that one or more infections occur among members of the public. The highest estimated probability is for RVFV (1.6×10^{-4}), which is about a one-in-6,000 chance. Combined with the central estimate estimated frequency of the occurrence of an earthquake release (one in 100,000 years), the frequency of an earthquake BDB release resulting in one or more infections of any pathogen is estimated to be well into the D frequency category. Many of the probabilities listed in the third column are exceedingly small and are not presumed to precisely represent the actual probability of an infection occurring. The numerical results are used only to the extent that they contribute to the argument that the frequency of infections from this event occur well into frequency category D.

For each pathogen in Table 8–9, a single dose-response estimate from Table 8–1 or 8–2 was applied as part of the calculations to arrive at the central estimate results. The literature-based dose-response estimate was applied in all cases except for 1918 H1N1V, JUNV, and TBEV-FE, for which estimates based on expert opinion were used.

Table 8–10. Summary of uncertainty results: number of 10,000 input combinations that resulted in the frequency of earthquake BDB release (urban site) leading to the given number of initial infections falling into each frequency category.

Pathogen	Number of initial infections	Frequency Category A	Frequency Category B	Frequency Category C	Frequency Category D
<i>B. anthracis</i>	1 or more	0	0	0	10000 (100%)
<i>F. tularensis</i>	1 or more	0	0	0	10000 (100%)
<i>Y. pestis</i>	1 or more	0	0	0	10000 (100%)
1918 H1N1V	1 or more	0	0	0	10000 (100%)
SARS-CoV	1 or more	0	0	0	10000 (100%)
RVFV	1 or more	0	0	0	10000 (100%)
ANDV	1 or more	0	0	0	10000 (100%)
EBOV	1 or more	0	0	0	10000 (100%)
MARV	1 or more	0	0	0	10000 (100%)
LASV	1 or more	0	0	0	10000 (100%)
JUNV	1 or more	0	0	0	10000 (100%)
TBEV-FE	1 or more	0	0	0	10000 (100%)
NIPV	1 or more	0	0	0	10000 (100%)

Frequency categories: A = 1 in 1 to 100 years; B = 1 in 100 to 10,000 years

C = 1 in 10,000 to 1 million years; D = 1 in > 1 million years

These uncertainty results apply for estimates using both the literature-based and the expert-based range of dose-response estimates. Every combination of dose-response estimates and earthquake release frequency estimates results in an estimated frequency of at least one initial infection in the D frequency category.

That means that even the most conservative dose-response assessments combined with the most conservative earthquake frequency (one per 10,000 years) results in an average return period estimate greater than one million years.

Results for urban residents, suburban site, and rural site

The results in Tables 8–9 and 8–10 were calculated using the overall estimated urban population, which includes estimates of area residents and daytime students, workers, hospital patients, and passersby within a 1-km radius. If the population inputs are restricted to residents only, the resulting probabilities in Table 8–9 are even lower, and the same conclusions are drawn regarding the frequency category for one or more infections occurring (D frequency category).

The average, per-person exposure estimates at the suburban and rural sites are slightly higher than at the urban site (see Chapter 4 and Appendix F), but the estimated suburban and rural populations are lower, which results in lower probabilities of at least one infection compared to the urban results in Table 8–9.

Therefore, the same conclusions are drawn regarding the frequency category for one or more infections occurring at the suburban and rural sites (D frequency category).

A more detailed discussion of the effects of site differences on the earthquake initial infections calculations is reserved for Section 8.5.3 in which site and population differences lead to placement of some results in different frequency categories under the larger exposure estimates for the Maximum Reasonably Foreseeable release quantities.

8.5.3 Results—Maximum Reasonably Foreseeable Release

For each pathogen, the results from Chapter 4 and Appendix F detailing the population estimates and exposure amounts from a maximum reasonably foreseeable (MRF) earthquake release are combined with the dose-response information from Appendix J. The MRF release represents an extreme scenario in which an earthquake causes total collapse of the facility. The overall results are tabulated for each pathogen. Step-by-step details for the calculations are shown in Appendix K.

8.5.3.1 Urban site

Table 8–11. Central initial infection and fatality estimates for urban MRF earthquake release, BSL-3 pathogens

Pathogen	Number of initial infections/deaths	Probability of initial infections or deaths from release	Frequency of release leading to initial infections or deaths	Frequency category
Initial infections				
<i>B. anthracis</i>	1 or more	0.0053%	> 10 million years	D
<i>F. tularensis</i>	1 or more	2.1%	5 million years	D
<i>Y. pestis</i>	1 or more	0.00014%	> 10 million years	D
1918 H1N1V	1 or more	0.045%	> 10 million years	D
SARS-CoV	1 or more	0.063%	> 10 million years	D
RVFV	1 or more	84%	100,000 years	C
	2 or more	54%	200,000 years	C
	3 or more	27%	400,000 years	C
	4 or more	11%	900,000 years	C
	5 or more	3.8%	3 million years	D
ANDV	1 or more	0.028%	> 10 million years	D

Pathogen	Number of initial infections/deaths	Probability of initial infections or deaths from release	Frequency of release leading to initial infections or deaths	Frequency category
Deaths among initially infected				
<i>B. anthracis</i>	1 or more	0.0024%	> 10 million years	D
<i>F. tularensis</i>	1 or more	0.043%	> 10 million years	D
<i>Y. pestis</i>	1 or more	0.000021%	> 10 million years	D
1918 H1N1V	1 or more	0.0011%	> 10 million years	D
SARS-CoV	1 or more	0.0063%	> 10 million years	D
RVFV	1 or more	3.6%	3 million years	D
ANDV	1 or more	0.014%	> 10 million years	D

Frequency categories: A = 1 in 1 to 100 years; B = 1 in 100 to 10,000 years
C = 1 in 10,000 to 1 million years; D = 1 in > 1 million years

The central estimate results for BSL-3 pathogens at the urban site show that, for all pathogens except for RVFV, the estimated probability of any infections occurring is less than 0.1 percent, which, when combined with the estimated low frequency of a release occurring, place the estimated frequency in the D frequency category. The exception, RVFV, produces an estimated 84 percent chance that at least one infection would occur, and up to 4 or more infections would be placed in the C frequency category. The probability of one or more deaths from RVFV infection after a release is estimated to be less than 4 percent under the central estimate assumptions. The calculations leading to these results made use of literature-based dose-response estimates except for 1918 H1N1V, for which dose-response estimates based on expert opinion were used.

Uncertainty results associated with these estimates are presented in Appendix K. They reveal that some parameter combinations for *F. tularensis* (< 20 percent) and 1918 H1N1V (< 10 percent) result in frequency estimates of one or more infections in the C frequency category. For RVFV, the uncertainty estimates reveal that 30 percent of estimates place the frequency of one or more deaths in the C frequency category. On the other hand, most (> 95 percent) of the inputs using the expert-based dose-response curves lead to estimates of one or more RVFV infection in D frequency category.

Table 8–12. Central initial infection and fatality estimates for urban MRF earthquake release, BSL-4 pathogens

Pathogen	Number of initial infections/deaths	Probability of initial infections or deaths from release	Average return period for initial infections or deaths	Frequency category
Initial infections				
EBOV	1 or more	1.7%	6 million years	D
MARV	1 or more	0.34%	> 10 million years	D
LASV	1 or more	1.0%	10 million years	D
JUNV	1 or more	0.18%	> 10 million years	D
TBEV-FE	1 or more	0.0025%	> 10 million years	D
NIPV	1 or more	0.065%	> 10 million years	D
Deaths among initially infected				
EBOV	1 or more	1.5%	7 million years	D
MARV	1 or more	0.34%	> 10 million years	D
LASV	1 or more	0.020%	> 10 million years	D
JUNV	1 or more	0.0018%	> 10 million years	D
TBEV-FE	1 or more	0.00098%	> 10 million years	D
NIPV	1 or more	0.045%	> 10 million years	D

Frequency categories: A = 1 in 1 to 100 years; B = 1 in 100 to 10,000 years

C = 1 in 10,000 to 1 million years; D = 1 in > 1 million years

The central estimate results for BSL-4 pathogens at the urban site show that the highest probabilities of an infection occurring from a release are estimated for EBOV and LASV (1-2 percent chance). However, even those probabilities are low enough that, when combined with the estimated low frequency of a release occurring, the corresponding frequencies are placed in the D frequency category. The calculations leading to these results made use of literature-based dose-response estimates except for JUNV and TBEV-FE, for which dose-response estimates based on expert opinion were used.

Uncertainty results associated with these estimates are presented in Appendix K. They reveal that some parameter combinations for each BSL-4 pathogen result in frequency estimates of one or more infections in the C frequency category, although the percentage of combinations leading to that result is small (< 5 percent, except for EBOV at 13 percent). The uncertainty estimates also reveal that 11 percent of estimates place the frequency of one or more deaths from EBOV in the C frequency category, while all other BSL-4 pathogens are > 99.9 percent D frequency category for the frequency of one or more deaths.

8.5.3.2 Urban residents

The results summarized in the previous section were calculated using the overall estimated urban population, which includes estimates of area residents as well as daytime students, workers, hospital patients, and passersby in a 1-km radius. Another set of results was calculated for population inputs restricted to estimates of the resident population only. Central estimates are shown in tables below.

BSL-3 Pathogens

Table 8–13. Central initial infection and mortality estimates among urban residents for MRF earthquake release, BSL-3 pathogens

Pathogen	Number of initial infections/deaths	Probability of initial infections or deaths from release	Average return period of release leading to initial infections or deaths
Initial infections			
<i>B. anthracis</i>	1 or more	8.7×10^{-6}	> 10 million years
<i>F. tularensis</i>	1 or more	3.5×10^{-3}	> 10 million years
<i>Y. pestis</i>	1 or more	2.3×10^{-7}	> 10 million years
1918 H1N1V	1 or more	2.1×10^{-6}	> 10 million years
SARS-CoV	1 or more	1.0×10^{-4}	> 10 million years
RVFV	1 or more	0.26	400,000 years
	2 or more	0.037	3 million years
ANDV	1 or more	4.6×10^{-5}	> 10 million years
Deaths among initially infected			
<i>B. anthracis</i>	1 or more	3.9×10^{-6}	> 10 million years
<i>F. tularensis</i>	1 or more	7.0×10^{-5}	> 10 million years
<i>Y. pestis</i>	1 or more	3.4×10^{-8}	> 10 million years
1918 H1N1V	1 or more	5.2×10^{-8}	> 10 million years
SARS-CoV	1 or more	1.0×10^{-5}	> 10 million years
RVFV	1 or more	6.0×10^{-3}	> 10 million years
ANDV	1 or more	2.3×10^{-5}	> 10 million years

Under the central estimate inputs, an earthquake MRF release resulting in one or more infections among urban residents would be placed in the D frequency category for every BSL-3 pathogen except for RVFV. It is estimated that one or more RVFV infections among residents would occur with about 26 percent probability given an MRF release. An MRF release resulting in multiple RVFV infections among residents would be placed in the D frequency category. The calculations leading to these results made use of literature-based dose-response estimates except for 1918 H1N1V, for which dose-response estimates based on expert opinion were used.

The uncertainty analysis (see Appendix K) reveals that, except for RVFV under the literature-based dose-response estimates, 100 percent of input combinations place the frequency of one or more infections with BSL-3 pathogens among urban residents in the D frequency category. For RVFV, up to three or more infections and one or more death are placed in the C frequency category for a small percentage of inputs (4 percent and 1 percent, respectively). However, the expert-based dose-response models lead to 100 percent D frequency category for even one RVFV infection among urban residents.

BSL-4 Pathogens

Table 8–14. Central initial infection and fatality estimates among urban residents for MRF earthquake release, BSL-4 pathogens

Pathogen	Number of initial infections/deaths	Probability of initial infections or deaths from release	Average return period of release leading to initial infections or deaths
Initial infections			
EBOV	1 or more	2.8×10^{-3}	> 10 million years
MARV	1 or more	5.6×10^{-4}	> 10 million years
LASV	1 or more	1.6×10^{-3}	> 10 million years
JUNV	1 or more	2.9×10^{-4}	> 10 million years
TBEV-FE	1 or more	4.8×10^{-9}	> 10 million years
NIPV	1 or more	1.1×10^{-4}	> 10 million years
Deaths among initially infected			
EBOV	1 or more	2.5×10^{-3}	> 10 million years
MARV	1 or more	5.6×10^{-4}	> 10 million years
LASV	1 or more	3.3×10^{-5}	> 10 million years
JUNV	1 or more	2.9×10^{-6}	> 10 million years
TBEV-FE	1 or more	1.9×10^{-9}	> 10 million years
NIPV	1 or more	7.4×10^{-5}	> 10 million years

Under the centrally estimated inputs, an earthquake MRF release resulting in one or more infections among urban residents would be placed in the D frequency category frequency for every BSL-4 pathogen. The highest estimated probabilities are for EBOV and LASV, for which it is estimated that one or more infections among residents would occur with about 0.2 or 0.3 percent probability given an MRF release. Combined with the centrally estimated frequency of the earthquake release (once per 100,000 years), those probabilities result in a projected return period for releases leading to infection among residents greater than ten million years. The calculations leading to these results made use of literature-based dose-

response estimates except for JUNV and TBEV-FE, for which dose-response estimates based on expert opinion were used.

The uncertainty analysis (see Appendix K) reveals that ≥ 99.9 percent of input combinations place the frequency of one or more infections among urban residents in the D frequency category for every BSL-4 pathogen.

8.5.3.3 Suburban site

Another set of results was calculated for exposure and population inputs from estimates on the basis of characteristic of the suburban site (see Chapter 4 and Appendix F). The central estimates are shown in tables below.

BSL-3 Pathogens

Table 8–15. Central initial infection and fatality estimates at suburban site for MRF earthquake release, BSL-3 pathogens

Pathogen	Number of initial infections/deaths	Probability of initial infections or deaths from release	Average return period of release leading to initial infections or deaths
Initial infections			
<i>B. anthracis</i>	1 or more	1.1×10^{-6}	> 10 million years
<i>F. tularensis</i>	1 or more	4.6×10^{-4}	> 10 million years
<i>Y. pestis</i>	1 or more	3.0×10^{-8}	> 10 million years
1918 H1N1V	1 or more	1.6×10^{-7}	> 10 million years
SARS-CoV	1 or more	1.3×10^{-5}	> 10 million years
RVFV	1 or more	3.8×10^{-2}	3 million years
ANDV	1 or more	6.0×10^{-6}	> 10 million years
Deaths among initially infected			
<i>B. anthracis</i>	1 or more	5.2×10^{-7}	> 10 million years
<i>F. tularensis</i>	1 or more	9.2×10^{-6}	> 10 million years
<i>Y. pestis</i>	1 or more	4.5×10^{-9}	> 10 million years
1918 H1N1V	1 or more	4.0×10^{-7}	> 10 million years
SARS-CoV	1 or more	1.3×10^{-6}	> 10 million years
RVFV	1 or more	7.8×10^{-4}	> 10 million years
ANDV	1 or more	3.0×10^{-6}	> 10 million years

BSL-4 Pathogens

Table 8–16. Central initial infection and fatality results at suburban site for MRF earthquake release, BSL-4 pathogens

Pathogen	Number of initial infections/deaths	Probability of initial infections or deaths from release	Average return period of release leading to initial infections or deaths
Initial infections			
EBOV	1 or more	3.7×10^{-4}	> 10 million years
MARV	1 or more	7.4×10^{-5}	> 10 million years
LASV	1 or more	2.2×10^{-4}	> 10 million years
JUNV	1 or more	3.8×10^{-5}	> 10 million years
TBEV-FE	1 or more	2.6×10^{-6}	> 10 million years
NIPV	1 or more	1.4×10^{-5}	> 10 million years
Deaths among initially infected			
EBOV	1 or more	3.3×10^{-4}	> 10 million years
MARV	1 or more	7.4×10^{-5}	> 10 million years
LASV	1 or more	4.3×10^{-6}	> 10 million years
JUNV	1 or more	3.8×10^{-7}	> 10 million years
TBEV-FE	1 or more	1.0×10^{-6}	> 10 million years
NIPV	1 or more	9.7×10^{-6}	> 10 million years

For the central estimate example, all pathogens are estimated to produce a low probability that one or more infections occur among members of the public at the suburban site. The highest estimated probability is for RVFV (3.8×10^{-9}), which is about a one-in-30 chance. Combined with the central estimate projected frequency of the occurrence of an earthquake release (one in 100,000 years), the frequency of an earthquake MRF release resulting in one or more infections of any pathogen at the suburban site is estimated to be in the D frequency category. The calculations leading to these results made use of literature-based dose-response estimates except for 1918 H1N1V, JUNV, and TBEV-FE for which dose-response estimates based on expert opinion were used.

In the uncertainty analysis (see Appendix K), every combination of dose-response estimates and earthquake release frequency estimates results in an estimated frequency of at least one initial infection at the suburban site in the D category, except for about 32 percent of the estimates using the literature-based dose-response estimates for RVFV.

8.5.3.4 Rural site

Another set of results was calculated for exposure and population inputs from estimates on the basis of characteristic of the rural site (see Chapter 4 and Appendix F). The central estimates are shown in tables below.

BSL-3 Pathogens

Table 8–17. Central initial infection and fatality estimates for rural site, MRF earthquake release, BSL-3 pathogens

Pathogen	Number of initial infections/deaths	Probability of initial infections or deaths from release	Average return period of release leading to initial infections or deaths
Initial infections			
<i>B. anthracis</i>	1 or more	5.8×10^{-7}	> 10 million years
<i>F. tularensis</i>	1 or more	2.3×10^{-4}	> 10 million years
<i>Y. pestis</i>	1 or more	1.5×10^{-8}	> 10 million years
1918 H1N1V	1 or more	9.1×10^{-6}	> 10 million years
SARS-CoV	1 or more	6.8×10^{-6}	> 10 million years
RVFV	1 or more	1.9×10^{-2}	5 million years
ANDV	1 or more	3.1×10^{-6}	> 10 million years
Deaths among initially infected			
<i>B. anthracis</i>	1 or more	2.6×10^{-7}	> 10 million years
<i>F. tularensis</i>	1 or more	4.7×10^{-6}	> 10 million years
<i>Y. pestis</i>	1 or more	2.3×10^{-9}	> 10 million years
1918 H1N1V	1 or more	2.3×10^{-7}	> 10 million years
SARS-CoV	1 or more	6.8×10^{-7}	> 10 million years
RVFV	1 or more	3.9×10^{-4}	> 10 million years
ANDV	1 or more	1.5×10^{-6}	> 10 million years

BSL-4 Pathogens

Table 8–18. Central initial infection and fatality estimates for the rural site, MRF earthquake release, BSL-4 pathogens

Pathogen	Number of initial infections/deaths	Probability of initial infections or deaths from release	Average return period of release leading to initial infections or deaths
Initial infections			
EBOV	1 or more	1.9×10^{-4}	> 10 million years
MARV	1 or more	3.7×10^{-5}	> 10 million years
LASV	1 or more	1.1×10^{-4}	> 10 million years
JUNV	1 or more	1.9×10^{-5}	> 10 million years
TBEV-FE	1 or more	1.3×10^{-6}	> 10 million years
NIPV	1 or more	7.0×10^{-6}	> 10 million years
Deaths among initially infected			
EBOV	1 or more	1.7×10^{-4}	> 10 million years
MARV	1 or more	3.7×10^{-5}	> 10 million years
LASV	1 or more	2.2×10^{-6}	> 10 million years
JUNV	1 or more	1.9×10^{-7}	> 10 million years
TBEV-FE	1 or more	5.4×10^{-7}	> 10 million years
NIPV	1 or more	4.9×10^{-6}	> 10 million years

For the central estimate example, all pathogens are estimated to produce a low probability that one or more infections occur at the rural site. The highest estimated probability is for RVFV (1.9×10^{-2}), which is about a one-in-50 chance. Combined with the central estimate projected frequency of the occurrence of an earthquake release (one in 100,000 years), the frequency of an earthquake MRF release resulting in one or more infections or deaths from any pathogen at the rural site is estimated to be in the D frequency category. The calculations leading to these results made use of literature-based dose-response estimates except for 1918 H1N1V, JUNV, and TBEV-FE, for which dose-response estimates based on expert opinion were used.

In the uncertainty analysis (see Appendix K), every combination of dose-response estimates and earthquake release frequency estimates results in an estimated frequency of at least one initial infection at the rural site in the D category, except for about 17 percent of the estimates using the literature-based dose-response models for RVFV.

8.6 Medically Vulnerable Subpopulations

8.6.1 Methodology

The methodology for the initial infections analyses up to this point uses an assumption that the dose-response and CFR estimates are applicable to all potentially exposed populations. That assumption could be violated for a population that has a different profile of vulnerability to disease or death than did the populations on which the dose-response and mortality estimates were based. For this RA, the issue of population vulnerability is investigated by evaluating populations at the three sites for the presence of five medically vulnerable subpopulations (MVSP), as discussed in Appendix I: children under 5, adults over 65, people with diabetes, people with HIV/AIDS, and pregnant women.

The dose-response models applied in the previous sections of this Chapter are presumed to be applicable to human populations containing MVSP to some extent. The derivation and justification of the literature-based models, discussed in detail in Appendix J, included consideration of the possibility that some potentially exposed individuals could be more susceptible to infection at a given dose than others. The expert-based dose-response models were based on the outcome of a modified Delphi process in which it was not specified to the experts that their estimates should be based on healthy individuals only; presumably, the experts took into consideration the susceptibility profile of a typical human population in arriving at their infectious dose estimates. For CFR estimates, the baseline rates assumed for each pathogen are based on data observed in human outbreaks, which occurred among populations containing many, if not all, of the MVSP considered in this RA.

Despite the fact that the dose-response and CFR estimates are already presumed to encompass MVSP, it is worth considering whether particular potentially exposed populations considered for this RA contain an atypical proportion of individuals belonging to certain MVSP, and then whether that proportion of MVSP is different enough from the norm to warrant adjusting the baseline initial infections and mortality estimates.

The quantitative analysis, described in Appendix K, is applied only to the earthquake release scenarios, in which the potentially exposed group (members of the public surrounding NEIDL) may contain MVSP of higher or lower proportion than a typical human population. As discussed in Appendix I, the population of laboratory workers, who are the potentially exposed group for the needlestick and centrifuge events, might include proportions of some but not all, of the five MVSPs. It is surmised that the population of laboratory workers assigned to work with BSL-3 or BSL-4 pathogens would have a lower proportion of each MVSP, and of unhealthy or immunocompromised individuals in general, than the proportions

1 occurring in the overall population. Therefore, it is acknowledged that the dose-response models applied
2 in the centrifuge initial infections analysis could overestimate the risk to laboratory workers in this regard,
3 but no attempt is made to quantify the potential degree of overestimation. The needlestick analysis
4 contained the assumption that every exposure would lead to an infection, regardless of whether the
5 exposed worker is a member of a MVSP.

6
7 The calculations leading to the central quantitative estimates presented in the next section make use, in
8 part, of MVSP-related values presented in Appendix I. The values for the proportion of MVSP in the
9 populations near the three sites are based on data, whereas the values for relative susceptibility of MVSP
10 members compared to healthy adults are based on expert opinion.

11 12 **8.6.2 Results**

13 In this section, results from calculations introduced in Appendix K are presented. The results are shown
14 only for the three pathogens that produced the highest estimated probabilities of infection and death under
15 the earthquake MRF release scenario as shown in Section 8.5.3. The three pathogens also represent the
16 highest estimated infection and death probabilities among bacteria (*F. tularensis*), BSL-3 viruses
17 (RVFV), and BSL-4 viruses (EBOV). Results from those three pathogens are sufficient to demonstrate
18 the estimated influence of the MVSP profile at the three sites in comparison to U.S. average rates of
19 MVSP.

20 21 **8.6.2.1 Earthquake MRF Release Results for Each MVSP**

22 This section contains results for estimated probabilities and frequencies of initial infections and deaths
23 among members of each individual MVSP at each site. Each set of results is compared to what the results
24 would be if the population at each site was the same estimated size but with MVSP in line with overall
25 U.S. proportions. Central estimates are presented here; the accompanying uncertainty results are also
26 presented in Appendix K.

Children under 5

Table 8–19. Central estimates for earthquake MRF release among children under 5

Pathogen	Results using local site MVSP estimates		Results using U.S. average MVSP estimates	
	Probability of 1 or more initial infections or deaths	Return period of release leading to 1 or more initial infections or deaths	Probability of 1 or more initial infections or deaths	Return period of release leading to 1 or more initial infections or deaths
URBAN SITE: Initial Infections				
<i>F. tularensis</i>	1.5×10^{-3}	> 10 million years	1.8×10^{-3}	> 10 million years
RVFV	0.12	≈ 830,000 years	0.14	≈ 720,000 years
EBOV	1.2×10^{-3}	> 10 million years	1.4×10^{-4}	> 10 million years
URBAN SITE: Deaths Among Initially Infected				
<i>F. tularensis</i>	3.3×10^{-5}	> 10 million years	3.9×10^{-5}	> 10 million years
RVFV	2.8×10^{-3}	> 10 million years	3.3×10^{-3}	> 10 million years
EBOV	1.1×10^{-3}	> 10 million years	1.3×10^{-4}	> 10 million years
SUBURBAN SITE: Initial Infections				
<i>F. tularensis</i>	3.0×10^{-5}	> 10 million years	3.8×10^{-5}	> 10 million years
RVFV	2.6×10^{-3}	> 10 million years	3.2×10^{-3}	> 10 million years
EBOV	2.4×10^{-5}	> 10 million years	3.1×10^{-5}	> 10 million years
SUBURBAN SITE: Deaths Among Initially Infected				
<i>F. tularensis</i>	6.7×10^{-7}	> 10 million years	8.4×10^{-7}	> 10 million years
RVFV	5.6×10^{-5}	> 10 million years	7.0×10^{-5}	> 10 million years
EBOV	2.3×10^{-5}	> 10 million years	2.8×10^{-5}	> 10 million years
RURAL SITE: Initial Infections				
<i>F. tularensis</i>	1.6×10^{-5}	> 10 million years	1.9×10^{-5}	> 10 million years
RVFV	1.4×10^{-3}	> 10 million years	1.6×10^{-3}	> 10 million years
EBOV	1.3×10^{-5}	> 10 million years	1.6×10^{-5}	> 10 million years
RURAL SITE: Deaths Among Initially Infected				
<i>F. tularensis</i>	3.6×10^{-7}	> 10 million years	4.2×10^{-7}	> 10 million years
RVFV	3.0×10^{-5}	> 10 million years	3.6×10^{-5}	> 10 million years
EBOV	1.2×10^{-5}	> 10 million years	1.4×10^{-5}	> 10 million years

The results in the left columns of the above table are the central estimate projected probability and return period for initial infection and mortality among children under five at each site after an earthquake MRF release. The calculations of the values incorporated the estimated proportion of children under five present at each site and increased vulnerability of children under five to disease and death. At each site, the estimated return periods would be placed in the D frequency category, except for at least one initial infection with RVFV at the urban site, which would be placed in the C frequency category.

The results in the right columns are displayed for comparison purposes—they are the equivalent estimates for a site with the same population size but with a typical U.S. rate of children under five. There are some small differences across each row, but all the return periods still fall in the D frequency category. The direction of the small differences in each row reflect the fact that all three sites were estimated to have a smaller-than-average proportion of children under five.

Adults over 65

Table 8–20. Central estimates for earthquake MRF release among adults over 65

Pathogen	Results using local site MVSP estimates		Results using U.S. average MVSP estimates	
	Probability of 1 or more initial infections or deaths	Return period of release leading to 1 or more initial infections or deaths	Probability of 1 or more initial infections or deaths	Return period of release leading to 1 or more initial infections or deaths
URBAN SITE: Initial Infections				
<i>F. tularensis</i>	3.6×10^{-3}	> 10 million years	3.6×10^{-3}	> 10 million years
RVFV	0.27	≈ 380,000 years	0.27	≈ 380,000 years
EBOV	2.9×10^{-3}	> 10 million years	2.9×10^{-3}	> 10 million years
URBAN SITE: Deaths Among Initially Infected				
<i>F. tularensis</i>	1.0×10^{-4}	> 10 million years	1.0×10^{-4}	> 10 million years
RVFV	8.4×10^{-3}	> 10 million years	8.4×10^{-3}	> 10 million years
EBOV	2.8×10^{-3}	> 10 million years	2.8×10^{-3}	> 10 million years
SUBURBAN SITE: Initial Infections				
<i>F. tularensis</i>	5.1×10^{-5}	> 10 million years	7.9×10^{-5}	> 10 million years

1 The results in the left columns of the table are the central estimate projected probability and return period
2 for initial infection and mortality among adults over 65 at each site after an earthquake MRF release. The
3 calculations of the values incorporated the estimated proportion of adults over 65 present at each site and
4 increased vulnerability of adults over 65 to disease and death. At each site, the estimated return periods
5 would be placed in the D frequency category, except for infections at the urban site, for which the
6 estimated return period is in the C frequency category.

7
8 The results in the right columns are displayed for comparison purposes—they are the equivalent estimates
9 for a site with the same population size but with a typical U.S. proportion of adults over 65. There are
10 some small differences across each row, but all the return periods still fall in the D frequency category.
11 The direction of the small differences in each row reflect the fact that the urban and suburban sites were
12 estimated to have a smaller-than-average proportion of adults over 65 and the rural site a higher-than-
13 average proportion.

People with diabetes

Table 8–21. Central estimates for earthquake MRF release among people with diabetes

Pathogen	Results using local site MVSP estimates		Results using U.S. average MVSP estimates	
	Probability of 1 or more initial infections or deaths	Return period of release leading to 1 or more initial infections or deaths	Probability of 1 or more initial infections or deaths	Return period of release leading to 1 or more initial infections or deaths
URBAN SITE: Initial Infections				
<i>F. tularensis</i>	2.1×10^{-3}	> 10 million years	1.4×10^{-3}	> 10 million years
RVFV	0.16	≈ 640,000 years	0.11	≈ 910,000 years
EBOV	1.6×10^{-3}	> 10 million years	1.1×10^{-3}	> 10 million years
URBAN SITE: Deaths Among Initially Infected				
<i>F. tularensis</i>	4.7×10^{-5}	> 10 million years	3.3×10^{-5}	> 10 million years
RVFV	3.9×10^{-3}	> 10 million years	2.7×10^{-3}	> 10 million years
EBOV	1.5×10^{-3}	> 10 million years	1.0×10^{-3}	> 10 million years
SUBURBAN SITE: Initial Infections				
<i>F. tularensis</i>	4.2×10^{-5}	> 10 million years	3.1×10^{-5}	> 10 million years
RVFV	3.4×10^{-3}	> 10 million years	2.5×10^{-3}	> 10 million years
EBOV	3.3×10^{-5}	> 10 million years	2.4×10^{-5}	> 10 million years
SUBURBAN SITE: Deaths Among Initially Infected				
<i>F. tularensis</i>	9.6×10^{-7}	> 10 million years	7.0×10^{-7}	> 10 million years
RVFV	7.8×10^{-5}	> 10 million years	5.7×10^{-5}	> 10 million years
EBOV	3.0×10^{-5}	> 10 million years	2.2×10^{-5}	> 10 million years
RURAL SITE: Initial Infections				
<i>F. tularensis</i>	1.8×10^{-5}	> 10 million years	1.6×10^{-5}	> 10 million years
RVFV	1.5×10^{-3}	> 10 million years	1.3×10^{-3}	> 10 million years
EBOV	1.4×10^{-5}	> 10 million years	1.2×10^{-5}	> 10 million years
RURAL SITE: Deaths Among Initially Infected				
<i>F. tularensis</i>	4.1×10^{-7}	> 10 million years	3.6×10^{-7}	> 10 million years
RVFV	3.3×10^{-5}	> 10 million years	2.9×10^{-5}	> 10 million years
EBOV	1.3×10^{-5}	> 10 million years	1.1×10^{-5}	> 10 million years

The results in the left columns of the table are the central estimate projected probability and return period for initial infection and mortality among people with diabetes at each site after an earthquake MRF release. The calculations of those values incorporated the estimated proportion of people with diabetes present at each site and increased vulnerability of people with diabetes to disease and death. At each site, the estimated return periods would be placed in the D frequency category except for initial infections with RVFV at the urban site, which would be placed in the C frequency category.

The results in the right columns are displayed for comparison purposes—they are the equivalent estimates for a site with the same population size but with a typical U.S. proportion of people with diabetes. There are some small differences across each row, but all the return periods still fall in the D frequency category. The direction of the small differences in each row reflect the fact that all three sites were estimated to have a higher-than-average proportion of people with diabetes.

People with HIV/AIDS

Table 8–22. Central estimates for earthquake MRF release among people with HIV/AIDS

Pathogen	Results using local site MVSP estimates		Results using U.S. average MVSP estimates	
	Probability of 1 or more initial infections or deaths	Return period of release leading to 1 or more initial infections or deaths	Probability of 1 or more initial infections or deaths	Return period of release leading to 1 or more initial infections or deaths
URBAN SITE: Initial Infections				
<i>F. tularensis</i>	1.4×10^{-4}	> 10 million years	1.1×10^{-4}	> 10 million years
RVFV	1.1×10^{-2}	≈ 8.7 million years	9.1×10^{-3}	> 10 million years
EBOV	1.1×10^{-4}	> 10 million years	8.7×10^{-5}	> 10 million years
URBAN SITE: Deaths Among Initially Infected				
<i>F. tularensis</i>	3.2×10^{-6}	> 10 million years	2.6×10^{-6}	> 10 million years
RVFV	2.7×10^{-4}	> 10 million years	2.2×10^{-4}	> 10 million years

<i>F. tularensis</i>	1.2×10^{-6}	> 10 million years	2.3×10^{-6}	> 10 million years
RVFV	9.8×10^{-5}	> 10 million years	2.0×10^{-4}	> 10 million years
EBOV	9.4×10^{-7}	> 10 million years	1.9×10^{-6}	> 10 million years
SUBURBAN SITE: Deaths Among Initially Infected				
<i>F. tularensis</i>	2.8×10^{-8}	> 10 million years	5.5×10^{-8}	> 10 million years
RVFV	2.3×10^{-6}	> 10 million years	4.6×10^{-6}	> 10 million years
EBOV	8.8×10^{-7}	> 10 million years	1.8×10^{-6}	> 10 million years
RURAL SITE: Initial Infections				
<i>F. tularensis</i>	3.2×10^{-7}	> 10 million years	1.2×10^{-6}	> 10 million years
RVFV	2.7×10^{-5}	> 10 million years	9.9×10^{-5}	> 10 million years
EBOV	2.6×10^{-7}	> 10 million years	9.5×10^{-7}	> 10 million years
RURAL SITE: Deaths Among Initially Infected				
<i>F. tularensis</i>	7.7×10^{-9}	> 10 million years	2.8×10^{-8}	> 10 million years
RVFV	6.5×10^{-7}	> 10 million years	2.3×10^{-6}	> 10 million years
EBOV	2.4×10^{-7}	> 10 million years	8.9×10^{-7}	> 10 million years

1 The results in the left columns of the table are the central estimate projected probability and return period
2 for initial infection and mortality among people with HIV/AIDS at each site after an earthquake MRF
3 release. The calculations of those values incorporated the estimated proportion of people with HIV/AIDS
4 present at each site and increased vulnerability of people with HIV/AIDS to disease and death. At each
5 site, the estimated return periods would be placed in the D frequency category.

6
7 The results in the right columns are displayed for comparison purposes—they are the equivalent estimates
8 for a site with the same population size but with a typical U.S. proportion of people with HIV/AIDS.
9 There are some small differences across each row, but all the return periods still fall in the D frequency
10 category. The direction of the small differences in each row reflect the fact that the urban site was
11 estimated to have a higher-than-average proportion of people with HIV/AIDS and the suburban and rural
12 sites a lower-than-average proportion.

Pregnant women

Table 8–23. Central estimates for earthquake MRF release among pregnant women

Pathogen	Results using local site MVSP estimates		Results using U.S. average MVSP estimates	
	Probability of 1 or more initial infections or deaths	Return period of release leading to 1 or more initial infections or deaths	Probability of 1 or more initial infections or deaths	Return period of release leading to 1 or more initial infections or deaths

EBOV	2.5×10^{-6}	> 10 million years	2.5×10^{-6}	> 10 million years
RURAL SITE: Deaths Among Initially Infected				
<i>F. tularensis</i>	6.0×10^{-8}	> 10 million years	6.0×10^{-8}	> 10 million years
RVFV	5.8×10^{-6}	> 10 million years	5.8×10^{-6}	> 10 million years
EBOV	2.3×10^{-6}	> 10 million years	2.3×10^{-6}	> 10 million years

The results in the left columns of the table are the central estimate projected probability and return period for initial infection and mortality among pregnant women at each site after an earthquake MRF release. The calculations of those values incorporated the estimated proportion of pregnant women present at each site and increased vulnerability of pregnant women to disease and death. At each site, the estimated return periods would be placed in the D frequency category.

The results in the right columns are displayed for comparison purposes—they are the equivalent estimates for a site with the same population size but with a typical U.S. proportion of pregnant women. There are no differences across any of the rows, because the proportion of pregnant women at each site and in the United States overall was estimated to be the same (1 percent of the population).

SUMMARY

As noted in the above tables, the frequency of one infection for a member of any MVSP as a result of this type of earthquake and exposure to pathogens is estimated to be in the D frequency category, except for RVFV infection among children under five, adults over 65, and people with diabetes at the urban site. The frequency of one death for a member of any MVSP as a result of such an event is estimated to be well into the D frequency category (less than one in 10 million years) for all pathogens at all three sites. If the local MVSP profiles at each site were in line with average U.S. proportions, the estimates would not change enough to alter these conclusions.

Because the inputs for susceptibility of MVSP relative to healthy adults, described in Appendix I, are based on expert opinion and not on direct data, it is possible that they significantly underestimate the true differences in susceptibility. The numerical results in the above Tables are sensitive to these inputs. The largest change in the results for a particular MVSP would occur if the relative susceptibility of that MVSP is increased and the relative susceptibility of all other MVSP remains the same, in which case the particular MVSP would be disproportionately affected relative to not only healthy adults, but also to the other MVSP. If the relative sensitivities for all MVSP are increased at the same time, then the estimated risk to each MVSP would still increase, but to a much lesser extent. In all cases, however, the results regarding the risk estimates to each local population as compared to what those results would be in a population with typical U.S. proportions of MVSP would not change substantially. Therefore, the relative differences across each row of in the above tables are not sensitive to potential inaccuracies of the estimated susceptibility differences of the MVSP.

8.6.2.2 Earthquake MRF Release Overall Results Adjusted for MVSP

In this section, the earthquake MRF release results presented in Section 8.5.3, for which dose-response and mortality estimates assumed to be applicable to a general U.S. population were used, are compared to adjusted results that apply site-specific MVSP data and estimates for increased susceptibility of MVSP, as described in Appendix K.

Table 8–24. Central estimates for earthquake MRF release

Pathogen	Adjusted results using local site MVSP estimates		Baseline results from Section 8.5.3	
	Probability of 1 or more initial infections or deaths	Return period of release leading to 1 or more initial infections or deaths	Probability of 1 or more initial infections or deaths	Return period of release leading to 1 or more initial infections or deaths
URBAN SITE: Initial Infections				
<i>F. tularensis</i>	2.1×10^{-2}	≈ 4.7 million years	2.1×10^{-2}	≈ 4.7 million years
RVFV	0.84	≈ 120,000 years	0.84	≈ 120,000 years
EBOV	1.7×10^{-2}	≈ 5.9 million years	1.7×10^{-2}	≈ 5.9 million years
URBAN SITE: Deaths Among Initially Infected				
<i>F. tularensis</i>	4.3×10^{-4}	> 10 million years	4.3×10^{-4}	> 10 million years
RVFV	3.6×10^{-2}	≈ 2.8 million years	3.6×10^{-2}	≈ 2.8 million years
EBOV	1.5×10^{-2}	≈ 6.5 million years	1.5×10^{-2}	≈ 6.5 million years
SUBURBAN SITE: Initial Infections				
<i>F. tularensis</i>	4.5×10^{-4}	> 10 million years	4.6×10^{-4}	> 10 million years
RVFV	3.7×10^{-2}	≈ 2.7 million years	3.8×10^{-2}	≈ 2.6 million years
EBOV	3.6×10^{-4}	> 10 million years	3.7×10^{-4}	> 10 million years
SUBURBAN SITE: Deaths Among Initially Infected				
<i>F. tularensis</i>	8.9×10^{-6}	> 10 million years	9.3×10^{-6}	> 10 million years
RVFV	7.5×10^{-4}	> 10 million years	7.8×10^{-4}	> 10 million years
EBOV	3.3×10^{-4}	> 10 million years	3.3×10^{-4}	> 10 million years
RURAL SITE: Initial Infections				
<i>F. tularensis</i>	2.4×10^{-4}	> 10 million years	2.3×10^{-4}	> 10 million years
RVFV	2.0×10^{-2}	≈ 5.0 million years	1.9×10^{-2}	≈ 5.1 million years
EBOV	1.9×10^{-4}	> 10 million years	1.9×10^{-4}	> 10 million years
RURAL SITE: Deaths Among Initially Infected				
<i>F. tularensis</i>	5.0×10^{-6}	> 10 million years	4.7×10^{-6}	> 10 million years
RVFV	4.2×10^{-4}	> 10 million years	3.9×10^{-4}	> 10 million years
EBOV	1.8×10^{-4}	> 10 million years	1.7×10^{-4}	> 10 million years

For the urban site, adjusting the overall results according to local proportions of MVSP does not change the estimates (to two significant figures) for probability and frequency of at least one infection or death. That result can be explained by the observation that, while the estimated proportions of people with diabetes and HIV/AIDS are higher at the urban site than the U.S. averages, the estimated proportions of children under five and adults over 65 are lower.

For the suburban site, the estimated probabilities of at least one infection or death are slightly lower after adjusting for the local proportions of MVSP. The largest contributor to that small difference is the estimated suburban site proportion of adults over 65, which is just over half the U.S. average proportion.

1 The new results here do not change the assigned frequency category for the occurrence of an MRF release
2 resulting in one or more infections or deaths at the suburban site (D frequency category).

3
4 For the rural site, the estimated probabilities of at least one infection or death are slightly higher after
5 adjusting for the local proportions of MVSP. The largest contributor to this small difference is the
6 estimated rural site proportion of adults over 65, which is appreciably higher than U.S. average
7 proportion. The new results here do not change the assigned frequency category for the occurrence of an
8 MRF release resulting in one or more infections or deaths at the rural site (D frequency category).

9
10 Note that the local site MVSP adjustments for the probability of deaths have a smaller effect on the
11 estimates for EBOV than for *F. tularensis* and RVFV. That can be explained by the fact that the estimated
12 EBOV mortality rate is already quite high, even for healthy adults, so there is little room for increase
13 when the estimates of MVSP-specific mortality rates are calculated.

14
15 Uncertainty analyses pertaining to these results are presented in Appendix K, which again show only
16 minor differences from the corresponding results that do not incorporate MVSP. In addition, sensitivity to
17 the inputs for susceptibility of MVSP relative to healthy adults, discussed in Appendix I, is considered.
18 Because those inputs are based on expert opinion and not on direct data, it is possible that they
19 significantly underestimate the true differences in susceptibility. However, the results shown above
20 exhibit very low sensitivity to those inputs. For example, even if the relative susceptibility values are
21 multiplied by a factor of 100, the results do not change appreciably, and all estimated return periods
22 correspond to the same frequency categories.

H. EXPERT ELICITATION ON ORGANISMS STUDIED IN NEIDL RISK ASSESSMENT

Expert Elicitation on Organisms Studied in the NEIDL Risk Assessment

Summary

The NIH is sponsoring a risk assessment of the National Emerging Infectious Diseases Laboratories (NEIDL) at Boston University Medical Center. The risk assessment will include a comprehensive qualitative analysis as well as a quantitative component with a focus on 13 pathogens selected by a Blue Ribbon Panel. Because information in the literature on four key parameters is not fully adequate for direct use by the quantitative component of the assessment, the NIH convened a distinguished expert panel and conducted an expert elicitation. The elicitation was conducted using a standard methodology, the modified Delphi, in a manner consistent with accepted practice. Panelists were asked to estimate the infectivity of aerosols for the 13 pathogens; estimate the half-life of the 13 pathogens in an aerosol on a cool humid night and a dry sunny day; estimate the percentage increase in vulnerability to disease and death among five population subgroups; and corroborate the TetraTech team's choices of the basic reproduction number (R_0) for five of the 13 pathogens. Through careful application of a widely-used and accepted technique for expert elicitation in biomedicine, the exercise provided defensible supplementary inputs to quantitative component of the comprehensive NEIDL risk assessment.

Introduction

The NIH, with the scientific and technical advice of a Blue Ribbon Panel, is sponsoring a risk assessment of the National Emerging Infectious Diseases Laboratories (NEIDL) at Boston University Medical Center.¹ The risk assessment is being conducted by TetraTech Inc. Part of

¹ The full name of the Blue Ribbon Panel is the NIH Blue Ribbon Panel to Advise on the Risk Assessment of the National Emerging Infectious Diseases Laboratories at Boston University Medical Center. See <http://nihblueribbonpanel-bumc-neidl.od.nih.gov/default.asp>

the assessment will include analyses of an array of pathogens and the events leading to exposure of individuals to these pathogens, including an assessment of potential differences at three different locations. The following 13 pathogens were selected for analysis by the Blue Ribbon Panel to cover a range of relevant characteristics:

- SARS-associated coronavirus,
- 1918 pandemic influenza virus,
- Andes hantavirus,
- Junin virus,
- Lassa fever virus,
- Marburg virus,
- Ebola virus,
- Nipah virus,
- Rift Valley
- Fever virus,
- Tick-borne encephalitis complex virus,
- *Yersinia pestis*,
- *Francisella tularensis*, and
- *Bacillus anthracis*.

In addition to a comprehensive qualitative analysis, the NIH believes that selected quantitative analyses are important to a thorough assessment and for fulfilling commitments made by the NIH and the Blue Ribbon Panel to the Boston community and other stakeholders. For this reason, the NIH has elected to include high quality quantitative modeling in the risk assessment. Mathematical models will estimate the risk of initial infection after release for all 13 pathogens. In addition, mathematical models will estimate the potential secondary spread of five representative pathogens for which human transmission data are sufficient to support modeling. These are:

- SARS-associated coronavirus,
- 1918 pandemic influenza virus,
- Rift valley fever virus,

- Ebola virus, and
- *Yersinia pestis*.

The quantitative component of this risk assessment, like all infectious disease modeling, necessarily entails making a number of assumptions. The evidence for these assumptions varies, but it is rare to have adequate empirical data that bear directly on the case to be modeled. In some cases, data are lacking. For example, there are no adequate data on dose-response for infection by the pathogens under study over the full range of likely exposure. In other cases, several sources of data - none of which may strictly apply to the population being modeled - may need to be reconciled. For example, several estimates are often available for the basic reproduction number (R_0), a key parameter for mathematical modeling of secondary transmission.² Therefore, expert judgment is necessary to establish reasonable initial values for these and other essential parameters needed for modeling of initial infection and secondary transmission.

The need for expert judgment is not confined to parameter estimates for the quantitative element; it is an integral part of this and every risk assessment. The required judgment is often applied quite informally by an individual or small group of professionals - for example, in choosing model structure and certain parameters. Informal approaches are also the most common way of estimating baseline parameters in infectious disease modeling. Many studies have based parameter estimates on the investigators' existing knowledge supplemented by literature searches and/or consensus reached in meetings, by telephone, or by other means (Halloran and personal communication, Steven Eubank). Because of the importance of the NEIDL risk assessment, the NIH elected to go beyond informal expert judgment and conduct a formal elicitation of outside expert opinion to estimate parameter values for which adequate empirical data is lacking.

The formal elicitation of expert opinion is widely endorsed as a means of filling knowledge gaps, and is routinely used in a number of fields. The Nuclear Regulatory Commission has

² The basic reproduction number is defined as "the mean number of secondary cases generated by a single infective case in a totally susceptible population" (Gail)

recommended that "expert elicitation should be considered" when "Empirical data are not reasonably obtainable, or the analyses are not practical to perform"(Kotra). The Environmental Protection Agency has stated, "In general, experts can be used to quantify the probability distributions of key parameters and relationships"(Expert Elicitation Task Force). In one report, the National Research Council endorsed "models based not only on available data but also on expert judgment" and in another it stated, "the rigorous use of expert elicitation for the analyses of risks is considered to be quality science" (Committee on Estimating the Health-Risk-Reduction Benefits, Committee on Risk Assessment of Hazardous Air Pollutants).

The NIH convened a distinguished expert panel and conducted an expert elicitation using the modified Delphi technique, a group process that is standard in biomedicine and many other settings (Kotra, Office of Management and Budget). This expert elicitation focused on four groups of needed parameters:

- infectivity,
- atmospheric stability,
- population vulnerability, and
- rate of spread.

Infectivity: The first area requiring expert elicitation relates to the likelihood of initial infection. Determining the likelihood of infection after exposure to a specified dose of a pathogen is an essential element in establishing the risk of that exposure and, therefore, in modeling the consequences of an event-pathogen pair on the public. This property, which can be termed infectivity, depends on many factors including the properties of the organism, the route of exposure, and the characteristics of the host. The traditional measure of infectivity is the Infectious Dose 50 (ID₅₀), which is the dose necessary to infect 50% of subjects (ID₅₀).

Atmospheric stability: The second area requiring expert elicitation is the stability of organisms in the atmosphere. Estimating the stability of a pathogen in the air is an essential element in determining the dose of that pathogen received after an aerosol exposure. However, the literature provides little information regarding the question of atmospheric stability for the pathogens under study in the NEIDL risk assessment (Appendix H-1).

1
2 *Population vulnerability:* The third area requiring expert elicitation relates to the possibility that
3 a release of a pathogens may affect medically vulnerable subpopulations (e.g., the elderly) than
4 the general population. These subpopulations are thought to be more likely to contract infections
5 and have severe or fatal outcomes from infectious diseases. This is a concern for the NEIDL risk
6 assessment because persons in medically vulnerable subpopulations are overrepresented in rural
7 areas and in environmental justice communities such as South Boston. However, how much
8 more vulnerable these populations are to various diseases is not well known. This is true even
9 for HIV/AIDS, where estimates are highly dependent on the usually unknown distribution of
10 CD4 cells in a population (Kaplan). Moreover, it is especially true for the pathogens studied in
11 the NEIDL risk assessment because very little is known about differential vulnerability to exotic
12 and aggressive diseases.

13
14 *Rate of spread:* The fourth area requiring expert opinion is the rate of spread as described by the
15 basic reproduction number or R_0 . Several estimates are available in the literature for the five
16 pathogens that will undergo full mathematical modeling of secondary transmission (Appendix
17 H-1). The risk assessment team used this literature in selecting values for use in modeling, but
18 external corroboration of their choices is desirable.

19 20 **Approach**

21
22 While expert opinion can be obtained in many ways, formal elicitation processes are preferred in
23 order to maximize validity, reliability, and consistency. This project sought to take advantage of
24 an expert panel's group wisdom with minimal interpretation by moderators or other staff.
25 Therefore, the NIH preferred a modified Delphi exercise to individual interviews, a simple
26 consensus meeting or call, or other approaches.

27
28 The Delphi method is the most widely accepted group process used for expert elicitation (Brook,
29 Dalkey 1962, Dalkey 1963, Fink, Jones, Linstone, Powell). In 1974, it was estimated that
30 approximately 10,000 studies on technological forecasting and policy analysis employed this
31 approach (Linstone). The U.S. Office of Management and Budget accepts that "expert judgment

as revealed, for example, through Delphi methods" is an acceptable approach to probability and parameter estimation (Office of Management and Budget).

The use of the Delphi technique is extremely common in biomedicine. "Delphi Technique" is a unique National Library of Medicine Medical Subject Heading (MeSH) term, and a PubMed keyword search on "Delphi" yields over 3,000 entries. Common uses relate to health services, nursing, and education (Anandarajah, Brook, Hewlett, Mangione-Smith, Powell, Richards, Shekelle, Smith). Clinical and biological issues are also common subjects, with topics including diagnosis, treatment, and outcomes for diverse diseases such as trauma, glaucoma, malaria, tuberculosis, and others, and, in at least one case, biological aspects of risk assessment (Adkinal, Appropriateness Study Group, Koplan, Milholland, Sudre).

The Delphi technique is an iterative process of soliciting anonymous input in repeated rounds with feedback of the group's aggregate responses and each expert's own responses between rounds. As outlined by Helmer, the classical steps in conducting a Delphi exercise are:

- selecting issues and knowledgeable experts,
- familiarizing experts with the problems and questions,
- elicitation of experts,
- aggregation and presentation of estimates as medians and ranges,
- review of results and initial answers by the experts,
- repeating elicitations for several cycles until convergence occurs, and
- summarizing results.

There are no consensus guidelines for the use of the Delphi technique in biomedicine and implementation varies substantially, but the focus is almost exclusively on estimation (Thomson). In the classical technique, there is no contact between panelists, but it is now common to convene panels for in-person or electronic meetings as part of the process (Brook, Shekelle). The number of rounds of estimation varies. Some studies iterate until formal criteria for convergence are met, but it is most common to conduct 2 to 4 rounds (Linstone). The amount of information distributed before and during the process also varies, with some studies distributing none and other providing exhaustive literature searches and/or training (Brook,

Sudre). Finally, the complexity of the queries varies, with some studies asking for simple numerical estimates or agreement with a few statements, while others include evaluations of 1000 or more complex scenarios (Appropriateness Study Group, Sudre).

Implementation

Many groups have provided guidance in the conduct of expert elicitation in the context of risk assessment. While much of the guidance is aimed primarily at individual rather than group approaches and at complex rather than straightforward questions, the steps recommended for the process are useful to consider. For example, the Nuclear Regulatory Commission has recommended the following steps (Kotra):

- definition of objectives,
- selection of experts,
- refinement of issues,
- assembly and dissemination of basic information,
- pre-elicitation training,
- elicitation of judgments,
- post-elicitation feedback,
- aggregation of judgments, and
- documentation.

This elicitation used a process that generally followed the steps above and falls well within the standards used in biomedical research. The process, organized according to Nuclear Regulatory Commission's recommended steps, is presented below.

Definition of objectives.

This modified Delphi exercise sought to elicit expert opinion on poorly known parameters deemed essential to the modeling element of the biomedical component for the comprehensive NEIDL risk assessment. Objectives included obtaining straightforward numerical estimates of two parameters for the pathogens under study: infectivity and atmospheric stability. The process

also sought estimates of increased vulnerability to infection and death for certain population subgroups and endorsement of the risk assessment team's estimates of the rates of spread.

Selection of experts.

As has been recommended, a formal process was used to select the experts in order to have "more relevant expertise, more explicitness, greater potential for reproducibility, more ease of execution, less sponsor control, and more balance than would result from a purely informal approach." (Hawkins). However, Hawkins and others also indicate that sponsor involvement in selection should be considered on a case-by-case basis (Hawkins, Expert Elicitation Task Force). In this case, the sponsors and their advisors were well positioned to identify individuals who were "at the forefront of knowledge in their field, and ... recognized as leaders by their peers" (Keeney).

The criteria used for selection of subject-matter experts were aligned with Nuclear Regulatory Commission recommendations that "The subject-matter experts selected for elicitation should be individuals who: (a) possess the necessary knowledge and expertise; (b) have demonstrated their ability to apply their knowledge and expertise..." (Kotra). With respect to conflict of interest, persons with direct ties to Boston University or the NEIDL were excluded. However, "if experts were always excluded from participation due to potential conflicts of interest, for some disciplines there might be few or no experts available to participate" (Expert Elicitation Task Force). In this case, it was inevitable that true experts would have ties to NIH and, in some sense, would be competitors with Boston University investigators.

The NIH developed a preliminary list of seven areas of expertise to be included in the panel and later removed three that were less relevant to the project's developing objectives. The remaining four areas were:

- Bacteriology,
- Biosafety,
- High Biocontainment Experience, and

- Virology.

At a face-to-face meeting on 19 March 2010, a group from the NIH and TetraTech developed an initial list of nominees. This list was supplemented by discussion with the NIH Blue Ribbon Panel and knowledgeable individuals then cut to 14 candidates based on "best-fit" with the desired areas of expertise. Invitations were issued in rank order within the four areas of expertise to fill a panel of 8 persons. The members are listed in the box below; biographic sketches are provided in Appendix H-2.

Refinement of issues.

Infectivity: The goal was not to generate dose-response curves *per se*, but to generate inputs to models that would estimate dose-response curves. The TetraTech team planned to fit three theory-based models including a one parameter exponential model and two parameter log-probit and beta Poisson models. In order to avoid placing undue burden on the panelists, queries were limited to the values necessary to fit the models; specifically estimates of the ID₁₀, ID₅₀, and ID₉₀. The unit used for the estimation was number of organisms. This straightforward approach has some limitations, but exploits the principle that one infectious particle is, put simply, one infectious particle.

Background information for this parameter was substantial, but most studies were of little or no relevance to human infectious doses in the required ranges (Appendix H-1). This value would ideally be calculated from experimental data from unprotected humans but, with the exception of *F. Tularensis* - for which older aerosol challenge data are available - such data are lacking for the agents studied in the NEIDL risk assessment and cannot be obtained for ethical reasons (Appendix H-1). Extrapolation from animal experiments is risky because of interspecies differences and because of the specialized inbred nature of many laboratory animals. Few studies are dose-ranging as investigators are most often using doses expected to infect all

1 unprotected animals. Finally, many available studies involve attenuated strains of the pathogens
2 or vaccines (Appendix H-1).

3
4 *Atmospheric Stability:* Estimates are needed to assess the potential that atmospheric conditions
5 might inactivate some portion of airborne pathogens. Differences in pathogens warranted
6 separate estimates for each. The task was simplified by asking for estimates that encompass the
7 range of inactivation rates: a cold humid night and a hot dry sunny day.³ In order to have a
8 common and commonly understood metric, the panelists were asked to express their estimates as
9 half-lives in minutes.

10
11 Background information for this parameter was scanty, and often difficult to interpret. Much of
12 the data were on organisms that were not in an aerosolized state and very few of the test
13 conditions reflected normal atmospheric conditions. Several were expressed as D37, or the
14 fluence of ultraviolet light that reduces the abundance to 37% of its original level. The latter
15 were converted to half-lives prior to inclusion in the evidence tables (Appendix H-1).

16
17 *Population Vulnerability:* The goal was to obtain coarse grain estimates of the degree of
18 increased vulnerability to infection and to severe disease that could be used as a starting point for
19 analyses of differential health effects. A distinction was made between medical vulnerability and
20 environmental justice, with the former being the topic of this estimation. The literature on
21 medical vulnerability to infection is fragmented, and extrapolation from less to more aggressive
22 pathogens or from (often inbred) laboratory animal to humans is difficult (Appendix H-1).
23 However, drawing on analogies from the medical literature and the experience of Infectious
24 Diseases physicians at the NIAID, in the risk assessment team, and expert consultants, five
25 groups were selected for consideration.

26
27 The five groups included those 5 years of age or younger, those 65 years of age or older, and
28 pregnant women because all three groups have increased vulnerability to influenza and certain
29 bacteria; diabetics because of increased vulnerability to pneumonia and other infections; and

³ Increasing temperature and UV exposure generally decrease the half-life of viable organisms.

those with HIV/AIDS because of increased vulnerability to a number of opportunistic infections (Brabin, High, Kaplan, Monto, Muller, Rothberg, Siston, Teo). Inclusion of transplantation recipients was considered, but as less than 0.01% of the population receives a transplant each year, there cannot be a meaningful differential impact on health outcomes (National Center for Health Statistics). Inclusion of persons with asthma was also considered, but evidence of an association between asthma and increased vulnerability to infection is lacking (Busse).⁴ Specific data on the prevalence of these conditions are available for use by the risk assessment from sources such as the Current Population Survey and the Health of Boston 2010 report (Boston Public Health Commission, US Census Bureau).

Querying about differential vulnerability to each of the 13 specific pathogens was deemed impractical and, given the similarity of defenses for similar organisms and the extreme aggressiveness of most of the pathogens studied, unnecessary. Nonetheless, some distinctions are informative. In general, defenses against bacterial and viral pathogens are quite distinct (Kohlmeier, Munford). For these reasons, experts were not asked about each bacterium or virus, but separately about bacteria and viruses in general. In addition, it is desirable to capture information on potential increased severity of disease. Severity is a complex issue; markers of disease severity and staging systems vary across diseases and might include specific physiologic (e.g., hypoxia, hypotension) and/or more general measures (e.g., hospitalization, intensive care unit admission). Moreover, information on sub-lethal severity is generally sparse. For these reasons, and because the most interest for these serious diseases lies in the most serious outcomes, mortality rate was used as the measure of severity.

Rate of Spread: The reproduction rate or R_0 is estimated using epidemiologic data from real outbreaks (see above). TetraTech researchers found multiple estimates of R_0 in the literature for the five organisms that will undergo modeling of secondary transmission (Appendix H-1). From these, they chose existing consensus estimates when available and developed a synthesis of the reported values when not. These were presented to the panel for affirmation or rejection.

⁴ The relationship between asthma and respiratory infections is complex. Respiratory infections contribute to the development of asthma and trigger asthmatic episodes, and certain viral infections may be more likely to progress to pneumonia. However, asthmatics do not appear to experience more respiratory infections (Busse).

1
2 Assembly and dissemination of basic information.

3 The TetraTech team prepared extensive background materials based on TetraTech's electronic
4 search of scientific literature as supplemented by selected hand searches and additional literature
5 suggested by the NIH and panelists. The literature provided to panelists from this review was
6 not intended to be truly comprehensive but rather to be a large representative sample of the most
7 informative articles.⁵ The included scientific literature was presented in evidence tables and
8 reference lists with abstracts (Appendix H-1). In addition, the full text of all referenced papers
9 was made available electronically to panelists.

10
11 For infectivity and population vulnerability, information was generally provided without further
12 processing. For atmospheric stability, information in the literature was supplemented by
13 calculations intended to convert that information into a common scale. For rate of spread,
14 information from the literature was synthesized and candidate values were presented for the
15 panel to affirm or disagree with.

16
17 Pre-elicitation training.

18 Two orientation calls were held. As part of the preparation for the calls, panelists were provided
19 with an agenda, roster, the draft elicitation questionnaire, and an introductory slide deck
20 (Appendix H-2, Appendix H-3). During the calls:

- 21 • the context of the development of the NEIDL risk assessment was reviewed,
- 22 • the goals of the exercise were presented,
- 23 • the Delphi process and panelists' role in it were explained,
- 24 • the questionnaire was shown, and the steps for completing it demonstrated, and
- 25 • questions were taken and discussions held.

⁵ The National Research Council committee reviewing the NEIDL risk assessment elected to review the preliminary Delphi report. The committee suggested a re-examination of the material on *F. tularensis* and *B. anthracis*, and provided additional articles. After independent evaluation by TetraTech, the NIAID, and the NIH consultant, it was concluded that one of these articles was relevant but consistent with material already provided while the others were either not relevant or already included. One additional article was found upon re-review, but this too was judged to be consistent with material already provided.

Elicitation of opinion.

The group elicitation was conducted using the Delphi technique of informed iterative confidential estimation with feedback, with typical modifications of allowing interaction among panelists and not requiring convergence of estimates. Three rounds of data collection were conducted, which is consistent with common practice (Linstone). The steps in the elicitation process were as follows:

- orientation calls (discussed above),
- distribution of background materials (discussed above),
- completion of a standardized electronic questionnaire for Round 1,
- face-to-face meeting consisting of :
 - feedback of round one results including the distribution of the group estimates and, for panelists who completed round one, that panelist's own responses,
 - general discussion,
 - detailed review and discussion of the background evidence table for each organism, and
 - completion of a paper questionnaire for round 2,
- round 2 feedback of group responses and each panelist's own responses,
- completion of the standardized electronic questionnaire for Round 3, and
- aggregation and analysis.

Post-elicitation feedback.

At the end of the exercise, brief individual semi-structured qualitative interviews with the panelists were conducted by telephone.

Aggregation of judgments.

Votes to agree or disagree with the TetraTech estimates for R_0 were tabulated. Numeric estimates were combined mathematically using equal weights in calculating and reporting the geometric mean, median, and range of the estimates. The use of varying weights was rejected because of the difficulty of assigning "quality" or "knowledgeability" weights on an organism-

by-organism basis and because many authors advise equal weights. As is the case in many areas of social science, these authors have found that "simple combination procedures, such as an equally weighted average, produce combined probabilities [values] that perform as well as those from more complex aggregation models" and that "the benefits of imposing the equal weights constraint often exceed the costs" (Clement, Clement and Winkler) .

Documentation.

This report will be made widely available by the NIH.

Process

Round 1.

The first or preliminary round was conducted electronically. Panel members were sent instructions, background materials, and an electronic questionnaire by email and asked to record their preliminary responses. After attending an orientation call, five of eight returned acceptably completed forms. These were processed and a feedback document prepared that summarized the aggregated results as histograms and tabulations for categorical data, and the low, high, median, and geometric mean for numeric data. These are provided in Appendix H-4. In addition, panelists' own responses were reformatted for confidential feedback to that panelist.

Round 2.

The second round was conducted at a meeting in Bethesda MD on 18 May 2010. The agenda and materials are provided in Appendix H-5. Six of eight panel members attended in person and one participated by telephone. Each participant was given an additional copy of the background materials, the summary of the first round responses, and, for those who returned forms in the round one, their own initial responses.

The meeting started with an overview of the Delphi process and of the ways in which the responses would be used, with associated discussions. The rest of the meeting was devoted to sections on infectivity, rate of spread, population vulnerability, and atmospheric stability. The format for each section was:

- brief introductory presentation and general discussion,
- detailed review and discussion of the summary background tables,
- review of round one responses, and
- round two estimation/voting.

Discussions of infectivity included comments on the listed data (e.g., how to interpret the susceptibility of lab animals), unpublished data and anecdotes (especially related to laboratory experience), and related data (especially regarding outbreaks, epidemics, and epizootics). There was also discussion of the ID₁₀ and ID₉₀ estimates with some thought that subpopulations with extreme vulnerability or resistance coupled with a poor evidentiary base made these estimates particularly challenging. Others thought that these issues could be incorporated by adjusting one's estimates.

The panelists had few comments on rate of spread and population vulnerability. Discussions of atmospheric stability centered on unpublished data, anecdotal experiences in the laboratory, and questioning of the usefulness of available data (especially those studies on organisms in liquid media but also all data not gathered under atmospheric conditions). There was also discussion of day-to-day variations in conditions and the likely mechanisms of release from a laboratory, but the panelists concluded that the Delphi questions would capture the extremes for the organisms being assessed.

Following the meeting, the materials and a transcript of the meeting were transmitted to the one panel member who attended by telephone and to the one member who was not present, and their responses taken. The results of round two contained a small number of inconsistencies in the estimates for infectivity that were resolved by simple queries.⁶ After these were resolved, the results of the round two responses from eight of eight panelists were processed as before.

Results are presented in Appendix H-5.

⁶ These were simple number errors or transpositions (e.g., a power of 10 error resulted in an ID₁₀ that was higher than the ID₅₀ for the same organism).

1 Round 3 (final round).

2 Panelists were sent round 2 aggregate results and their own responses, and a third round of
3 electronic responses requested. The results of round three also contained a small number of
4 inconsistencies similar to those found in the second round. After these were resolved, results
5 were processed as before. The raw and tabulated data for eight of eight panel members are
6 presented in Appendix H-6, and summarized below under Results.

7
8 Post-elicitation interviews.

9 Consistent with best practices, brief semi-structured follow-up interviews with panelists were
10 conducted during January 2011. Seven of eight panelists participated. The following topics
11 were included.

12
13 *Panel membership:* Four of the seven panelists agreed that the panel membership was a strength.
14 Comments from these panelists included that the membership was "outstanding," that the
15 panelist's "expertise was a big plus," that the membership was "as appropriate as possible," that
16 those who worked with the pathogens were "highly respected," and that "generalists would be
17 useless." One panelist thought that the specific fund of relevant knowledge was "not great" for
18 some panelists while another thought that the expertise represented was not broad enough. The
19 latter also thought that there were "too many MD's."

20
21 *Literature Review:* None of the panelists found the literature review deficient, although five
22 expressed dissatisfaction with the state of knowledge. One panelist said, "(I) wish that it would
23 have been possible to provide additional relevant literature" but the inadequate literature "is what
24 it is." Two panelists noted that they had contributed papers to the literature review. One
25 indicated that all of the key papers in their field were included. Another indicated that some
26 potentially useful older papers were missing, but that their inclusion would not have changed
27 outcomes. Several indicated that they learned from the material provided.

28
29 *Role of face-to-face discussions:* Five of the seven panelists found the discussions useful. Two
30 of these indicated that they were highly influenced by the discussions. One indicated that the
31 discussions provided background but did not affect responses and one wished that there was

more discussion. The panelist who joined by telephone did not find it useful nor did another who indicated, "best practices would have included more interchange of ideas."

Estimation: All seven panelists indicated that they used their own prior knowledge as a primary source for at least some of the opinions rendered, including one panelist who estimated the ID₁₀ and ID₉₀ values by mathematical means. Four panelists indicated that the face-to-face meeting was at least somewhat influential, especially the discussions of unpublished and anecdotal information. Three indicated that the background material was also highly influential and one indicated that he queried his most knowledgeable colleague about each organism prior to responding.

Overall impression: Five of seven panelists had an overall positive impression. Several of the panelists were uncomfortable with aspects of the process but felt that it was "the best that could be done given the state of the literature." One panelist characterized it as "scientific." Another thought it "interesting, useful, even valuable." A third was initially skeptical but "became enamored" with the effort. Two panelists had unfavorable impressions. One was uncomfortable with using opinion generally and the iterative process specifically because of a concern that the latter could lead to false precision. The other thought it "an interesting process but not well executed."

Results of the Delphi Exercise

The summary results for aerosol infectivity, expressed as number of airborne organisms, were as follows for the ID₅₀:

ID ₅₀	Median	Low	High	Geometric Mean
<i>B. anthracis</i>	10,000	5,000	30,000	9,949
<i>F. tularensis</i>	40	10	500	42
<i>Y. pestis</i>	4,000	500	100,000	4,349
Andes hantavirus	400	10	1,000	308
Ebola virus	250	120	1,000	331
Marburg virus	175	100	1,000	255

Final Supplementary Risk Assessment for the Boston University National Emerging Infectious Diseases Laboratories (NEIDL)

Junin virus	50	15	1,000	84
Lassa fever virus	65	18	30,000	134
Nipah virus	1,000	500	30,000	1,715
Rift Valley fever virus	1,000	40	5,000	678
Russian spring-summer encephalitis virus	200	71	10,000	441
SARS virus	3,500	283	8,000	2,197
1918 influenza virus	850	100	250,000	1,497

ID₁₀ and ID₉₀ estimates are intended to help determine the shape of the dose-response curve, and to allow fitting of multi-parameter models. The results for the ID₁₀, expressed as number of airborne organisms, were:

ID₁₀	Median	Low	High	Geometric Mean
<i>B. anthracis</i>	750	200	4,000	709
<i>F. tularensis</i>	8	2	100	9
<i>Y. pestis</i>	200	100	700	202
Andes hantavirus	55	1	160	42
Ebola virus	45	19	100	49
Marburg virus	20	10	100	25
Junin virus	20	2	100	17
Lassa fever virus	15	3	300	17
Nipah virus	100	75	1,000	180
Rift Valley fever virus	100	10	1,000	79
Russian spring-summer encephalitis virus	25	11	1,000	48
SARS virus	100	43	1,000	156
1918 influenza virus	55	10	50,000	93

The results for the ID₉₀, expressed as number of airborne organisms, were:

ID₉₀	Median	Low	High	Geometric Mean
<i>B. anthracis</i>	100,000	10,000	300,000	86,028
<i>F. tularensis</i>	200	41	1,000	245
<i>Y. pestis</i>	35,000	1,500	1,000,000	32,993
Andes hantavirus	4,500	100	30,000	3,980
Ebola virus	3,000	400	10,000	2,847

Final Supplementary Risk Assessment for the Boston University National Emerging Infectious Diseases Laboratories (NEIDL)

Marburg virus	2,000	400	10,000	2,707
Junin virus	1,000	49	10,000	1,026
Lassa fever virus	1,000	59	3,000,000	1,792
Nipah virus	10,000	1,650	500,000	15,919
Rift Valley fever virus	10,000	300	50,000	5,148
Russian spring-summer encephalitis virus	2,500	230	1,000,000	6,384
SARS virus	40,000	950	300,000	24,861
1918 influenza virus	15,000	3,000	1,000,000	30,941

The results for atmospheric stability, expressed as a half-life in minutes, were estimated for a humid, cool night and a warm, dry, sunny day. For night, the estimates of the half-life in minutes were:

Night	Median	Low	High	Geometric Mean
<i>B. anthracis</i>	Indefinite			
<i>F. tularensis</i>	48	20	60	41
<i>Y. pestis</i>	25	8	60	21
Andes hantavirus	48	30	60	44
Ebola virus	20	2	60	15
Marburg virus	18	10	60	20
Junin virus	20	10	30	19
Lassa fever virus	22	15	60	24
Nipah virus	18	5	20	14
Rift Valley fever virus	23	20	60	27
Russian spring-summer encephalitis virus	28	20	120	36
SARS virus	125	60	200	117
1918 influenza virus	55	30	300	68

For day, the estimates of the half-life in minutes were:

Day	Median	Low	High	Geometric Mean
<i>B. anthracis</i>	Indefinite			
<i>F. tularensis</i>	20	3	25	15
<i>Y. pestis</i>	10	2	15	8
Andes hantavirus	10	10	30	13

Ebola virus	10	1	30	7
Marburg virus	10	2	30	9
Junin virus	10	5	10	9
Lassa fever virus	10	5	30	11
Nipah virus	5	2	10	6
Rift Valley fever virus	10	10	20	13
Russian spring-summer encephalitis virus	11	10	60	15
SARS virus	25	10	60	25
1918 influenza virus	20	5	30	20

Increased vulnerability was divided into increased vulnerability to disease and to death from disease, each expressed as the percentage of increase in vulnerability. For increased vulnerability to disease, the results were:

Disease (% increase in vulnerability)		Median	Low	High	Geometric Mean
Young	Bacteria	18%	5%	33%	15%
	Viruses	20%	0%	33%	9%
Older	Bacteria	28%	5%	50%	23%
	Viruses	23%	5%	50%	21%
Diabetes	Bacteria	20%	5%	30%	16%
	Viruses	15%	5%	25%	13%
HIV	Bacteria	30%	10%	40%	26%
	Viruses	30%	10%	40%	28%
Pregnancy	Bacteria	5%	0%	30%	3%
	Viruses	5%	2%	50%	8%

For increased vulnerability to death from disease, the results were:

Death (% increase in vulnerability)		Median	Low	High	Geometric Mean
Young	Bacteria	10%	5%	20%	11%
	Viruses	10%	5%	20%	12%
Older	Bacteria	10%	5%	50%	14%
	Viruses	15%	5%	50%	16%
Diabetes	Bacteria	10%	5%	25%	10%
	Viruses	10%	5%	25%	10%

HIV	Bacteria	25%	10%	30%	22%
	Viruses	25%	10%	30%	22%
Pregnancy	Bacteria	5%	1%	20%	5%
	Viruses	4%	1%	20%	5%

A total of 40 'votes' were cast regarding the TetraTech team's estimates for R_0 . Of these, 36 were to affirm those estimates. This included eight of eight for SARS virus and seven of eight for *Y. pestis*, Ebola virus, Rift Valley Fever virus, and 1918 Influenza. The four disagree votes came from two panelists. One panelist disagreed with estimates for *Y. pestis* (1.3), Ebola virus (1.5), and Rift Valley Fever virus (1.2), thinking them too low. A different panelist disagreed with the estimate for 1918 influenza (3.0 with a range of 1.5-4), thinking it too high.

Number agreeing/total panelists	
<i>Y. pestis</i>	7/8
Ebola virus	7/8
Rift Valley fever virus	7/8
SARS virus	8/8
1918 influenza virus	7/8

Conclusions:

The NIH believes that adding a quantitative component to the qualitative components of the NEIDL risk assessment is important to a comprehensiveness that will satisfy stakeholder expectations. The NIH, its consultants, TetraTech, and the Blue Ribbon Panel all agreed that the expert opinion was needed to complete the modeling. The NIH preferred formal to informal approaches for obtaining expert opinion. It convened a distinguished expert panel and conducted a formal expert elicitation. The elicitation used the widely accepted Delphi technique and a careful standard process. Panelists were asked to:

- estimate the infectivity of aerosols for the 13 pathogens studied in the NEIDL risk assessment in terms of number of organisms for the ID_{10} , ID_{50} , and ID_{90} ,
- estimate the half-life in minutes of the 13 pathogens in an aerosol on a cool humid night and a dry sunny day,

- estimate the percentage increase in vulnerability to disease and death among five groups: those 5 years of age or younger, those 65 years of age or older, those with diabetes mellitus, those with HIV/AIDS, and those who are pregnant, and
- corroborate the TetraTech team's choices for R_0 in the base case for the five pathogens undergoing modeling of secondary spread.

The distribution of responses was reasonably balanced with geometric means approximating the medians for a large majority of the estimates. Results seem consistent with the fragmentary literature, biomedical experience, and known differences between experimental and actual circumstances.

The Delphi technique is the most widely used approach to expert elicitation in biomedicine, and the majority of the panelists viewed the exercise favorably. The NIH, its consultants, TetraTech, and the Blue Ribbon Panel found the process and the estimates highly credible. The results of the elicitation provide defensible supplemental inputs to the NEIDL risk assessment.

H.1 BACKGROUND MATERIAL

Background Materials Prepared by Tetra Tech Inc.

(Completed 26 April 2010)

26 April 2010

A: Tables

Section 1: Infectiousness

Part A. Dose-Response

Estimating the proportion of persons exposed to an organism who will become infected requires an estimate of the dose-response curve for infection. We will use traditional measures of infectivity to elucidate points on these curves:

- the Infectious Dose 50 (ID50), or the minimum dose required to infect 50% of a susceptible population;
- the Infectious Dose 10 (ID10), or the minimum dose required to infect 10% of a susceptible population;
- the Infectious Dose 90 (ID90), or the minimum dose required to infect 90% of a susceptible population.

Once the expert panel has reached consensus on these 3 values for each organism, we will mathematically fit curves to the points, thereby interpolating values for intermediate doses.

Table 1.A below contains information on infectious doses, human infectious doses (HID), and lethal doses (LD) for the 13 organisms being studied in the NEIDL Risk Assessment.

1 **Table 1.A.** Prior information: infectious doses¹

	Human	Non-human primate	Other animal	Values used in prior models
<i>Bacillus anthracis</i>	<p>8-50 x 10³ spores estimated HID₅₀ (Franz, Jahrling et al. 1997)</p> <p>8,600 spores estimated HID₅₀ (Wilkening 2006)</p> <p>100 spores estimated LD₁₀ and 2.5-55 x 10³ spores estimated LD₅₀ (Peters and Hartley 2002)</p>	<p>As few as 100 spores (Brachman, Kaufman et al. 1966)</p> <p>LD₅₀ of 4,130 (95% C.I. 1,980-8,630) spores (Glassman 1966); rough estimates derived from incomplete data description by author: LD₁₀ of 50 (95% C.I. 14-112), LD₉₀ of 340,000 (95% C.I. 153,000-1,200,000)</p> <p>ID₅₀ 61,800 (34,000-110,000) CFU, aerosol, in macaques (Vasconcelos, Barnewall et al. 2003)</p> <p>LD₅₀ of 96,800 spores (95% C.I. 70,7000-136,000), LD₁₀ of 14,700 spores (95% C.I. 10,800-20,700), LD₉₀ of 322,000 spore (95% C.I. 235,000-451,000) calculated by Haas (Haas 2002) using data from rhesus monkeys obtained by Druett et al (Druett, Henderson et al. 1953).</p>		<p>“Model A”: ID₁₀ of 110 spores; ID₅₀ of 8,600 spores, ID₉₀ of 700,000 spores; “Model D”: ID₁₀ of 1,300 spores; ID₅₀ of 8,600 spores, ID₉₀ of 29,000 spores (Wilkening 2006)</p> <p>ID₁₀ of 150 spores; ID₅₀ of 10,000 spores, ID₉₀ of 680,000 spores (Baccam and Boechler 2007)</p>

		LD ₅₀ of 45,000 spores, aerosol, in rhesus monkeys (Druett, Henderson et al. 1953)		
<i>Francisella tularensis</i>	HID ₇₈ (14/18) for aerosolized challenge doses of 10-52 CFU (Saslaw, Eigelsbach et al. 1961) 200 aerosolized cells infected 2/2 volunteers (McCrumb 1961)	LD ₅₀ as little as 14 cells in primates (Lyons and Wu 2007) ID ₁₀₀ from 10 cells aerosol, type B strain (Lyons and Wu 2007)	Mouse, rat, guinea pig, rabbit data available	
<i>Yersinia pestis</i> (pneumonic)	100-500 cells in humans as "infective dose" (% not specified) (Franz, Jahrling et al. 1997)	LD ₅₀ of 2.3×10^4 (range $1-3.3 \times 10^4$) CFU via aerosol in rhesus monkeys (Speck and Wolochow 1957) LD ₁₀₀ of 1.4×10^2 (lower doses not tested) via aerosol in African green monkeys (Davis, Fritz et al. 1996) 120-270 cells, intratracheal dose, cells caused lethal infection in 8 of 12 rhesus monkeys (Ehrenkranz and Meyer 1955)	Rats, LD ₅₀ of 1.6×10^3 (Agar, Sha et al. 2009) Mice, Swiss-Webster & BALB/c, intranasal LD50 of 340 and 100 cells, respectively (Sha, Agar et al. 2008)	
Andes hantavirus				
Ebola virus		2 of 2 rhesus monkeys rapidly killed by		

		<p>400 pfu (Johnson, Jaax et al. 1995)</p> <p>7 of 7 <i>Macaca fascicularis</i> infected by 1,000 PFU intramuscular (Geisbert, Geisbert et al. 2009)</p> <p>4 of 4 <i>Macaca fascicularis</i>, and 3 of 3 rhesus monkeys, infected by 1,000 PFU aerosolized or intramuscular (Pratt, Wang et al.)</p>		
Marburg virus		<p>0.1 to 0.003 guinea pig LD₅₀ killed 6 of 10 African green monkeys (Leffel and Reed 2004)</p> <p>1 of 1 <i>Macaca fascicularis</i> infected by 1,000 PFU intramuscular (Geisbert, Geisbert et al. 2009)</p>	<p>1,000 PFU, intraperitoneal, uniformly fatal (10/10 BABL/c mice); intranasal, subcutaneous, or intramuscular injection of the same dose was not fatal (Warfield, Bradfute et al. 2009)</p>	
Junin virus (Argentine hemorrhagic fever virus)			<p>ID₅₀ (considered synonymous with LD₅₀) of 15 PFU in outbred guinea pigs (Peters, Jahrling et al. 1987)</p> <p>ID₆₆ (66% infection, no mortality) for an intranasal dose of 10^{3.5} TCID₅₀ in guinea pigs (Peters, Jahrling et al. 1987)</p>	

			In guinea pig, some Junin virus strains required < 1 PFU to produce an LD ₅₀ while other strains killed 20% regardless of dose (Peters, Jahrling et al. 1987)	
Lassa fever virus		Macaques, aerosol doses 2.7 – 4.5 log ₁₀ PFU - all died (Peters, Jahrling et al. 1987)	Median infectious dose (ID ₅₀) for guinea pigs was 15 PFU (Stephenson, Larson et al. 1984) LD ₅₀ in guinea pigs as low as 0.3 PFU depending on virus strain and host strain (Peters, Jahrling et al. 1987)	Model values (best fit) derived from previously published guinea pig data: ID ₁₀ , ID ₅₀ , and ID ₉₀ = 2.7, 18, and 59 PFU, respectively (Tamrakar and Haas 2008)
Nipah virus		Squirrel monkeys (<i>Saimiri sciureus</i>), IV or intranasal inoc of 10 ³ or 10 ⁷ PFU (3 animals per group); 10 ³ PFU intranasal failed to infect (Marianneau, Guillaume et al.),	MID ₅₀ (minimum ID ₅₀) in ferrets 500 TCID ₅₀ by oro-nasal route (Bossart, Zhu et al. 2009). LD ₅₀ in golden hamster model of 270 & 47,000 PFU for intraperitoneal and intranasal routes, respectively (Wong, Grosjean et al. 2003) LD ₁₀₀ of 10 ⁴ TCID ₅₀ in golden hamster, intraperitoneal	

			(Freiberg, Worthy et al.)	
Rift Valley fever virus		4 rhesus monkeys inoc with $10^{5.3}$ PFU: viremia in 3 of 4 (Peters, Jones et al. 1988)	<p>Susceptible rat strains develop fulminate disease when inoculated with less than 5 PFU (ZH-501 viral strain), while resistant strains become infected asymptotically following inoculation with as much as 500,000 PFU virus dose (Shimshony and Barzilai 1983)</p> <p>Other animal studies published; results are highly strain-host variable.</p>	
Russian spring-summer encephalitis virus (TBE complex virus)				
SARS-associated coronavirus		<p>ID₆₃ (5/8 rhesus macaques)</p> <p>Used 10^3, 10^5, 10^7 TCID₅₀ in rhesus macaques; found 10^5 to be "optimum". All 8 animals had brief fever but neutralizing antibodies were found only in 5. (Qin, Wang et al. 2005)</p>	<p>10^3 - 10^6 intranasal, mice (Cheng, Lau et al. 2007)</p> <p>10^3 intranasal, golden Syrian hamster (Cheng, Lau et al. 2007)</p> <p>10^6 intratracheal, marmosets (Cheng, Lau et al. 2007)</p>	

		10 ³ - 10 ⁷ intranasal (Cheng, Lau et al. 2007)	<p>10⁶ intratracheal, cats (Cheng, Lau et al. 2007)</p> <p>10⁶ intranasal or intratracheal, ferrets (Cheng, Lau et al. 2007)</p> <p>10⁶ intranasal or intratracheal, civets (Cheng, Lau et al. 2007)</p>	
1918 Influenza virus	<p>Estimated “infectious dose” 1-10 virions (Subbarao)</p> <p>9/17 (53%) infected via intranasal instillation; inocula: 10², 10³, 10⁴, or 10⁵ TCID₅₀ H3N2 (Zaas, Chen et al. 2009)</p> <p>A2 virus, aerosol challenge of 5-126 TCID₅₀; 7/23 volunteers infected = HID30 (Alford, Kasel</p>		<p>1918 H1N1 LD₅₀ in ferrets is 10⁶ PFU. The same dose in susceptible mouse strain is 100% lethal (Tumpey 2008)</p> <p>1918 H1N1 LD₅₀ in susceptible mouse strain is 3.5 log PFU₅₀ or EID₅₀ (Tumpey 2008)</p> <p>H3N2 ID₅₀ in guinea pig is 5 pfu (Lowen, Mubareka et al. 2006)</p> <p>H0N1 ID₅₀ in mice is 0.079 - 5 EID₅₀ (Yetter, Lehrer et al. 1980)</p>	<p>Not 1918 virus: 0.671 TCID₅₀ and 500 TCID₅₀ for respiratory and nasal epithelium, respectively (Atkinson and Wein 2008)</p>

	<p>et al. 1966)</p> <p>362/532 (68%) infected via intranasal instillation; inocula range: 10^3-$10^{7.2}$ TCID₅₀ of H1N1 (not 1918) (Carrat, Vergu et al. 2008)</p> <p>11/15 (73%) infected with 10^4 TCID₅₀ of H1N1 (not 1918); H3N2 testing infected 93%; all via intranasal instillation (Clements, Betts et al. 1986)</p>			
	Human	Non-human primate	Other animal	Values used in prior models

¹ Data are representative of the open literature as of January 2009, but are not necessarily exhaustive. A cursory update from the open literature was performed in April, 2010. Additional relevant data may exist under classified status. Experimental data are presented when possible. Data presented for *F. tularensis*, *Y. pestis*, and Lassa virus are consistent with data derived by modeling (Sinclair, Boone et al. 2008).

Part B: R_0

Modeling of secondary spread requires an estimate of an infection's propensity to transmit in a population. The Basic Reproduction Number (R_0) is often used as a measure of this. It is the expected number of secondary infections caused by a typical primary case in

a fully susceptible population, in the absence of interventions to control the infection and its transmission. While some researchers have attempted to quantify R_0 directly from contact tracing data from the early stages of real outbreaks, more often researchers estimate R_0 indirectly by using more easily observed data from outbreaks, such as case incidence rates, incubation period, and generation time. Usually, this information is then translated into R_0 mathematically.

Table 1B outlines estimates of R_0 from the literature for each of the 5 pathogens that will undergo transmission modeling, and the modeling team's proposal for the nominal value to be used in modeling. Note that in all cases, the values only apply before control measures are put in place. Also note that we will be analyzing the sensitivity of model outputs to the value of R_0 by assessing a range of values around the proposed nominal value.

Table 1.B. Prior information: R_0 ¹

	Epidemiologically-derived values/ Values used in prior models	Initial estimates (without intervention)
		Ro
<i>Yersinia pestis</i> (pneumonic)	1.3 (model-derived estimate) (Gani and Leach 2004) 1.32 (90% confidence interval: (1.01-1.61)) estimated from six historical outbreaks (Lloyd-Smith, Schreiber et al. 2005)	1.3
Ebola virus	Estimated to be 1.83 (SD 0.06) and 1.34 (SD 0.03) for the 1995 Congo and 2000 Uganda outbreaks, respectively. Alternate analysis gives median 1.89 (Interquartile range 1.66-2.28) based on empirical data from Zaire 1976 outbreak (Chowell, Hengartner et al. 2004) 1.36 (SD 0.13) estimated from 1995 Congo outbreak (Lekone and Finkenstadt 2006)	1.5

	1.50 (90% confidence interval: (0.85-2.08)) estimated from 2000 Uganda outbreak (Lloyd-Smith, Schreiber et al. 2005)	
Rift Valley fever virus	Predicted by one modeling effort to have a mean of 1.193 (95% CI 1.177-1.209), (median 1.113, max. 3.743, min. 0.037) (Gaff, Hartley et al. 2007). Note this is an estimate for R_0 for spread through a mosquito population via mosquito-mosquito and mosquito-livestock-mosquito transmission. It is not a prediction for R_0 for human transmission.	1.2 (for mosquitoes)
SARS-associated coronavirus	<p>1.63 (90% confidence interval: 0.54-2.65) for first three generations of transmission in Singapore 2003; 2.55 (90% confidence interval: 0.50-4.50) for first two generations of transmission in Singapore 2003. Third generation occurred before centralized control measures were in place, but after WHO's global alert on SARS, so drop in R_0 estimate could be explained by informal behavior changes or informal increased isolation of patients. These are direct estimates of R in Singapore from contact tracing data (Lloyd-Smith, Schreiber et al. 2005)</p> <p>1.88 (90% confidence interval 0.41-3.32) for first two generations of transmission in Beijing 2003; 0.94 (90% confidence interval 0.27-1.51) for only second generation of transmission in Beijing 2003. The first generation consisted of a single infected individual who directly transmitted to 33 others. These are direct estimates of R in Beijing from contact tracing data (Lloyd-Smith, Schreiber et al. 2005).</p> <p>3.6 (95% confidence interval 3.1-4.2) for Hong Kong. 2.4 (95% confidence interval 1.8-3.1) for Vietnam. 3.1 (95% confidence interval 2.3-4.0) for Singapore. 2.7 (95% confidence interval 1.8-3.6) for Canada.</p> <p>These are estimates inferred from epidemic curves and generation interval data from each city, using a likelihood-based estimation procedure (Wallinga and Teunis 2004)</p> <p>Estimated 0.86 (0.24-1.18) for Toronto, 1.70 (0.44-2.29) for Hong Kong, 1.83 (0.47-2.47) for Singapore</p>	<p>3.0 - consensus estimate determined by review paper (Bauch, Lloyd-Smith et al. 2005). Simulation of control measures will decrease R value as outbreak progresses. Individual variation will be incorporated as in Lloyd-Smith et al (Lloyd-Smith, Schreiber et al. 2005) and James et al. (James, Shindo et al. 2006).</p>

	<p>(Chowell, Castillo-Chavez et al. 2004). Ranges are the inter-quartile range. These are model-based estimates assuming a portion of population is less susceptible, which explains why these are lower than other estimates. For example, with uniform susceptibility, estimate for Hong Kong increases to 2.6 (Bauch, Lloyd-Smith et al. 2005)</p> <p>2.7 (95% confidence interval 2.2-3.7) for Hong Kong (Riley, Fraser et al. 2003). This excluded super-spreading events. Including them may increase the estimate to about 3.2 (Bauch, Lloyd-Smith et al. 2005). Estimate based on fitting stochastic spatial simulation to case-incidence data.</p> <p>3.5 (90% confidence interval 1.5-7.7) for Singapore using Bayesian procedure. Range of 2.2-3.6 using deterministic model estimate (Lipsitch, Cohen et al. 2003)</p> <p>4.80 for Toronto; 3.60 for Hong Kong; 5.04 for Singapore; 4.91 for Beijing (Gumel, Ruan et al. 2004).</p> <p>These are deterministic dynamic model-based estimates. The reason they are higher than other estimates may be because of unrealistic assumptions about the efficacy of control measures (Bauch, Lloyd-Smith et al. 2005)</p> <p>4.2 for Taiwan (Hsieh, Chen et al. 2004). May be higher than other estimates because of uncertainties in model infectiousness parameters and/or unusually high rate of hospital transmission in Taiwan.</p> <p>2.1 for Hong Kong (Zhou and Yan 2003). Lower because estimate includes data from after implementation of control measures (Bauch, Lloyd-Smith et al. 2005)</p> <p>1.5 for Toronto, 2.0 for Hong Kong (Choi 2003). Estimates are too low because of authors' interpretation of</p>	
--	---	--

	<p>generation time parameter. After adjusting for this, results are 2.5 for Toronto and 3.4 for Hong Kong (Bauch, Lloyd-Smith et al. 2005)</p> <p>1.1-3.3 for Beijing (Wang and Ruan 2004). Lower end of range assumes no transmission after entering hospital, highly unrealistic (Bauch, Lloyd-Smith et al. 2005).</p> <p>2.23 for Taiwan (Bombardt 2006) using approach similar to Wallinga and Teunis (Wallinga and Teunis 2004)</p> <p>2.87 for mainland China (Zhang 2007)</p> <p>3 (range 1.5-5)) (Lloyd-Smith, Galvani et al. 2003)</p> <p>2-3 (Anderson, Fraser et al. 2004)</p> <p>2.5-2.9 Hong Kong (Fang, Chen et al. 2005)</p>	
1918 Influenza virus	<p>2.2 (95% C.I. 1.7-2.7) extreme at 3.5, Iceland (Gottfredsson, Halldorsson et al. 2008)</p> <p>1.33-1.86, England and Wales (Chowell, Bettencourt et al. 2008)</p> <p>2.0-5.4 (summer), 1.2-1.6 (fall), Scandinavia: (Andreasen, Viboud et al. 2008)</p> <p>“Initial R” = 2.0 (Interquartile range 1.7-2.3); “Extreme R” = 2.7 (Interquartile range 2.3-3.4); Maximum R = 6.5 (upper bound); estimate over 45 U.S. cities (Mills, Robins et al. 2004)</p> <p>2.1, England and Wales (Viboud, Tam et al. 2006)</p> <p>1.49 (95% CI 1.45-1.53) spring wave; 3.75 (95% CI 3.57-3.93) fall wave, Geneva (Chowell, Ammon et al.</p>	<p>3.0 as nominal value. Will investigate range 1.5-4.0. Will incorporate control measures and individual variation as appropriate.</p>

	<p>2006)</p> <p>1.79 – 2.1, estimates from eight model variants over 16 U.S. cities; largest confidence interval 1.3-3.2 (Bootsma and Ferguson 2007)</p> <p>1.58 – 3.41 for Prussia, Germany (Nishiura 2007)</p> <p>1.3 – 3.1, New Zealand(Sertsou, Wilson et al. 2006)</p> <p>2.68, Sao Paulo, Brazil (Massad, Burattini et al. 2007)</p> <p>1.7-2.0, 83 cities in U.K. (Ferguson, Cummings et al. 2006)</p> <p>1.70, UK and Wales (Gani, Hughes et al. 2005)</p> <p>2.4, 3.5, San Francisco (Chowell, Nishiura et al. 2007)</p>

Data presented for *F. tularensis*, *Y. pestis*, and Lassa virus are consistent with data derived by modeling (Sinclair, Boone et al. 2008).

Part C: Infection in the vulnerable.

The Risk Assessment will take into account the differential vulnerability of certain groups of persons to disease and death. The groups have been dictated in part by the level of data available for the sites being evaluated. The groups are persons are children younger than 5, adults older than 65, persons with diabetes, persons with HIV infection, and pregnant women.

There are published papers on increased risk of specific infections such as influenza in the young and elderly, pandemic influenza in pregnancy, tuberculosis in HIV/AIDS patients and pneumonia in diabetics. From these it is inferred that there is an increased risk of infection in these vulnerable groups. However, there are few published reports on the increased risk to infections in general in these groups. References are provided are for increased morbidity and mortality in the elderly (High 2004), diabetics (Muller 1985) and pregnant women (Brabin 1985; Jamieson 2006).

Section 2: Atmospheric decay

Determining the probabilities of infection in certain circumstances requires estimates of the rate at which pathogens would be inactivated by atmospheric factors such as sunlight, humidity, and temperature during airborne transport of aerosols. More specifically, this is needed to estimate the dose of organisms received by persons situated at various distances from an external release.

The various references found during a literature search on the topic use multiple different units to describe the inactivation of pathogens in airborne transport. These various units of measure include: time for a 3-log decay, time for a 1-log decrease, %/min reduction, and D_{37} (the amount of ultraviolet light needed to reduce the number of organisms to 37% of the original value). In order to

compare these values, we present both the raw data and the same information using a common unit of measure. The half-life (HL), or period of time it takes for a substance undergoing decay to decrease by half, was selected as the common unit of measure.

Table 2 contains information regarding viability of organisms under various conditions. In the table, times are converted to half-lives (HL), which are noted in [square brackets]. D_{37} values were also converted to a HL using the estimated midday effective solar flux for Boston.

Table 2. Prior information: Stability in ambient environmental conditions^{1,2}

	Experimental data/Estimations
<i>Bacillus anthracis</i> ³	<p>Spores seeded into a plant/soil model had survival ratio at day 2 and day 4 of approx. 60% and 53%, respectively, and the percentage of cells that were vegetative was 47% and 43% , respectively (Saile and KoeHLer 2006).</p> <p>resist drying, heat, UV light, and some disinfectants (Turnbull 1998).</p> <p>Anthrax spores can survive for months or even decades depending on pH, temperature, and nutrients in the soil (Lewerin, Elvander et al.; Manchee, Broster et al. 1990; Montville, Dengrove et al. 2005).</p>
<i>Francisella tularensis</i>	<p>Viability of <i>F. tularensis</i> aerosols in a chamber ventilated with outdoor air ranged from 7% (45 minutes at 79-82% RH) [<u>HL=11.7 min</u>] to 25% (30 minutes at 73% relative humidity) [<u>HL=15min</u>] (Hood 2009).</p> <p>Oxygen toxicity is minimal for <i>F. tularensis</i> (Cox 1995)</p>
<i>Yersinia pestis</i>	<p>3-log decay over 90 minutes [<u>HL⁴=9 min</u>] using an avirulent strain in aerosolized heart infusion broth at conditions of 26C and RH varying from 20-50% (Won and Ross 1966).</p> <p>estimated that aerosolized <i>Y. pestis</i> would remain viable for 1 hour (Borio and Hynes 2010).</p> <p>dry surface stability varies: steel (6h), glass (7h), polyethylene (24h), paper (5d) (Rose, Donlan et al. 2003).</p> <p>Can survive days to weeks in flea feces, tissues of dead animals, and up to 40 weeks in some soils (Drancourt, Houhamdi et al. 2006; Ayyadurai, Houhamdi et al. 2008; Eisen, Petersen et al. 2008)</p>
Andes hantavirus ⁵	The D_{37} value (the dose of UV_{254} in J/m^2 that reduces the surviving virus to 37% of its original) for hanta virus was calculated to

	be 12 [<u>HL=28 min</u> at maximum solar radiation] (Lytle and Sagripanti 2005).
Ebola virus ⁵	<p>Predicted inactivation of a filovirus was calculated for six geographic points for as many as five times of year. The time for a 1 log decrease varied from 20 to 100 minutes[<u>HL range of 6 to 30 min</u>] (Lytle and Sagripanti 2005). The D₃₇ value (the dose of UV₂₅₄ in J/m² that reduces the surviving virus to 37% of its original) for filovirus was calculated to be 7.3 [<u>HL=17 min</u> at maximum solar radiation] (Lytle and Sagripanti 2005).</p> <p>Filoviruses are relatively stable in aerosols, retain virulence after lyophilization, and can persist for long periods on contaminated surfaces (Leffel and Reed 2004)</p> <p>Filoviruses retain infectivity @ room temperature on environmental surfaces; thus, fomites may be sources of transmission, e.g., blankets and sleeping mats identified (Salvaggio and Baddley 2004)</p>
Marburg virus ⁵	<p>Predicted inactivation of a filovirus was calculated for six geographic points for as many as five times of year. The time for a 1 log decrease varied from 20 to 100 minutes [<u>HL range of 6 to 30 min</u>] (Lytle and Sagripanti 2005). The D₃₇ value (the dose of UV₂₅₄ in J/m² that reduces the surviving virus to 37% of its original) for filovirus was calculated to be 7.3 [<u>HL=17 min</u> at maximum solar radiation] (Lytle and Sagripanti 2005).</p> <p>Survives up to 5 days on contaminated surfaces; unstable in aerosols with specific rate of inactivation= 0.05/min (Belanov, Muntianov et al. 1996) [assumed for purposes herein to be 5%/min, resulting in <u>HL=13.5 min</u>]</p> <p>Filoviruses are relatively stable in aerosols, retain virulence after lyophilization, and can persist for long periods on contaminated surfaces (Leffel and Reed 2004)</p> <p>Filoviruses retain infectivity @ room temperature on environmental surfaces; thus, fomites may be sources of transmission, e.g., blankets and sleeping mats identified (Salvaggio and Baddley 2004)</p>
Junin virus (Argentina)	The D ₃₇ value (the dose of UV ₂₅₄ in J/m ² that reduces the surviving virus to 37% of its original) for Junin was calculated to be 13

hemorrhagic fever virus) ⁵	<p><u>[HL = 30 min at maximum solar radiation]</u> (Lytle and Sagripanti 2005),.</p> <p>Inactivation at 37°C is 47%, 59%, and 99.9% at timepoints of 1, 6, and 26 hours <u>[HL of 65,280, and 156 min]</u>, respectively. At 25°C, inactivation was 75% and 99% at 26 and 72 hours <u>[HL of 780 and 650 min]</u>, respectively (Parodi, Coto et al. 1966)</p>
Lassa fever virus ⁵	<p><u>Biological half-lives of the virus in aerosols at both 24 and 32°C ranged from 10.1 to 54.6 min</u>, and were sufficient for aerosol dispersion of virus to considerable distances in natural situations (Stephenson, Larson et al. 1984)</p> <p>The D₃₇ value (the dose of UV₂₅₄ in J/m² that reduces the surviving virus to 37% of its original) for Lassa was calculated to be 13 <u>[HL = 30 min at maximum solar radiation]</u> (Lytle and Sagripanti 2005).</p>
Nipah virus	<p>al of henipaviruses in the environment is high^{HLy} sensitive to temperature and desiccation. Under most conditions survival time was brief, with half-lives limited to a few hours, indicating that transmission to a new host requires close contact with an infected animal or exposure to contaminated material shortly after excretion. However, under optimal conditions henipaviruses can persist for a number of days and under these circumstances, vehicle-borne transmission may be possible.” (Fogarty, Halpin et al. 2008)</p> <p>Henipavirus viable >4 days in bat urine and viable 1-4 days in various fruit juices @22°C; tolerates a wide range of pH. It is inactivated in 1 day @37°C and is high^{HLy} susceptible to dessication (Fogarty, Halpin et al. 2008)</p>
Rift Valley fever virus ⁵	<p>Geometric mean biological decay rate 2.3% per minute over range of 50 and 80% relative humidity; aerosol stability not influenced by relative humidity <u>[HL=30 min]</u> (Miller, Demchak et al. 1963)</p> <p><u>Viral half life of 77, 15.8, and 6.9 min</u> for 30%, 55% and 80% relative humidity, respectively (Brown, Dominik et al. 1982)</p> <p>The D₃₇ value (the dose of UV₂₅₄ in J/m²) that reduces the surviving virus to 37% of its original) for Rift Valley fever virus was calculated to be 12 <u>[HL=28 min at maximum solar radiation]</u> (Lytle and Sagripanti 2005).</p> <p>Virus very stable in aerosols @23°C and 50-85% relative humidity (Shimshony and Barzilai 1983; Swanepoel and Coetzer 1994)</p>

<p>Russian spring-summer encephalitis virus (TBE complex virus)⁵</p>	<p>The D₃₇ value for West Nile virus was calculated to be 24 [HL=56 min at maximum solar UV conditions](Lytle and Sagripanti 2005). RSSE virus and West Nile virus are classified in the genus <i>Flavivirus</i>.</p> <p>Stable for at least 6 h in liquid aerosol suspension @ room temperature and 23–80% humidity (Gritsun, Lashkevich et al. 2003)</p>
<p>SARS-associated coronavirus⁵</p>	<p>The D₃₇ value for BEV (Berne) was calculated to be 3.1 [HL=7 min at maximum solar radiation] (Lytle and Sagripanti 2005). BEV and SARS-CoV are classified in the family <i>Coronaviridae</i>.</p> <p>Virus was inactivated by ultraviolet light (UV) at 254 nm (UVC wavelength). UVA had no significant effect. Details as follows: virus suspension 1 cm deep in 24-well plates, UV source at height of 3 cm from the bottom of the wells. UVC (254 nm) at 4016 µW/cm² (where µW = 10⁻⁶ J/s) and UVA (365 nm) at 2133 µW/cm². UVA had no significant effect. UVC resulted in a 1 log reduction at 1 minute, a 2 log reduction at 2 minutes, a 3 log reduction at 3 minutes, a 3.5 log reduction at 4 minutes, a 4 log reduction at 6 minutes, complete inactivation at 15 minutes (Darnell, Subbarao et al. 2004). However, note that UVC radiation consists of wavelengths of 100-280 nm and is absorbed by the ozone layer; a negligible amount [of UV 254 nm] reaches earth's surface (World Health Organization 2002).</p> <p>Titer decreased from 10^{7.5} CCID₅₀ to 10^{3.2} CCID₅₀ within 5 days @ room temperature (details not available) (from Bao, et al, 2003 [Chinese]) (Wang, Li et al. 2005)</p> <p>In vitro, virus persists for 2 days in hospital wastewater, domestic sewage and decHLorinated tap water; 3 days in feces, 14 days in PBS, 17 days in urine at 20 °C; @ 4 °C, virus persists for 14 days in wastewater and >17 days in feces or urine: free cHLorine inactivates virus better than cHLorine dioxide; free residue cHLorine over 0.5 mg/L for cHLorine or 2.19 mg/L for cHLorine dioxide in wastewater ensures complete inactivation (Wang, Li et al. 2005)</p> <p>Virus survived at RT for 9 days in cell culture suspension and 6 days in dried state on plastics (Rabenau, Cinatl et al. 2005)</p>

	<p>Virus persists in the environment-- 1+ day on surfaces and 4 days in feces (McKinney, Gong et al. 2006)</p> <p>On dry surfaces@ room temperature, virus survives for 2-3 days; in fecal samples, survival for 2-4 days (Wong and Yuen 2005)</p> <p>At Amoy Gardens, optimum environmental temperature range associated with SARS cases was 16-28°C [~61-82F] (Yip, Chang et al. 2007)</p> <p>At Amoy Gardens, virus is believed to have spread between apartment block buildings via aerosols from sewage system carried by ambient wind (Yip, Chang et al. 2007)</p> <p>Virus can survive in respiratory samples for 5 days @ room temperature (Lim, Ng et al. 2006)</p> <p>In diarrheal feces, can survive for a few days @ room temperature; fecal droplets with a high titer of virus, 10⁶ CCID₅₀/mL, can remain infectious for 4-5 days (Lim, Ng et al. 2006)</p>
1918 Influenza virus ⁵	<p>The D₃₇ value for influenza A virus was calculated to be 7.5 [<u>HL=18 min</u> at maximum solar conditions] (Lytle and Sagripanti 2005).</p> <p>Solar radiation-induced infectivity reduction for influenza A virus has been reported to range from 0.1 to 7.5 log₁₀ /day in U.S. locations depending on latitude and season (Sagripanti and Lytle 2007)</p> <p>“The study of the inactivation of influenza virus as a function of relative humidity and temperature has produced contradictory results.” “Maximum survival times vary between 1 h (80% RH) and 24 h (20% RH).” (Weber and Stilianakis 2008)</p> <p>Effects of humidity on the ability of influenza viruses to infect mice in a nonventilated room with constantly agitated air have</p>

	<p>been studied (Loosli, Lemon et al. 1943). At a relative humidity of 17%–24%, animals became infected with influenza as late as 24 h after the virus was first aerosolized into the room, although the proportion of animals infected decreased over time. Infectivity was enhanced at 22h after influenza virus was introduced, when the floor was vigorously swept, suggesting that desiccation of the virus does not eliminate infectivity. Whether sufficient numbers of virus laden particles can remain viable to infect humans in a similar setting is unknown (Bridges, Kuehnert et al. 2003).</p> <p>Human influenza viruses can survive on a variety of surfaces at 35%–49% humidity and a temperature of 28 degrees C. Both influenza A and B viruses were cultured from experimentally contaminated, nonporous surfaces, such as steel and plastic, up to 24–48 h after inoculation, and from cloth, paper, and tissues up to 8–12 h after inoculation (Bean, Moore et al. 1982).</p> <p>“Avian influenza viruses can be isolated from natural, open fresh water.” (Weber and Stilianakis 2008)</p>
--	---

¹ Data are representative of the open literature as of January 2009, but are not necessarily exhaustive. A cursory update from the open literature was performed in April, 2010. Additional relevant data may exist under classified status. Experimental data are presented when possible. Data presented for *F. tularensis*, *Y. pestis*, and Lassa virus are consistent with data derived by modeling (Sinclair, Boone et al. 2008).

² “Viral agents are hardier and reach further into the environment than previously expected. For example, an information leak in 2002 from the former Soviet Union reported an accidental infection in 1971 of naval personnel 11 miles offshore from a smallpox testing site in the Soviet city of Aralsk (Tucker and Zilinskas 2003)” (Lytle and Sagripanti 2005).

³ Few data are published for survival of vegetative cells in the environment (Saile and Koehler 2006). At 26 °C in the laboratory, sporulation begins no earlier than 24, 28, 40, and 60 hours, under relative humidities of 90-100%, 80%, 50-70%, and 20-40%, respectively (Davis 1960).

⁴ Half-life values were calculated and inserted.

⁵ Virtually all data on UV inactivation of various viruses have been generated using UV₂₅₄ radiation from an artificial source (mercury lamp). However, this wavelength does not reach the surface of the earth (World Health Organization 2002; Lytle and Sagripanti 2005). In the absence of experimental data on

1 aerosolized pathogens exposed under actual solar conditions, estimation of virus inactivation by other wavelengths of solar exposure via extrapolation has been
2 attempted for viruses relevant to biodefense (Lytle and Sagripanti 2005). It is important to note these values were determined based on the minimum solar zenith
3 angle, that is, the time of day when UV radiation is most intense. Validation of the extrapolation method was attempted using data from two experiments using
4 TMV virus and bacteriophages T1 and T7. Predicted inactivation of a filovirus, as an example, was calculated for six geographic points for as many as five times
5 of year. The time for a 1 log decrease in filovirus viability varied from 20 to 100 minutes.

Agar, S. L., J. Sha, et al. (2009). "Characterization of the rat pneumonic plague model: infection kinetics following aerosolization of *Yersinia pestis* CO92." Microbes Infect **11**(2): 205-14.

Yersinia pestis, the causative agent of human bubonic and pneumonic plague, is spread during natural infection by the fleas of rodents. Historically associated with infected rat fleas, studies on the kinetics of infection in rats are surprisingly few, and these reports have focused mainly on bubonic plague. Although the natural route of primary infection results in bubonic plague in humans, it is commonly thought that aerosolized *Y. pestis* will be utilized during a biowarfare attack. Accordingly, based on our previous characterization of the mouse model of pneumonic plague, we sought to examine the progression of infection in rats exposed in a whole-body Madison chamber to aerosolized *Y. pestis* CO92. Following an 8.6 LD(50) dose of *Y. pestis*, injury was apparent in the rat tissues based on histopathology, and chemokines and cytokines rose above control levels (1h post infection [p.i.]) in the sera and organ homogenates over a 72-h infection period. Bacteria disseminated from the lungs to peripheral organs, with the largest increases in the spleen, followed by the liver and blood at 72h p.i. compared to the 1h controls. Importantly, rats were as sensitive to pneumonic plague as mice, having a similar LD(50) dose by the intranasal and aerosolized routes. Further, we showed direct transmission of plague bacteria from infected to uninfected rats. Taken together, the data allowed us to characterize for the first time a rat pneumonic plague model following aerosolization of *Y. pestis*.

2 SARS: the 2002-2003 epidemic." Philos Trans R Soc Lond B Biol Sci **359**(1447): 1091-105.

3 This paper reviews current understanding of the epidemiology, transmission dynamics
4 and control of the aetiological agent of severe acute respiratory syndrome (SARS). We
5 present analyses of data on key parameters and distributions and discuss the processes of
6 data capture, analysis and public health policy formulation during the SARS epidemic are
7 discussed. The low transmissibility of the virus, combined with the onset of peak
8 infectiousness following the onset of clinical symptoms of disease, transpired to make
9 simple public health measures, such as isolating patients and quarantining their contacts,
10 very effective in the control of the SARS epidemic. We conclude that we were lucky this
11 time round, but may not be so with the next epidemic outbreak of a novel aetiological
12 agent. We present analyses that help to further understanding of what intervention
13 measures are likely to work best with infectious agents of defined biological and
14 epidemiological properties. These lessons learnt from the SARS experience are presented
15 in an epidemiological and public health context.

17 Andreasen, V., C. Viboud, et al. (2008). "Epidemiologic characterization of the 1918 influenza
18 pandemic summer wave in Copenhagen: implications for pandemic control strategies." J Infect
19 Dis **197**(2): 270-8.

20 BACKGROUND: The 1918-1919 A/H1N1 influenza pandemic killed approximately 50
21 million people worldwide. Historical records suggest that an early pandemic wave struck
22 Europe during the summer of 1918. METHODS: We obtained surveillance data that were
23 compiled weekly, during 1910-1919, in Copenhagen, Denmark; the records included
24 medically treated influenza-like illnesses (ILIs), hospitalizations, and deaths by age. We
25 used a Serfling seasonal regression model to quantify excess morbidity and mortality, and
26 we estimated the reproductive number (R) for the summer, fall, and winter pandemic
27 waves. RESULTS: A large epidemic occurred in Copenhagen during the summer of
28 1918; the age distribution of deaths was characteristic of the 1918-1919 A/H1N1
29 pandemic overall. That summer wave accounted for 29%-34% of all excess ILIs and
30 hospitalizations during 1918, whereas the case-fatality rate (0.3%) was many-fold lower
31 than that of the fall wave (2.3%). Similar patterns were observed in 3 other Scandinavian

1 cities. R was substantially higher in summer (2.0-5.4) than in fall (1.2-1.6) in all cities.

2 CONCLUSIONS: The Copenhagen summer wave may have been caused by a precursor
3 A/H1N1 pandemic virus that transmitted efficiently but lacked extreme virulence. The R
4 measured in the summer wave is likely a better approximation of transmissibility in a
5 fully susceptible population and is substantially higher than that found in previous US
6 studies. The summer wave may have provided partial protection against the lethal fall
7 wave.

9 Atkinson, M. P. and L. M. Wein (2008). "Quantifying the routes of transmission for pandemic
10 influenza." Bull Math Biol **70**(3): 820-67.

11 Motivated by the desire to assess nonpharmaceutical interventions for pandemic
12 influenza, we seek in this study to quantify the routes of transmission for this disease. We
13 construct a mathematical model of aerosol (i.e., droplet-nuclei) and contact transmission
14 of influenza within a household containing one infected. An analysis of this model in
15 conjunction with influenza and rhinovirus data suggests that aerosol transmission is far
16 more dominant than contact transmission for influenza. We also consider a separate
17 model of a close expiratory event, and find that a close cough is unlikely (approximately
18 1% probability) to generate traditional droplet transmission (i.e., direct deposition on the
19 mucous membranes), although a close, unprotected and horizontally-directed sneeze is
20 potent enough to cause droplet transmission. There are insufficient data on the frequency
21 of close expiratory events to assess the relative importance of aerosol transmission and
22 droplet transmission, and it is prudent to leave open the possibility that droplet
23 transmission is important until proven otherwise. However, the rarity of close,
24 unprotected and horizontally-directed sneezes-coupled with the evidence of significant
25 aerosol and contact transmission for rhinovirus and our comparison of hazard rates for
26 rhinovirus and influenza-leads us to suspect that aerosol transmission is the dominant
27 mode of transmission for influenza.

29 Ayyadurai, S., L. Houhamdi, et al. (2008). "Long-term persistence of virulent *Yersinia pestis* in
30 soil." Microbiology **154**(Pt 9): 2865-71.

1 Plague is characterized by geographical foci from which it re-emerges after decades of
2 silence, a fact currently explained by enzootic and epizootic cycles between plague-
3 susceptible and plague-resistant rodents. To assess the potential role of soil in plague
4 epidemiology, we experimentally investigated whether *Yersinia pestis* could persist alive
5 and virulent in soil. Sterilized soil inoculated with virulent *Y. pestis* biotype *Orientalis*
6 was regularly sampled for 40 weeks in duplicate. Each sample was observed by acridine
7 orange staining and immunofluorescence using an anti-*Y. pestis* polyclonal antibody, and
8 DNA was extracted for PCR amplification and sequencing of the *Y. pestis* *ureD*, *caf1* and
9 *pla* genes. All samples were inoculated onto selective agar, and samples from soil that
10 had been incubated for 10, 60, 165, 210 and 280 days were also inoculated into each of
11 two BALB/c female mice. The mouse experiment was performed in triplicate. Non-
12 inoculated, sterilized soil samples were used as negative controls. Micro-organisms
13 fluorescing orange and detected by immunofluorescence were identified as *Y. pestis* in
14 all samples. They were recovered in pure agar cultures for up to 30 weeks but thereafter
15 were contaminated with *Pseudomonas* spp. Soil that had been inoculated with *Y. pestis*
16 proved to be fully virulent in mice, which died with *Y. pestis* septicaemia and multiple
17 organ involvement. Negative control mice showed no signs of disease. These data
18 indicate that *Y. pestis* biotype *Orientalis* can remain viable and fully virulent after 40
19 weeks in soil. This study is a first step on which to base further investigations of a
20 potential telluric reservoir for *Y. pestis*, which could represent an alternative mechanism
21 for the maintenance of plague foci.

23 Baccam, P. and M. Boechler (2007). "Public health response to an anthrax attack: an evaluation
24 of vaccination policy options." *Biosecure Bioterror* **5**(1): 26-34.

25 A discrete-time, deterministic, compartmental model was developed and analyzed to
26 provide insight into how the use of anthrax vaccine before or after a large-scale attack
27 can reduce casualties. The model accounts for important response and protection factors
28 such as antibiotic and vaccine efficacy, the protective effects of buildings, the timing of
29 emergency response, and antibiotic adherence and vaccine coverage in the population
30 prior to the attack. The relative benefit of pre- versus post-exposure vaccination is
31 influenced by the timing of the post-exposure antibiotic distribution campaign as well as

assumptions of antibiotic adherence. The results indicate that, regardless of which vaccination policy is adopted, a rapid and effective post-attack medical response has a large impact on the number of lives that can be saved by a post-exposure prophylaxis (PEP) campaign. A sensitivity analysis of the model indicates that uncertainty in medical efficacy and the time to initiate a PEP campaign are the model parameters that have the greatest impact on the number of predicted deaths. It is shown that for each day that a mass prophylaxis campaign is delayed, more casualties and deaths result than for each day that the completion of the campaign is delayed.

Bauch, C. T., J. O. Lloyd-Smith, et al. (2005). "Dynamically modeling SARS and other newly emerging respiratory illnesses: past, present, and future." *Epidemiology* **16**(6): 791-801.

The emergence and rapid global spread of the severe acute respiratory syndrome (SARS) coronavirus in 2002-2003 prompted efforts by modelers to characterize SARS epidemiology and inform control policies. We overview and discuss models for emerging infectious diseases (EIDs), provide a critical survey of SARS modeling literature, and discuss promising future directions for research. We reconcile discrepancies between published estimates of the basic reproductive number R_0 for SARS (a crucial epidemiologic parameter), discuss insights regarding SARS control measures that have emerged uniquely from a modeling approach, and argue that high priorities for future modeling of SARS and similar respiratory EIDs should include informing quarantine policy and better understanding the impact of population heterogeneity on transmission patterns.

Bean, B., B. M. Moore, et al. (1982). "Survival of influenza viruses on environmental surfaces." *J Infect Dis* **146**(1): 47-51.

To investigate the transmission of influenza viruses via hands and environmental surfaces, the survival of laboratory-grown influenza A and influenza B viruses on various surfaces was studied. Both influenza A and B viruses survived for 24-48 hr on hard, nonporous surfaces such as stainless steel and plastic but survived for less than 8-12 hr on cloth, paper, and tissues. Measurable quantities of influenza A virus were transferred from stainless steel surfaces to hands for 24 hr and from tissues to hands for up to 15 min.

Virus survived on hands for up to 5 min after transfer from the environmental surfaces. These observations suggest that the transmission of virus from donors who are shedding large amounts could occur for 2-8 hr via stainless steel surfaces and for a few minutes via paper tissues. Thus, under conditions of heavy environmental contamination, the transmission of influenza virus via fomites may be possible.

Belanov, E. F., V. P. Muntianov, et al. (1996). "[Survival of Marburg virus infectivity on contaminated surfaces and in aerosols]." *Vopr Virusol* **41**(1): 32-4.

Marburg virus was shown to survive for up to 4-5 days on contaminated surfaces. In aerosol it was not stable, the specific rate of its inactivation being 0.05 min⁻¹. This brought the authors to a conclusion that a relatively close contact is needed for virus transmission from man to man, although the possibility of aerosol transmission of the infection may be appreciably increased in case of the hemorrhagic syndrome with a high level of viremia.

Bombardt, J. N. (2006). "Congruent epidemic models for unstructured and structured populations: analytical reconstruction of a 2003 SARS outbreak." *Math Biosci* **203**(2): 171-203.

Both the threat of bioterrorism and the natural emergence of contagious diseases underscore the importance of quantitatively understanding disease transmission in structured human populations. Over the last few years, researchers have advanced the mathematical theory of scale-free networks and used such theoretical advancements in pilot epidemic models. Scale-free contact networks are particularly interesting in the realm of mathematical epidemiology, primarily because these networks may allow meaningfully structured populations to be incorporated in epidemic models at moderate or intermediate levels of complexity. Moreover, a scale-free contact network with node degree correlation is in accord with the well-known preferred mixing concept. The present author describes a semi-empirical and deterministic epidemic modeling approach that (a) focuses on time-varying rates of disease transmission in both unstructured and structured populations and (b) employs probability density functions to characterize disease progression and outbreak controls. Given an epidemic curve for a historical outbreak, this modeling approach calls for Monte Carlo calculations (that define the average new infection rate) and solutions to integro-differential equations (that describe

1 outbreak dynamics in an aggregate population or across all network connectivity classes).
2 Numerical results are obtained for the 2003 SARS outbreak in Taiwan and the dynamical
3 implications of time-varying transmission rates and scale-free contact networks are
4 discussed in some detail.

6 Bootsma, M. C. and N. M. Ferguson (2007). "The effect of public health measures on the 1918
7 influenza pandemic in U.S. cities." Proc Natl Acad Sci U S A **104**(18): 7588-93.

8 During the 1918 influenza pandemic, the U.S., unlike Europe, put considerable effort into
9 public health interventions. There was also more geographic variation in the autumn
10 wave of the pandemic in the U.S. compared with Europe, with some cities seeing only a
11 single large peak in mortality and others seeing double-peaked epidemics. Here we
12 examine whether differences in the public health measures adopted by different cities can
13 explain the variation in epidemic patterns and overall mortality observed. We show that
14 city-specific per-capita excess mortality in 1918 was significantly correlated with 1917
15 per-capita mortality, indicating some intrinsic variation in overall mortality, perhaps
16 related to sociodemographic factors. In the subset of 23 cities for which we had partial
17 data on the timing of interventions, an even stronger correlation was found between
18 excess mortality and how early in the epidemic interventions were introduced. We then
19 fitted an epidemic model to weekly mortality in 16 cities with nearly complete
20 intervention-timing data and estimated the impact of interventions. The model
21 reproduced the observed epidemic patterns well. In line with theoretical arguments, we
22 found the time-limited interventions used reduced total mortality only moderately
23 (perhaps 10-30%), and that the impact was often very limited because of interventions
24 being introduced too late and lifted too early. San Francisco, St. Louis, Milwaukee, and
25 Kansas City had the most effective interventions, reducing transmission rates by up to 30-
26 50%. Our analysis also suggests that individuals reactively reduced their contact rates in
27 response to high levels of mortality during the pandemic.

2 Bossart, K. N., Z. Zhu, et al. (2009). "A neutralizing human monoclonal antibody protects
3 against lethal disease in a new ferret model of acute nipah virus infection." *PLoS Pathog* 5(10):
4 e1000642.

5 Nipah virus is a broadly tropic and highly pathogenic zoonotic paramyxovirus in the
6 genus Henipavirus whose natural reservoirs are several species of Pteropus fruit bats.
7 Nipah virus has repeatedly caused outbreaks over the past decade associated with a
8 severe and often fatal disease in humans and animals. Here, a new ferret model of Nipah
9 virus pathogenesis is described where both respiratory and neurological disease are
10 present in infected animals. Severe disease occurs with viral doses as low as 500
11 TCID₅₀ within 6 to 10 days following infection. The underlying pathology seen in the
12 ferret closely resembles that seen in Nipah virus infected humans, characterized as a
13 widespread multisystemic vasculitis, with virus replicating in highly vascular tissues
14 including lung, spleen and brain, with recoverable virus from a variety of tissues. Using
15 this ferret model a cross-reactive neutralizing human monoclonal antibody, m102.4,
16 targeting the henipavirus G glycoprotein was evaluated in vivo as a potential therapeutic
17 agent. All ferrets that received m102.4 ten hours following a high dose oral-nasal Nipah
18 virus challenge were protected from disease while all controls died. This study is the first
19 successful post-exposure passive antibody therapy for Nipah virus using a human
20 monoclonal antibody.

21 Brabin BJ. (1985). "Epidemiology of infection in pregnancy. [Rev Infect Dis.](#) 7(5):579-603.

22 In this article the immunologic, clinical, and epidemiologic evidence for altered host
23 susceptibility to infection during pregnancy is reviewed in an attempt to determine
24 general principles that can be applied to interpret the wide range of information available
25 and that can be utilized for epidemiologic analysis and study design. Gestational changes
26 in immunity are related to the maternal history of infection during pregnancy. Primary
27 infections are distinguished from recurrent infections, and the different patterns of
28 recurrent infection in pregnancy are defined. This classification system is then used to
29 interpret a wide range of data. The impact of infection in pregnancy on the offspring is
30 discussed in relation to vertical transmission and pregnancy immune status: in pregnant
31 women the clearance, if not the incidence, of infection is similar to that in nonpregnant

women; maternal susceptibility to infection alters early in gestation (at less than 12 weeks); the degree of maternal recovery from early gestational infection affects vertical transmission rates; there are few data on how patterns of infection with the major tropical parasites during pregnancy relate to vertical transmission.

Brachman, P. S., A. F. Kaufman, et al. (1966). "Industrial inhalation Anthrax." Bacteriol Rev **30**(3): 646-59.

Bridges, C. B., M. J. Kuehnert, et al. (2003). "Transmission of influenza: implications for control in health care settings." Clin Infect Dis **37**(8): 1094-101.

Annual influenza epidemics in the United States result in an average of >36,000 deaths and 114,000 hospitalizations. Influenza can spread rapidly to patients and health care personnel in health care settings after influenza is introduced by visitors, staff, or patients. Influenza outbreaks in health care facilities can have potentially devastating consequences, particularly for immunocompromised persons. Although vaccination of health care personnel and patients is the primary means to prevent and control outbreaks of influenza in health care settings, antiviral influenza medications and isolation precautions are important adjuncts. Although droplet transmission is thought to be the primary mode of influenza transmission, limited evidence is available to support the relative clinical importance of contact, droplet, and droplet nuclei (airborne) transmission of influenza. In this article, the results of studies on the modes of influenza transmission and their relevant isolation precautions are reviewed.

Brown, J. L., J. W. Dominik, et al. (1982). Airborne survival of Rift Valley fever virus. U.S. Army Medical Research Institute of Infectious Diseases Aerobiology Division. Frederick, U.S. Department of Defense: 1-11.

The aerosol stability characteristics of an Egyptian isolate of Rift Valley fever virus (ZH-501 strain) were determined in a static aerosol chamber. Aerosolized particles had a mass median diameter of 4.0 pm. At 30, 55, 80% relative humidity (RH) the biological decay rate was 0.9, 4.1, and 10.1% per min, respectively. The decay rate data tested significantly different ($P < 0.001$) at each RH. The biological half-life values were 6.9 min at 80% RH,

15.8 min at 55% RH, and 77.0 min at 30% RH. Comparable decay rates were obtained with a strain (SA-51) isolated in South Africa in 1951.

Carrat, F., E. Vergu, et al. (2008). "Time lines of infection and disease in human influenza: a review of volunteer challenge studies." *Am J Epidemiol* **167**(7): 775-85.

The dynamics of viral shedding and symptoms following influenza virus infection are key factors when considering epidemic control measures. The authors reviewed published studies describing the course of influenza virus infection in placebo-treated and untreated volunteers challenged with wild-type influenza virus. A total of 56 different studies with 1,280 healthy participants were considered. Viral shedding increased sharply between 0.5 and 1 day after challenge and consistently peaked on day 2. The duration of viral shedding averaged over 375 participants was 4.80 days (95% confidence interval: 4.31, 5.29). The frequency of symptomatic infection was 66.9% (95% confidence interval: 58.3, 74.5). Fever was observed in 37.0% of A/H1N1, 40.6% of A/H3N2 ($p = 0.86$), and 7.5% of B infections ($p = 0.001$). The total symptoms scores increased on day 1 and peaked on day 3. Systemic symptoms peaked on day 2. No such data exist for children or elderly subjects, but epidemiologic studies suggest that the natural history might differ. The present analysis confirms prior expert opinion on the duration of viral shedding or the frequency of asymptomatic influenza infection, extends prior knowledge on the dynamics of viral shedding and symptoms, and provides original results on the frequency of respiratory symptoms or fever.

Cheng, V. C., S. K. Lau, et al. (2007). "Severe acute respiratory syndrome coronavirus as an agent of emerging and reemerging infection." *Clin Microbiol Rev* **20**(4): 660-94.

Before the emergence of severe acute respiratory syndrome (SARS) coronavirus (SARS-CoV) in 2003, only 12 other animal or human coronaviruses were known. The discovery of this virus was soon followed by the discovery of the civet and bat SARS-CoV and the human coronaviruses NL63 and HKU1. Surveillance of coronaviruses in many animal species has increased the number on the list of coronaviruses to at least 36. The explosive nature of the first SARS epidemic, the high mortality, its transient reemergence a year later, and economic disruptions led to a rush on research of the epidemiological, clinical,

1 pathological, immunological, virological, and other basic scientific aspects of the virus
2 and the disease. This research resulted in over 4,000 publications, only some of the most
3 representative works of which could be reviewed in this article. The marked increase in
4 the understanding of the virus and the disease within such a short time has allowed the
5 development of diagnostic tests, animal models, antivirals, vaccines, and epidemiological
6 and infection control measures, which could prove to be useful in randomized control
7 trials if SARS should return. The findings that horseshoe bats are the natural reservoir for
8 SARS-CoV-like virus and that civets are the amplification host highlight the importance
9 of wildlife and biosecurity in farms and wet markets, which can serve as the source and
10 amplification centers for emerging infections.

11
12 Choi, B. C. K., Pak, A. W. P. (2003). "A simple approximate mathematical model to predict the
13 number of severe acute respiratory syndrome cases and deaths
14 " J Epidemiol Community Health **57**: 831-835.

15 Background: Severe acute respiratory syndrome (SARS) is currently spreading in many
16 countries. This paper proposes a simple approximate mathematical model for public
17 health practitioners to predict the number of SARS cases and deaths. Methods: The
18 model is based on four parameters: R_0 (basic reproductive number), F (case-fatality rate),
19 i (incubation period), and d (duration of disease). The calculations can be done by hand or
20 by using a computer spreadsheet. Results: The best parameters to fit Canadian data as of
21 6 April 2003 (before infection controls took effect) are $R_0 = 1.5$, $F = 30\%$, $i = 5$ days, $d =$
22 14 days. On 6 April (day 40) there were 74 cases and 7 deaths. If this trend continues,
23 SARS numbers in Canada are predicted to be as follows: 387 cases and 34 deaths by 26
24 April (day 60), 4432 cases and 394 deaths by 26 May (day 90), and 50 500 cases and
25 4489 deaths by 25 June (day 120). By comparison, the best parameters to fit Hong Kong
26 data as of 10 April 2003 are $R_0 = 2.0$, $F = 20\%$, $i = 5$ days, $d = 14$ days. Conclusions:
27 Using the proposed mathematical model, it was estimated that about 1.5 to 2 new
28 infectious cases were produced per infectious case every five days. Also, about 20% to
29 30% of the cases die within 14 days. The case-fatality may therefore be considerably
30 higher than initially thought. The model indicates that SARS can spread very fast when
31 there are no interventions.

2 Chowell, G., C. E. Ammon, et al. (2006). "Transmission dynamics of the great influenza
3 pandemic of 1918 in Geneva, Switzerland: Assessing the effects of hypothetical interventions." *J*
4 *Theor Biol* **241**(2): 193-204.

5 Recurrent outbreaks of the avian H5N1 influenza virus in Asia represent a constant
6 global pandemic threat. We characterize and evaluate hypothetical public health
7 measures during the 1918 influenza pandemic in the Canton of Geneva, Switzerland. The
8 transmission rate, the recovery rate, the diagnostic rate, the relative infectiousness of
9 asymptomatic cases, and the proportion of clinical cases are estimated through least-
10 squares fitting of the model to epidemic curve data of the cumulative number of hospital
11 notifications. The latent period and the case fatality proportion are taken from published
12 literature. We determine the variance and identifiability of model parameters via a
13 simulation study. Our epidemic model agrees well with the observed epidemic data. We
14 estimate the basic reproductive number for the spring wave $R_1=1.49$ (95% CI: 1.45-
15 1.53) and the reproductive number for the fall wave $R_2=3.75$ (95% CI: 3.57-3.93). In
16 addition, we estimate the clinical reporting for these two waves to be 59.7% (95% CI:
17 55.7-63.7) and 83% (95% CI: 79-87). We surmise that the lower reporting in the first
18 wave can be explained by a lack of initial awareness of the epidemic and the relative
19 higher severity of the symptoms experienced during the fall wave. We found that
20 effective isolation measures in hospital clinics at best would only ensure control with
21 probability 0.87 while reducing the transmission rate by >76.5% guarantees stopping an
22 epidemic.

23
24 Chowell, G., L. M. Bettencourt, et al. (2008). "The 1918-1919 influenza pandemic in England
25 and Wales: spatial patterns in transmissibility and mortality impact." *Proc Biol Sci* **275**(1634):
26 501-9.

27 Spatial variations in disease patterns of the 1918-1919 influenza pandemic remain poorly
28 studied. We explored the association between influenza death rates, transmissibility and
29 several geographical and demographic indicators for the autumn and winter waves of the
30 1918-1919 pandemic in cities, towns and rural areas of England and Wales. Average
31 measures of transmissibility, estimated by the reproduction number, ranged between 1.3

1 and 1.9, depending on model assumptions and pandemic wave and showed little spatial
2 variation. Death rates varied markedly with urbanization, with 30-40% higher rates in
3 cities and towns compared with rural areas. In addition, death rates varied with
4 population size across rural settings, where low population areas fared worse. By
5 contrast, we found no association between transmissibility, death rates and indicators of
6 population density and residential crowding. Further studies of the geographical mortality
7 patterns associated with the 1918-1919 influenza pandemic may be useful for pandemic
8 planning.

9
10 Chowell, G., C. Castillo-Chavez, et al. (2004). "Model parameters and outbreak control for
11 SARS." Emerg Infect Dis **10**(7): 1258-63.

12 Control of the 2002-2003 severe acute respiratory syndrome (SARS) outbreak was based
13 on rapid diagnosis coupled with effective patient isolation. We used uncertainty and
14 sensitivity analysis of the basic reproductive number R_0 to assess the role that model
15 parameters play in outbreak control. The transmission rate and isolation effectiveness
16 have the largest fractional effect on R_0 . We estimated the distribution of the reproductive
17 number R_0 under perfect isolation conditions. The distribution lies in the interquartile
18 range 0.19-1.08, with a median of 0.49. Even though the median of R_0 is <1 , we found
19 that 25% of our R_0 distribution lies at $R_0 > 1$, even with perfect isolation. This implies
20 the need to simultaneously apply more than one method of control.

21
22 Chowell, G., N. W. Hengartner, et al. (2004). "The basic reproductive number of Ebola and the
23 effects of public health measures: the cases of Congo and Uganda." J Theor Biol **229**(1): 119-26.

24 Despite improved control measures, Ebola remains a serious public health risk in African
25 regions where recurrent outbreaks have been observed since the initial epidemic in 1976.
26 Using epidemic modeling and data from two well-documented Ebola outbreaks (Congo
27 1995 and Uganda 2000), we estimate the number of secondary cases generated by an
28 index case in the absence of control interventions R_0 . Our estimate of R_0 is 1.83 (SD
29 0.06) for Congo (1995) and 1.34 (SD 0.03) for Uganda (2000). We model the course of
30 the outbreaks via an SEIR (susceptible-exposed-infectious-removed) epidemic model that
31 includes a smooth transition in the transmission rate after control interventions are put in

1 place. We perform an uncertainty analysis of the basic reproductive number R_0 to
2 quantify its sensitivity to other disease-related parameters. We also analyse the sensitivity
3 of the final epidemic size to the time interventions begin and provide a distribution for
4 the final epidemic size. The control measures implemented during these two outbreaks
5 (including education and contact tracing followed by quarantine) reduce the final
6 epidemic size by a factor of 2 relative the final size with a 2-week delay in their
7 implementation.

8
9 Chowell, G., H. Nishiura, et al. (2007). "Comparative estimation of the reproduction number for
10 pandemic influenza from daily case notification data." *J R Soc Interface* **4**(12): 155-66.

11 The reproduction number, R , defined as the average number of secondary cases generated
12 by a primary case, is a crucial quantity for identifying the intensity of interventions
13 required to control an epidemic. Current estimates of the reproduction number for
14 seasonal influenza show wide variation and, in particular, uncertainty bounds for R for
15 the pandemic strain from 1918 to 1919 have been obtained only in a few recent studies
16 and are yet to be fully clarified. Here, we estimate R using daily case notifications during
17 the autumn wave of the influenza pandemic (Spanish flu) in the city of San Francisco,
18 California, from 1918 to 1919. In order to elucidate the effects from adopting different
19 estimation approaches, four different methods are used: estimation of R using the early
20 exponential-growth rate (Method 1), a simple susceptible-exposed-infectious-recovered
21 (SEIR) model (Method 2), a more complex SEIR-type model that accounts for
22 asymptomatic and hospitalized cases (Method 3), and a stochastic susceptible-infectious-
23 removed (SIR) with Bayesian estimation (Method 4) that determines the effective
24 reproduction number R_t at a given time t . The first three methods fit the initial
25 exponential-growth phase of the epidemic, which was explicitly determined by the
26 goodness-of-fit test. Moreover, Method 3 was also fitted to the whole epidemic curve.
27 Whereas the values of R obtained using the first three methods based on the initial
28 growth phase were estimated to be 2.98 (95% confidence interval (CI): 2.73, 3.25), 2.38
29 (2.16, 2.60) and 2.20 (1.55, 2.84), the third method with the entire epidemic curve yielded
30 a value of 3.53 (3.45, 3.62). This larger value could be an overestimate since the
31 goodness-of-fit to the initial exponential phase worsened when we fitted the model to the

entire epidemic curve, and because the model is established as an autonomous system without time-varying assumptions. These estimates were shown to be robust to parameter uncertainties, but the theoretical exponential-growth approximation (Method 1) shows wide uncertainty. Method 4 provided a maximum-likelihood effective reproduction number 2.10 (1.21, 2.95) using the first 17 epidemic days, which is consistent with estimates obtained from the other methods and an estimate of 2.36 (2.07, 2.65) for the entire autumn wave. We conclude that the reproduction number for pandemic influenza (Spanish flu) at the city level can be robustly assessed to lie in the range of 2.0-3.0, in broad agreement with previous estimates using distinct data.

Clements, M. L., R. F. Betts, et al. (1986). "Resistance of adults to challenge with influenza A wild-type virus after receiving live or inactivated virus vaccine." *J Clin Microbiol* **23**(1): 73-6.

The efficacy of live attenuated cold-adapted (ca) reassortant influenza A H3N2 and H1N1 virus vaccines against experimental challenge with homologous wild-type virus 7 months after vaccination was compared with that of licensed inactivated virus vaccine in 106 seronegative (hemagglutination-inhibiting antibody titer less than or equal to 1:8) college students. The live attenuated virus vaccines induced as much resistance against illness as did the inactivated vaccine. Vaccine efficacy, measured by reduction in febrile or systemic illness in vaccines, compared with that in controls was 100% for ca H3N2 vaccine, 84% for inactivated H3N2 vaccine, 79% for ca H1N1 vaccine, and 67% for inactivated H1N1 vaccine. Less protection was conferred against upper respiratory tract illness; there was 50 and 77% protection in ca and inactivated H3N2 vaccines, respectively, but there was no protection in ca or inactivated H1N1 vaccinees. The duration, but not the magnitude, of H1N1 wild-type virus shedding in both ca and inactivated vaccinees was significantly reduced compared with controls. In contrast, a significant reduction in the duration and magnitude of H3N2 virus shedding was observed in ca vaccinees but not in inactivated vaccines. After wild-type virus challenge, live ca virus vaccinees demonstrated resistance at least as great 7 months postvaccination as did inactivated virus vaccinees. These observations indicate that live virus vaccines may be a satisfactory alternative to inactivated vaccines for healthy persons.

1 Cori, A., P. Y. Boelle, et al. (2009). "Temporal variability and social heterogeneity in disease
2 transmission: the case of SARS in Hong Kong." PLoS Comput Biol **5**(8): e1000471.

3 The extent to which self-adopted or intervention-related changes in behaviors affect the
4 course of epidemics remains a key issue for outbreak control. This study attempted to
5 quantify the effect of such changes on the risk of infection in different settings, i.e., the
6 community and hospitals. The 2002-2003 severe acute respiratory syndrome (SARS)
7 outbreak in Hong Kong, where 27% of cases were healthcare workers, was used as an
8 example. A stochastic compartmental SEIR (susceptible-exposed-infectious-removed)
9 model was used: the population was split into healthcare workers, hospitalized people
10 and general population. Super spreading events (SSEs) were taken into account in the
11 model. The temporal evolutions of the daily effective contact rates in the community and
12 hospitals were modeled with smooth functions. Data augmentation techniques and
13 Markov chain Monte Carlo (MCMC) methods were applied to estimate SARS
14 epidemiological parameters. In particular, estimates of daily reproduction numbers were
15 provided for each subpopulation. The average duration of the SARS infectious period
16 was estimated to be 9.3 days (+/-0.3 days). The model was able to disentangle the impact
17 of the two SSEs from background transmission rates. The effective contact rates, which
18 were estimated on a daily basis, decreased with time, reaching zero inside hospitals. This
19 observation suggests that public health measures and possible changes in individual
20 behaviors effectively reduced transmission, especially in hospitals. The temporal patterns
21 of reproduction numbers were similar for healthcare workers and the general population,
22 indicating that on average, an infectious healthcare worker did not infect more people
23 than any other infectious person. We provide a general method to estimate time
24 dependence of parameters in structured epidemic models, which enables investigation of
25 the impact of control measures and behavioral changes in different settings.

30 Darnell, M. E., K. Subbarao, et al. (2004). "Inactivation of the coronavirus that induces severe
31 acute respiratory syndrome, SARS-CoV." J Virol Methods **121**(1): 85-91.

Severe acute respiratory syndrome (SARS) is a life-threatening disease caused by a novel coronavirus termed SARS-CoV. Due to the severity of this disease, the World Health Organization (WHO) recommends that manipulation of active viral cultures of SARS-CoV be performed in containment laboratories at biosafety level 3 (BSL3). The virus was inactivated by ultraviolet light (UV) at 254 nm, heat treatment of 65 degrees C or greater, alkaline (pH > 12) or acidic (pH < 3) conditions, formalin and glutaraldehyde treatments. We describe the kinetics of these efficient viral inactivation methods, which will allow research with SARS-CoV containing materials, that are rendered non-infectious, to be conducted at reduced safety levels.

Davis, D. G. (1960). "The influence of temperature and humidity on spore formation and germination in *Bacillus anthracis*." The Journal of Hygiene **58**(2): 177-186.

Davis, K. J., D. L. Fritz, et al. (1996). "Pathology of experimental pneumonic plague produced by fraction 1-positive and fraction 1-negative *Yersinia pestis* in African green monkeys (*Cercopithecus aethiops*)." Arch Pathol Lab Med **120**(2): 156-63.

OBJECTIVE: The protein capsule of *Yersinia pestis*, known as Fraction 1 or F1, is a protective immunogen and is an assumed, but not proven, virulence factor. Our objectives were to determine if inhaled F1-negative and/or F1-positive strains of *Y. pestis* were virulent in the African green monkey and, if so, to differentiate F1-negative from F1-positive monkeys. Because F1-negative strains have been isolated from natural sources and have caused experimental fatal disease, we felt that this information was crucial to the development of future vaccines and diagnostic tests. **MATERIALS AND METHODS:** Adult African green monkeys were exposed by aerosol to F1-positive (CO92, n=15) or F1-negative (CO92-C12, n=6; Java-9, n=2) *Y. pestis* strains. **RESULTS:** All monkeys died 4 to 10 days postexposure and had lesions consistent with primary pneumonic plague. Antibodies to F1 antigen and other *Y. pestis* antigens allowed us to differentiate F1-positive from F1-negative *Y. pestis* strains in fixed tissues. **CONCLUSIONS:** In this study, F1 antigen was not a required virulence factor. Therefore, there may be a need for vaccines and diagnostic assays that are not solely based on the F1 antigen.

Drancourt, M., L. Houhamdi, et al. (2006). "*Yersinia pestis* as a telluric, human ectoparasite-borne organism." Lancet Infect Dis **6**(4): 234-41.

The classic epidemiological model of plague is an infection of rodents that is transmitted to human beings by rodent ectoparasites. This model fits with observations of sporadic and limited outbreaks, but hardly explains the persistence of plague foci for millennia or the epidemiological features drawn from the descriptions of historical pandemics. A comprehensive review of the published data, including scientific papers published in France between 1920 and 1940, allows the completion of the epidemiological chain by introducing soil as a reservoir, burrowing rodents as a first link, and human ectoparasites as the main driving force for pandemics. Modern studies are needed to confirm the validity of this controversial model and to assess the relative contribution of each link in the various epidemiological presentations of plague. If confirmed, these data should be taken into account to update public-health policies and bioterrorism risk management, particularly among ectoparasite-infested people.

Fang, H., J. Chen, et al. (2005). "Modelling the SARS epidemic by a lattice-based Monte-Carlo simulation." Conf Proc IEEE Eng Med Biol Soc **7**: 7470-3.

We have analyzed the SARS data and the effect of the control measure in HongKong, based on a spatial Monte-Carlo model (SEIR) with susceptibles, exposed(latent), infective, and recovered. The SARS data can be well fit by numerical simulations. The control measure is effective to decreasing the transmission by reducing the contact rate. The average value of the reproductive number is consistent with many of the previous models.

Ferguson, N. M., D. A. Cummings, et al. (2006). "Strategies for mitigating an influenza pandemic." Nature **442**(7101): 448-52.

Development of strategies for mitigating the severity of a new influenza pandemic is now a top global public health priority. Influenza prevention and containment strategies can be considered under the broad categories of antiviral, vaccine and non-pharmaceutical (case isolation, household quarantine, school or workplace closure, restrictions on travel) measures. Mathematical models are powerful tools for exploring this complex landscape of intervention strategies and quantifying the potential costs and benefits of different options. Here we use a large-scale epidemic simulation to examine intervention options should initial containment of a novel influenza outbreak fail, using Great Britain and the United States as examples. We find that border restrictions and/or internal travel restrictions are unlikely to delay spread by more than 2-3 weeks unless more than 99% effective. School closure during the peak of a pandemic can reduce peak attack rates by up to 40%, but has little impact on overall attack rates, whereas case isolation or household quarantine could have a significant impact, if feasible. Treatment of clinical cases can reduce transmission, but only if antivirals are given within a day of symptoms starting. Given enough drugs for 50% of the population, household-based prophylaxis coupled with reactive school closure could reduce clinical attack rates by 40-50%. More widespread prophylaxis would be even more logistically challenging but might reduce

1 attack rates by over 75%. Vaccine stockpiled in advance of a pandemic could
2 significantly reduce attack rates even if of low efficacy. Estimates of policy effectiveness
3 will change if the characteristics of a future pandemic strain differ substantially from
4 those seen in past pandemics.

6 Fogarty, R., K. Halpin, et al. (2008). "Henipavirus susceptibility to environmental variables."
7 Virus Res **132**(1-2): 140-4.

8 The routes of henipavirus transmission between hosts are poorly understood. The purpose
9 of this study was to measure the persistence of henipaviruses under various
10 environmental conditions and thereby gain an insight into likely mechanisms of
11 transmission. Henipaviruses survived for more than 4 days at 22 degrees C in pH-neutral
12 fruit bat urine but were sensitive to higher temperatures and pH changes. On mango flesh,
13 survival time varied depending on temperature and fruit pH, ranging from 2h to more
14 than 2 days. Desiccation of viruses substantially reduced survival time to less than 2h.
15 The sensitivity of henipaviruses to pH, temperature and desiccation indicates a need for
16 close contact between hosts for transmission to occur, although under ideal conditions
17 henipaviruses can persist for extended periods facilitating vehicle-borne transmission.

19 Franz, D. R., P. B. Jahrling, et al. (1997). "Clinical recognition and management of patients
20 exposed to biological warfare agents." JAMA **278**(5): 399-411.

21 Concern regarding the use of biological agents--bacteria, viruses, or toxins--as tools of
22 warfare or terrorism has led to measures to deter their use or, failing that, to deal with the
23 consequences. Unlike chemical agents, which typically lead to violent disease syndromes
24 within minutes at the site of exposure, diseases resulting from biological agents have
25 incubation periods of days. Therefore, rather than a paramedic, it will likely be a
26 physician who is first faced with evidence of the results of a biological attack. We
27 provide here a primer on 10 classic biological warfare agents to increase the likelihood of
28 their being considered in a differential diagnosis. Although the resultant diseases are
29 rarely seen in many countries today, accepted diagnostic and epidemiologic principles
30 apply; if the cause is identified quickly, appropriate therapy can be initiated and the
31 impact of a terrorist attack greatly reduced.

Freiberg, A. N., M. N. Worthy, et al. "Combined chloroquine and ribavirin treatment does not prevent death in a hamster model of Nipah and Hendra virus infection." J Gen Virol **91**(Pt 3): 765-72.

Hendra virus (HeV) and Nipah virus (NiV) are recently emerged, closely related and highly pathogenic paramyxoviruses that cause severe disease such as encephalitis in animals and humans with fatality rates of up to 75 %. Due to their high case fatality rate following human infection and because of the lack of effective vaccines or therapy, they are classified as Biosafety Level 4 pathogens. A recent study reported that chloroquine, an anti-malarial drug, was effective in preventing NiV and HeV infection in cell culture experiments. In the present study, the antiviral efficacy of chloroquine was analysed, individually and in combination with ribavirin, in the treatment of NiV and HeV infection in in vivo experiments, using a golden hamster model. Although the results confirmed the strong antiviral activity of both drugs in inhibiting viral spread in vitro, they did not prove to be protective in the in vivo model. Ribavirin delayed death from viral disease in NiV-infected hamsters by approximately 5 days, but no significant effect in HeV-infected hamsters was observed. Chloroquine did not protect hamsters when administered either individually or in combination with ribavirin, the latter indicating the lack of a favourable drug-drug interaction.

Gani, R., H. Hughes, et al. (2005). "Potential Impact of Antiviral Drug Use during Influenza Pandemic." Emerging Infectious Diseases **11**(9): 1355-1362.

The recent spread of highly pathogenic strains of avian influenza has highlighted the threat posed by pandemic influenza. In the early phases of a pandemic, the only treatment available would be neuraminidase inhibitors, which many countries are considering stockpiling for pandemic use. We estimate the effect on hospitalization rates of using different antiviral stockpile sizes to treat infection. We estimate that stockpiles that cover 20%–25% of the population would be sufficient to treat most of the clinical cases and

1 could lead to 50% to 77% reductions in hospitalizations. Substantial reductions in
2 hospitalization could be achieved with smaller antiviral stockpiles if drugs are reserved
3 for persons at high risk.

4
5 Gani, R. and S. Leach (2004). "Epidemiologic determinants for modeling pneumonic plague
6 outbreaks." *Emerg Infect Dis* **10**(4): 608-14.

7 Pneumonic plague poses a potentially increasing risk to humans in plague nonendemic
8 regions either as a consequence of an aerosolized release or through importation of the
9 disease. Pneumonic plague is person-to-person transmissible. We provide a quantitative
10 assessment of transmissibility based on past outbreaks that shows that the average
11 number of secondary cases per primary case (R_0) was 1.3 (variance = 3.1), assuming a
12 geometric probability distribution, prior to outbreak control measures. We also show that
13 the latent and infectious periods can be approximated by using lognormal distributions
14 with means (SD) of 4.3 (1.8) and 2.5 (1.2) days. Based on this parameter estimation, we
15 construct a Markov-chain epidemic model to demonstrate the potential impact of delays
16 in implementing outbreak control measures and increasing numbers of index cases on the
17 incidence of cases in simulated outbreaks.

18
19 Geisbert, T. W., J. B. Geisbert, et al. (2009). "Single-injection vaccine protects nonhuman
20 primates against infection with marburg virus and three species of ebola virus." *J Virol* **83**(14):
21 7296-304.

22 The filoviruses Marburg virus and Ebola virus cause severe hemorrhagic fever with high
23 mortality in humans and nonhuman primates. Among the most promising filovirus
24 vaccines under development is a system based on recombinant vesicular stomatitis virus
25 (VSV) that expresses a single filovirus glycoprotein (GP) in place of the VSV
26 glycoprotein (G). Here, we performed a proof-of-concept study in order to determine the
27 potential of having one single-injection vaccine capable of protecting nonhuman primates
28 against Sudan ebolavirus (SEBOV), Zaire ebolavirus (ZEBOV), Cote d'Ivoire ebolavirus
29 (CIEBOV), and Marburgvirus (MARV). In this study, 11 cynomolgus monkeys were
30 vaccinated with a blended vaccine consisting of equal parts of the vaccine vectors
31 VSVDeltaG/SEBOVGP, VSVDeltaG/ZEBOVGP, and VSVDeltaG/MARVGP. Four

1 weeks later, three of these animals were challenged with MARV, three with CIEBOV,
2 three with ZEBOV, and two with SEBOV. Three control animals were vaccinated with
3 VSV vectors encoding a nonfilovirus GP and challenged with SEBOV, ZEBOV, and
4 MARV, respectively, and five unvaccinated control animals were challenged with
5 CIEBOV. Importantly, none of the macaques vaccinated with the blended vaccine
6 succumbed to a filovirus challenge. As expected, an experimental control animal
7 vaccinated with VSVDeltaG/ZEBOVGP and challenged with SEBOV succumbed, as did
8 the positive controls challenged with SEBOV, ZEBOV, and MARV, respectively. All
9 five control animals challenged with CIEBOV became severely ill, and three of the
10 animals succumbed on days 12, 12, and 14, respectively. The two animals that survived
11 CIEBOV infection were protected from subsequent challenge with either SEBOV or
12 ZEBOV, suggesting that immunity to CIEBOV may be protective against other species
13 of Ebola virus. In conclusion, we developed an immunization scheme based on a single-
14 injection vaccine that protects nonhuman primates against lethal challenge with
15 representative strains of all human pathogenic filovirus species.

20 Gottfredsson, M., B. V. Halldorsson, et al. (2008). "Lessons from the past: familial aggregation
21 analysis of fatal pandemic influenza (Spanish flu) in Iceland in 1918." Proc Natl Acad Sci U S A
22 **105**(4): 1303-8.

23 The pandemic influenza of 1918 (Spanish flu) killed 21-50 million people globally,
24 including in Iceland, where the characteristics and spread of the epidemic were well
25 documented. It has been postulated that genetic host factors may have contributed to this
26 high mortality. We identified 455 individuals who died of the Spanish flu in Iceland
27 during a 6-week period during the winter of 1918, representing >92% of all fatal
28 domestic cases mentioned by historical accounts. The highest case fatality proportion was
29 2.8%, and peak excess mortality was 162/100,000/week. Fatality proportions were
30 highest among infants, young adults, and the elderly. A genealogical database was used
31 to study relatedness and relative risk (RR) of the fatal influenza victims and relatives of

1 their unaffected mates. The significance of these RR computations was assessed by
2 drawing samples randomly from the genealogical database matched for age, sex, and
3 geographical distribution. Familial aggregation of fatalities was seen, with RRs for death
4 ranging from 3.75 for first-degree relatives ($P < 0.0001$) to 1.82 ($P = 0.005$), 1.12 ($P =$
5 0.252), and 1.47 ($P = 0.0001$) for second- to fourth-degree relatives of fatal influenza
6 victims, respectively. The RRs within the families of unaffected mates of fatal influenza
7 victims were 2.95 ($P < 0.0001$), 1.27 ($P = 0.267$), 1.35 ($P = 0.04$), and 1.42 ($P = 0.001$),
8 for first- to fourth-degree relatives, respectively. In conclusion, the risk of death from the
9 Spanish flu was similar within families of patients who succumbed to the illness and
10 within families of their mates who survived. Our data do not provide conclusive evidence
11 for the role of genetic factors in susceptibility to the Spanish flu.

12
13 Gritsun, T. S., V. A. Lashkevich, et al. (2003). "Tick-borne encephalitis." *Antiviral Res* **57**(1-2):
14 129-46.

15 Tick-borne encephalitis (TBE) is one of the most dangerous human infections occurring
16 in Europe and many parts of Asia. The etiological agent Tick-borne encephalitis virus
17 (TBEV), is a member of the virus genus *Flavivirus*, of the family *Flaviviridae*. TBEV is
18 believed to cause at least 11,000 human cases of encephalitis in Russia and about 3000
19 cases in the rest of Europe annually. Related viruses within the same group, Louping ill
20 virus (LIV), Langat virus (LGTV) and Powassan virus (POWV), also cause human
21 encephalitis but rarely on an epidemic scale. Three other viruses within the same group,
22 Omsk hemorrhagic fever virus (OHFV), Kyasanur Forest disease virus (KFDV) and
23 Alkhurma virus (ALKV), are closely related to the TBEV complex viruses and tend to
24 cause fatal hemorrhagic fevers rather than encephalitis. This review describes the clinical
25 manifestations associated with TBEV infections, the main molecular-biological
26 properties of these viruses, and the different factors that define the incidence and severity
27 of disease. The role of ticks and their local hosts in the emergence of new virus variants
28 with different pathogenic characteristics is also discussed. This review also contains a
29 brief history of vaccination against TBE including trials with live attenuated vaccine and
30 modern tendencies in developing of vaccine virus strains.

1 Gumel, A. B., S. Ruan, et al. (2004). "Modelling strategies for controlling SARS outbreaks."
2 Proc Biol Sci **271**(1554): 2223-32.

3 Severe acute respiratory syndrome (SARS), a new, highly contagious, viral disease,
4 emerged in China late in 2002 and quickly spread to 32 countries and regions causing in
5 excess of 774 deaths and 8098 infections worldwide. In the absence of a rapid diagnostic
6 test, therapy or vaccine, isolation of individuals diagnosed with SARS and quarantine of
7 individuals feared exposed to SARS virus were used to control the spread of infection.
8 We examine mathematically the impact of isolation and quarantine on the control of
9 SARS during the outbreaks in Toronto, Hong Kong, Singapore and Beijing using a
10 deterministic model that closely mimics the data for cumulative infected cases and
11 SARS-related deaths in the first three regions but not in Beijing until mid-April, when
12 China started to report data more accurately. The results reveal that achieving a reduction
13 in the contact rate between susceptible and diseased individuals by isolating the latter is a
14 critically important strategy that can control SARS outbreaks with or without quarantine.
15 An optimal isolation programme entails timely implementation under stringent hygienic
16 precautions defined by a critical threshold value. Values below this threshold lead to
17 control, but those above are associated with the incidence of new community outbreaks
18 or nosocomial infections, a known cause for the spread of SARS in each region.
19 Allocation of resources to implement optimal isolation is more effective than to
20 implement sub-optimal isolation and quarantine together. A community-wide eradication
21 of SARS is feasible if optimal isolation is combined with a highly effective screening
22 programme at the points of entry.

24 Haas, C. N. (2002). "On the risk of mortality to primates exposed to anthrax spores." Risk Anal
25 **22**(2): 189-93.

26 Current events have heightened the importance of understanding the risks from inhalation
27 exposure to small numbers of spores of *Bacillus anthracis*. Previously reported data sets
28 have not been fully assessed using current understanding of microbial dose response.
29 This article presents an assessment of the reported primate dose-response data. At low
30 doses, the risk to large populations of low doses of inhaled spores (e.g., < 100) is not
31 insignificant.

High KP, Bradley S, Loeb M, Palmer R, Quagliarello V, Yoshikawa T (2005). "A new paradigm for clinical investigation of infectious syndromes in older adults: assessment of functional status as a risk factor and outcome measure." Clinical Infectious Diseases 40:114–22

Adults aged ≥ 65 years comprise the fastest-growing segment of the United States population, and older adults experience greater morbidity and mortality due to infection than do young adults. Although age is well established as a risk factor for infection, most clinical investigations of infectious diseases in older adults focus on microbiology and on crude end points of clinical success, such as cure rates or death; however, they often fail to assess functional status, which is a critical variable in geriatric care. Functional status can be evaluated either as a risk factor for infectious disease or as an outcome of interest after specific interventions using well-validated instruments. This article outlines the currently available data that suggest an association between infection, immunity, and impaired functional status in elderly individuals, summarizes the instruments commonly used to determine specific aspects of functional status, and provides recommendations for a new paradigm in which clinical trials that involve older adults include assessment of functional status.

Hood, A. M. (2009). "The effect of open-air factors on the virulence and viability of airborne *Francisella tularensis*." Epidemiol Infect **137**(6): 753-61.

Unidentified open-air factors (OAFs) found to be adverse to the survival of microorganisms suspended on microthreads were investigated for their effect on realistic aerosols of *Francisella tularensis* in an open-air environment. This organism was chosen because it is probably the most infectious organism known to be capable of infecting both animals and man via the respiratory route, hence its potential use as a bioterrorist agent. A direct correlation was found between an open-air adverse effect on viability and virulence of airborne particles of <3 microm via the respiratory route in guinea pigs. One viable organism was sufficient to initiate an infection that resulted in a fatal tularemia infection. The lethal effect of OAFs on *F. tularensis* was found to vary from day to day and was related to the source of the air in the UK. The adverse effect on viability was associated with an inverse effect according to the size of the airborne particle.

2 Hsieh, Y. H., C. W. Chen, et al. (2004). "SARS outbreak, Taiwan, 2003." Emerg Infect Dis
3 **10**(2): 201-6.

4 We studied the severe acute respiratory syndrome (SARS) outbreak in Taiwan, using the
5 daily case-reporting data from May 5 to June 4 to learn how it had spread so rapidly. Our
6 results indicate that most SARS-infected persons had symptoms and were admitted
7 before their infections were reclassified as probable cases. This finding could indicate
8 efficient admission, slow reclassification process, or both. The high percentage of
9 nosocomial infections in Taiwan suggests that infection from hospitalized patients with
10 suspected, but not yet classified, cases is a major factor in the spread of disease. Delays in
11 reclassification also contributed to the problem. Because accurate diagnostic testing for
12 SARS is currently lacking, intervention measures aimed at more efficient diagnosis,
13 isolation of suspected SARS patients, and reclassification procedures could greatly
14 reduce the number of infections in future outbreaks.

15
16 Inglesby, T. V., T. O'Toole, et al. (2002). "Anthrax as a biological weapon, 2002: updated
17 recommendations for management." JAMA **287**(17): 2236-52.

18 OBJECTIVE: To review and update consensus-based recommendations for medical and
19 public health professionals following a *Bacillus anthracis* attack against a civilian
20 population. PARTICIPANTS: The working group included 23 experts from academic
21 medical centers, research organizations, and governmental, military, public health, and
22 emergency management institutions and agencies. EVIDENCE: MEDLINE databases
23 were searched from January 1966 to January 2002, using the Medical Subject Headings
24 anthrax, *Bacillus anthracis*, biological weapon, biological terrorism, biological warfare,
25 and biowarfare. Reference review identified work published before 1966. Participants
26 identified unpublished sources. CONSENSUS PROCESS: The first draft synthesized the
27 gathered information. Written comments were incorporated into subsequent drafts. The
28 final statement incorporated all relevant evidence from the search along with consensus
29 recommendations. CONCLUSIONS: Specific recommendations include diagnosis of
30 anthrax infection, indications for vaccination, therapy, postexposure prophylaxis,
31 decontamination of the environment, and suggested research. This revised consensus

1 statement presents new information based on the analysis of the anthrax attacks of 2001,
2 including developments in the investigation of the anthrax attacks of 2001; important
3 symptoms, signs, and laboratory studies; new diagnostic clues that may help future
4 recognition of this disease; current anthrax vaccine information; updated antibiotic
5 therapeutic considerations; and judgments about environmental surveillance and
6 decontamination.

8 James, L., N. Shindo, et al. (2006). "Public health measures implemented during the SARS
9 outbreak in Singapore, 2003." Public Health **120**(1): 20-6.

10 The SARS outbreak hit Singapore between March and May 2003. Public health control
11 measures were applied along three fronts; prevention and control within healthcare
12 settings, community and at the borders. Nosocomial spread composed majority of SARS
13 cases in Singapore. To prevent infection within healthcare facilities, cases were
14 centralized in a SARS-designated hospital, a no-visitors rule was applied and movement
15 of patients and healthcare staff were restricted. For triaging purposes, fever clinics were
16 established. A dedicated ambulance service was used to transport possible cases to the
17 SARS-designated hospital. Hospitals were surveyed for fever clusters. The challenge was
18 to identify cases with atypical presentation. Effective and safe discharge criteria were
19 established from the lessons learnt. To prevent community spread, contacts of cases were
20 stringently traced, quarantined in their homes and monitored daily. For prompt
21 identification of a case and to reduce the time between onset of symptoms and isolation,
22 the Infectious Diseases Act was amended. A large wholesale market closure resulted in
23 massive quarantine thereby limiting the spread of infection. A mass education campaign
24 was implemented in order to educate and raise awareness of the public. At all air, sea and
25 land points-of-entry, exit and entry screening took place that resulted in zero importation
26 and exportation of SARS cases after implementation of screening. Coordinated effort of
27 the cross sectional inter-ministerial collaboration and strong coordination by the Task
28 Force and commitment from different professionals made it possible to conquer the
29 disease.

1 Jamieson DJ, Theiler RN, Rasmussen SA (2006). Emerging infections and pregnancy. *Emerg*
2 *Infect Dis.* 12(11):1638-43

3 A key component of the response to emerging infections is consideration of special
4 populations, including pregnant women. Successful pregnancy depends on adaptation of
5 the woman's immune system to tolerate a genetically foreign fetus. Although the immune
6 system changes are not well understood, a shift from cell-mediated immunity toward
7 humoral immunity is believed to occur. These immunologic changes may alter
8 susceptibility to and severity of infectious diseases in pregnant women. For example,
9 pregnancy may increase susceptibility to toxoplasmosis and listeriosis and may increase
10 severity of illness and increase mortality rates from influenza and varicella. Compared
11 with information about more conventional disease threats, information about emerging
12 infectious diseases is quite limited. Pregnant women's altered response to infectious
13 diseases should be considered when planning a response to emerging infectious disease
14 threats.

17 Johnson, E., N. Jaax, et al. (1995). "Lethal experimental infections of rhesus monkeys by
18 aerosolized Ebola virus." *Int J Exp Pathol* 76(4): 227-36.

19 The potential of aerogenic infection by Ebola virus was established by using a head-only
20 exposure aerosol system. Virus-containing droplets of 0.8-1.2 microns were generated
21 and administered into the respiratory tract of rhesus monkeys via inhalation. Inhalation of
22 viral doses as low as 400 plaque-forming units of virus caused a rapidly fatal disease in 4-
23 5 days. The illness was clinically identical to that reported for parenteral virus
24 inoculation, except for the occurrence of subcutaneous and venipuncture site bleeding
25 and serosanguineous nasal discharge. Immunocytochemistry revealed cell-associated
26 Ebola virus antigens present in airway epithelium, alveolar pneumocytes, and
27 macrophages in the lung and pulmonary lymph nodes; extracellular antigen was present
28 on mucosal surfaces of the nose, oropharynx and airways. Aggregates of characteristic
29 filamentous virus were present within type I pneumocytes, macrophages, and air spaces
30 of the lung by electron microscopy. Demonstration of fatal aerosol transmission of this

1 virus in monkeys reinforces the importance of taking appropriate precautions to prevent
2 its potential aerosol transmission to humans.

3
4 Leffel, E. K. and D. S. Reed (2004). "Marburg and Ebola viruses as aerosol threats." Biosecur
5 Bioterror **2**(3): 186-91.

6 Ebola and Marburg viruses are the sole members of the genus Filovirus in the family
7 Filoviridae. There has been considerable media attention and fear generated by outbreaks
8 of filoviruses because they can cause a severe viral hemorrhagic fever (VHF) syndrome
9 that has a rapid onset and high mortality. Although they are not naturally transmitted by
10 aerosol, they are highly infectious as respirable particles under laboratory conditions. For
11 these and other reasons, filoviruses are classified as category A biological weapons.
12 However, there is very little data from animal studies with aerosolized filoviruses.
13 Animal models of filovirus exposure are not well characterized, and there are
14 discrepancies between these models and what has been observed in human outbreaks.
15 Building on published results from aerosol studies, as well as a review of the history,
16 epidemiology, and disease course of naturally occurring outbreaks, we offer an
17 aerobiologist's perspective on the threat posed by aerosolized filoviruses.

18
19 Lekone, P. E. and B. F. Finkenstadt (2006). "Statistical inference in a stochastic epidemic SEIR
20 model with control intervention: Ebola as a case study." Biometrics **62**(4): 1170-7.

21 A stochastic discrete-time susceptible-exposed-infectious-recovered (SEIR) model for
22 infectious diseases is developed with the aim of estimating parameters from daily
23 incidence and mortality time series for an outbreak of Ebola in the Democratic Republic
24 of Congo in 1995. The incidence time series exhibit many low integers as well as zero
25 counts requiring an intrinsically stochastic modeling approach. In order to capture the
26 stochastic nature of the transitions between the compartmental populations in such a
27 model we specify appropriate conditional binomial distributions. In addition, a relatively
28 simple temporally varying transmission rate function is introduced that allows for the
29 effect of control interventions. We develop Markov chain Monte Carlo methods for
30 inference that are used to explore the posterior distribution of the parameters. The
31 algorithm is further extended to integrate numerically over state variables of the model,

1 which are unobserved. This provides a realistic stochastic model that can be used by
2 epidemiologists to study the dynamics of the disease and the effect of control
3 interventions.

4
5 Lewerin, S. S., M. Elvander, et al. "Anthrax outbreak in a Swedish beef cattle herd--1st case in
6 27 years: Case report." *Acta Vet Scand* **52**: 7.

7 After 27 years with no detected cases, an outbreak of anthrax occurred in a beef cattle
8 herd in the south of Sweden. The outbreak was unusual as it occurred in winter, in
9 animals not exposed to meat-and-bone meal, in a non-endemic country. The affected herd
10 consisted of 90 animals, including calves and young stock. The animals were kept in a
11 barn on deep straw bedding and fed only roughage. Seven animals died during 10 days,
12 with no typical previous clinical signs except fever. The carcasses were reportedly
13 normal in appearance, particularly as regards rigor mortis, bleeding and coagulation of
14 the blood. Subsequently, three more animals died and anthrax was suspected at necropsy
15 and confirmed by culture and PCR on blood samples. The isolated strain was susceptible
16 to tetracycline, ciprofloxacin and ampicillin. Subtyping by MLVA showed the strain to
17 cluster with isolates in the A lineage of *Bacillus anthracis*. Environmental samples from
18 the holding were all negative except for two soil samples taken from a spot where
19 infected carcasses had been kept until they were picked up for transport. The most likely
20 source of the infection was concluded to be contaminated roughage, although this could
21 not be substantiated by laboratory analysis. The suspected feed was mixed with soil and
22 dust and originated from fields where flooding occurred the previous year, followed by a
23 dry summer with a very low water level in the river allowing for the harvesting on soil
24 usually not exposed. In the early 1900s, animal carcasses are said to have been dumped in
25 this river during anthrax outbreaks and it is most likely that some anthrax spores could
26 remain in the area. The case indicates that untypical cases in non-endemic areas may be
27 missed to a larger extent than previously thought. Field tests allowing a preliminary risk
28 assessment of animal carcasses would be helpful for increased sensitivity of detection and
29 prevention of further exposure to the causative agent.

1 Lim, W., K. C. Ng, et al. (2006). "Laboratory containment of SARS virus." Ann Acad Med
2 Singapore **35**(5): 354-60.

3 Following the severe acute respiratory syndrome (SARS) outbreak in 2003, a large
4 number of clinical and environmental samples containing/potentially containing SARS
5 coronavirus (SARSCoV) as well as SARS-CoV stocks were retained in clinical and
6 research laboratories. The importance of laboratory biosafety was demonstrated by the
7 occurrence of laboratory incidents in Singapore, Taiwan and Beijing. It is imperative that
8 safe practice and techniques, safety equipment and appropriate facility design should be
9 in place to reduce or eliminate exposure of laboratory workers, other persons and the
10 outside environment to SARS-CoV containing materials. Discussion on laboratory
11 containment of SARS-CoV was initiated in Hong Kong in August 2003. It was agreed
12 that an inventory of all specimens with the potential presence of SARS-CoV collected for
13 any diagnostic or research purposes from November 2002 to July 2003 should be
14 established in each laboratory. They should be stored in a secure place at the appropriate
15 biosafety level with access control. Un-needed samples collected during the period
16 should be destroyed. These laboratories should be audited to ensure inventories are
17 updated. The audit should include safety and security measures to detect irregularities.
18 Any laboratory accidents involving materials suspected of containing SARS-CoV should
19 be reported to the authorities and all personnel exposed closely followed medically. A
20 contingency plan should be in place in the laboratory and a drill conducted regularly to
21 test its efficacy. By January 2004, all clinical laboratories performing SARS-CoV testing
22 in Hong Kong set up inventories to document location and types of SARS-CoV
23 containing materials retained in their laboratory. Audits of these laboratories in 2004
24 showed that laboratory safety and containment requirements as recommended were
25 generally met.

26
27 Lipsitch, M., T. Cohen, et al. (2003). "Transmission dynamics and control of severe acute
28 respiratory syndrome." Science **300**(5627): 1966-70.

29 Severe acute respiratory syndrome (SARS) is a recently described illness of humans that
30 has spread widely over the past 6 months. With the use of detailed epidemiologic data
31 from Singapore and epidemic curves from other settings, we estimated the reproductive

1 number for SARS in the absence of interventions and in the presence of control efforts.
2 We estimate that a single infectious case of SARS will infect about three secondary cases
3 in a population that has not yet instituted control measures. Public-health efforts to reduce
4 transmission are expected to have a substantial impact on reducing the size of the
5 epidemic.

6
7 Lloyd-Smith, J. O., A. P. Galvani, et al. (2003). "Curtailling transmission of severe acute
8 respiratory syndrome within a community and its hospital." *Proc Biol Sci* **270**(1528): 1979-89.

9 Severe acute respiratory syndrome (SARS) has been transmitted extensively within
10 hospitals, and healthcare workers (HCWs) have comprised a large proportion of SARS
11 cases worldwide. We present a stochastic model of a SARS outbreak in a community and
12 its hospital. For a range of basic reproductive numbers ($R(0)$) corresponding to conditions
13 in different cities (but with emphasis on $R(0)$ approximately 3 as reported for Hong Kong
14 and Singapore), we evaluate contact precautions and case management (quarantine and
15 isolation) as containment measures. Hospital-based contact precautions emerge as the
16 most potent measures, with hospital-wide measures being particularly important if
17 screening of HCWs is inadequate. For $R(0) = 3$, case isolation alone can control a SARS
18 outbreak only if isolation reduces transmission by at least a factor of four and the mean
19 symptom-onset-to-isolation time is less than 3 days. Delays of a few days in contact
20 tracing and case identification severely degrade the utility of quarantine and isolation,
21 particularly in high-transmission settings. Still more detrimental are delays between the
22 onset of an outbreak and the implementation of control measures; for given control
23 scenarios, our model identifies windows of opportunity beyond which the efficacy of
24 containment efforts is reduced greatly. By considering pathways of transmission in our
25 system, we show that if hospital-based transmission is not halted, measures that reduce
26 community-HCW contact are vital to preventing a widespread epidemic. The
27 implications of our results for future emerging pathogens are discussed.

28
29 Lloyd-Smith, J. O., S. J. Schreiber, et al. (2005). "Superspreading and the effect of individual
30 variation on disease emergence." *Nature* **438**(7066): 355-9.

Population-level analyses often use average quantities to describe heterogeneous systems, particularly when variation does not arise from identifiable groups. A prominent example, central to our current understanding of epidemic spread, is the basic reproductive number, $R(0)$, which is defined as the mean number of infections caused by an infected individual in a susceptible population. Population estimates of $R(0)$ can obscure considerable individual variation in infectiousness, as highlighted during the global emergence of severe acute respiratory syndrome (SARS) by numerous 'superspreading events' in which certain individuals infected unusually large numbers of secondary cases. For diseases transmitted by non-sexual direct contacts, such as SARS or smallpox, individual variation is difficult to measure empirically, and thus its importance for outbreak dynamics has been unclear. Here we present an integrated theoretical and statistical analysis of the influence of individual variation in infectiousness on disease emergence. Using contact tracing data from eight directly transmitted diseases, we show that the distribution of individual infectiousness around $R(0)$ is often highly skewed. Model predictions accounting for this variation differ sharply from average-based approaches, with disease extinction more likely and outbreaks rarer but more explosive. Using these models, we explore implications for outbreak control, showing that individual-specific control measures outperform population-wide measures. Moreover, the dramatic improvements achieved through targeted control policies emphasize the need to identify predictive correlates of higher infectiousness. Our findings indicate that superspreading is a normal feature of disease spread, and to frame ongoing discussion we propose a rigorous definition for superspreading events and a method to predict their frequency.

Loosli, C. G., H. M. Lemon, et al. (1943). "Experimental airborne influenza infection. I. Influence of humidity on survival of virus in air." Proc. Soc. Exp. Biol. **53**: 205-206.

Lowen, A. C., S. Mubareka, et al. (2006). "The guinea pig as a transmission model for human influenza viruses." Proc Natl Acad Sci U S A **103**(26): 9988-92.

The severity of epidemic and pandemic influenza outbreaks is dictated in part by the efficiency with which the causative strain transmits between human hosts. The

mechanisms underlying influenza virus spread are poorly understood, in part because of the lack of a convenient animal model to study this phenomenon. Indeed, despite extremely efficient transmission among humans and virulence in the mouse model, we have shown that even the 1918 pandemic influenza virus does not transmit between mice. We therefore evaluated the guinea pig as a model mammalian host for influenza virus. Using the recent human isolate A/Panama/2007/99 (Pan/99) (H3N2) virus, we found that guinea pigs were highly susceptible to infection with the unadapted virus (ID₅₀ = 5 plaque-forming units). Pan/99 virus grew to high titers in the upper respiratory tract and was shed in nasal washings of infected animals. Moreover, influenza virus was transmitted from infected guinea pigs to noninfected guinea pigs housed in the same cage, an adjacent cage, and a cage placed 91 cm away. Our results demonstrate that influenza virus can pass between guinea pigs by means of droplet spread and thereby establish the suitability of the guinea pig as a model host for influenza virus transmission studies.

Luby, S. P., M. J. Hossain, et al. (2009). "Recurrent zoonotic transmission of Nipah virus into humans, Bangladesh, 2001-2007." *Emerg Infect Dis* **15**(8): 1229-35.

Human Nipah outbreaks recur in a specific region and time of year in Bangladesh. Fruit bats are the reservoir host for Nipah virus. We identified 23 introductions of Nipah virus into human populations in central and northwestern Bangladesh from 2001 through 2007. Ten introductions affected multiple persons (median 10). Illness onset occurred from December through May but not every year. We identified 122 cases of human Nipah infection. The mean age of case-patients was 27 years; 87 (71%) died. In 62 (51%) Nipah virus-infected patients, illness developed 5-15 days after close contact with another Nipah case-patient. Nine (7%) Nipah case-patients transmitted virus to others. Nipah case-patients who had difficulty breathing were more likely than those without respiratory difficulty to transmit Nipah (12% vs. 0%, $p = 0.03$). Although a small minority of infected patients transmit Nipah virus, more than half of identified cases result from person-to-person transmission. Interventions to prevent virus transmission from bats to humans and from person to person are needed.

1 Lyons, C. R. and T. H. Wu (2007). "Animal models of Francisella tularensis infection." Ann N Y
2 Acad Sci **1105**: 238-65.

3 The increased incidence of emerging infections has caused a resurgence in the
4 development of animal models in order to study their pathophysiology and develop
5 therapeutics against them. Optimizing these models and improving our ability to
6 extrapolate information from animals to humans is critical because in many cases the
7 animal model will represent the only modality for efficacy testing. Francisella tularensis
8 (F. tularensis) is an emerging pathogen that fits this category. While there is a significant
9 body of literature that has examined infections with F. tularensis in a variety of species,
10 the optimal small animal model has yet to be defined. A vast majority of studies have
11 used two strains of F. tularensis, the more virulent type A strain commonly found in
12 North America and the less virulent type B strain common to Europe. None of the small
13 animal models described in the literature thus far behave in a fashion identical to humans
14 with respect to their sensitivity to SCHU S4 (type A) or live vaccine strains (LVS)
15 (attenuated type B) and an ability of LVS vaccination to consistently protect against a
16 SCHU S4 aerosol challenge, suggesting that significant work on animal model
17 development still remains. This report briefly describes the parameters important for
18 animal model development and reviews the literature related to animal models of F.
19 tularensis, including the human model, and the characterization performed for those
20 models.

22 Lytle, C. D. and J. L. Sagripanti (2005). "Predicted inactivation of viruses of relevance to
23 biodefense by solar radiation." J Virol **79**(22): 14244-52.

24 UV radiation from the sun is the primary germicide in the environment. The goal of this
25 study was to estimate inactivation of viruses by solar exposure. We reviewed published
26 reports on 254-nm UV inactivation and tabulated the sensitivities of a wide variety of
27 viruses, including those with double-stranded DNA, single-stranded DNA, double-
28 stranded RNA, or single-stranded RNA genomes. We calculated D(37) values (fluence
29 producing on average one lethal hit per virion and reducing viable virus to 37%) from all
30 available data. We defined "size-normalized sensitivity" (SnS) by multiplying UV(254)
31 sensitivities (D(37) values) by the genome size, and SnS values were relatively constant

for viruses with similar genetic composition. In addition, SnS values were similar for complete virions and their defective particles, even when the corresponding D(37) values were significantly different. We used SnS to estimate the UV(254) sensitivities of viruses for which the genome composition and size were known but no UV inactivation data were available, including smallpox virus, Ebola, Marburg, Crimean-Congo, Junin, and other hemorrhagic viruses, and Venezuelan equine encephalitis and other encephalitis viruses. We compiled available data on virus inactivation as a function of wavelength and calculated a composite action spectrum that allowed extrapolation from the 254-nm data to solar UV. We combined our estimates of virus sensitivity with solar measurements at different geographical locations to predict virus inactivation. Our predictions agreed with the available experimental data. This work should be a useful step to understanding and eventually predicting the survival of viruses after their release in the environment.

Marianneau, P., V. Guillaume, et al. "Experimental infection of squirrel monkeys with nipah virus." Emerg Infect Dis **16**(3): 507-10.

We infected squirrel monkeys (*Saimiri sciureus*) with Nipah virus to determine the monkeys' suitability for use as primate models in preclinical testing of preventive and therapeutic treatments. Infection of squirrel monkeys through intravenous injection was followed by high death rates associated with acute neurologic and respiratory illness and viral RNA and antigen production.

Massad, E., M. N. Burattini, et al. (2007). "The 1918 influenza A epidemic in the city of Sao Paulo, Brazil." Med Hypotheses **68**(2): 442-5.

The 1918 pandemic H1N1 outbreak in the city of Sao Paulo is revisited. The outbreak lasted for 10 weeks and reached 116,771 officially recorded cases amongst 523,194 inhabitants. The total number of deaths summed up to 5331, with a lethality rate of 4.5% and an overall mortality rate of around 1%. We propose a mathematical model that tallies available data with good accuracy and allows the estimation of the basic reproductive

number, $R(0)$. The model showed a remarkably good accuracy in retrieving the real data from Sao Paulo city outbreak considering the total number of recorded cases and deaths and the timing of the outbreak. The basic reproduction number calculated of 2.68 can be compared to estimates carried out for other flu strains, like the estimates for H3N2, whose values ranged from 1.5 to 2.5. We hypothesize that the Southern parts of the world in which there was relatively little impact of the Great War, like South America, suffered a much lower H1N1 influenza mortality as compared with that reported for the Northern hemisphere heavily affected by the I World War.

McKinney, K. R., Y. Y. Gong, et al. (2006). "Environmental transmission of SARS at Amoy Gardens." J Environ Health **68**(9): 26-30; quiz 51-2.

Recent investigations into the March 2003 outbreak of SARS in Hong Kong have concluded that environmental factors played an important role in the transmission of the disease. These studies have focused on a particular outbreak event, the rapid spread of SARS throughout Amoy Gardens, a large, private apartment complex. They have demonstrated that, unlike a typical viral outbreak that is spread through person-to-person contact, the SARS virus in this case was spread primarily through the air. High concentrations of viral aerosols in building plumbing were drawn into apartment bathrooms through floor drains. The initial exposures occurred in these bathrooms. The virus-laden air was then transported by prevailing winds to adjacent buildings at Amoy Gardens, where additional exposures occurred. This article reviews the results of the investigations and provides recommendations for maintenance and other measures that building owners can take to help prevent environmental transmission of SARS and other flulike viruses in their buildings.

Meselson, M., J. Guillemin, et al. (1994). "The Sverdlovsk anthrax outbreak of 1979." Science **266**(5188): 1202-8.

1 In April and May 1979, an unusual anthrax epidemic occurred in Sverdlovsk, Union of
2 Soviet Socialist Republics. Soviet officials attributed it to consumption of contaminated
3 meat. U.S. agencies attributed it to inhalation of spores accidentally released at a military
4 microbiology facility in the city. Epidemiological data show that most victims worked or
5 lived in a narrow zone extending from the military facility to the southern city limit.
6 Farther south, livestock died of anthrax along the zone's extended axis. The zone
7 paralleled the northerly wind that prevailed shortly before the outbreak. It is concluded
8 that the escape of an aerosol of anthrax pathogen at the military facility caused the
9 outbreak.

11 Miller, W. S., C. R. Demchak, et al. (1963). "Stability and infectivity of airborne yellow fever
12 and Rift Valley fever viruses." American Journal of Hygiene **77**: 114-121.

13
14 Mills, C. E., J. M. Robins, et al. (2004). "Transmissibility of 1918 pandemic influenza." Nature
15 **432**(7019): 904-6.

16 The 1918 influenza pandemic killed 20-40 million people worldwide, and is seen as a
17 worst-case scenario for pandemic planning. Like other pandemic influenza strains, the
18 1918 A/H1N1 strain spread extremely rapidly. A measure of transmissibility and of the
19 stringency of control measures required to stop an epidemic is the reproductive number,
20 which is the number of secondary cases produced by each primary case. Here we
21 obtained an estimate of the reproductive number for 1918 influenza by fitting a
22 deterministic SEIR (susceptible-exposed-infectious-recovered) model to pneumonia and
23 influenza death epidemic curves from 45 US cities: the median value is less than three.
24 The estimated proportion of the population with A/H1N1 immunity before September
25 1918 implies a median basic reproductive number of less than four. These results strongly
26 suggest that the reproductive number for 1918 pandemic influenza is not large relative to
27 many other infectious diseases. In theory, a similar novel influenza subtype could be
28 controlled. But because influenza is frequently transmitted before a specific diagnosis is
29 possible and there is a dearth of global antiviral and vaccine stores, aggressive
30 transmission reducing measures will probably be required.

Montville, T. J., R. Dengrove, et al. (2005). "Thermal resistance of spores from virulent strains of *Bacillus anthracis* and potential surrogates." *J Food Prot* **68**(11): 2362-6.

The objective of this study was to determine the thermal resistance of spores of *Bacillus anthracis* and potential surrogates. The heat resistance of spores suspended in buffer (pH 7.0 or 4.5), milk, or orange juice was determined at 70, 80, and 90 degrees C. D-values for *B. anthracis* strains Sterne, Vollum, and Pasteur ranged from < 1 min at 90 degrees C to approximately 200 min at 70 degrees C and were lower under acidic than under neutral conditions. The D-values for *B. anthracis* spores fell within the range obtained for spores from eight strains of *Bacillus cereus*, *Bacillus thuringiensis*, *Bacillus mycoides*, and *Bacillus subtilis*. However, there were significant differences ($P < 0.001$) among the D-values of the strains. The z-values in pH 7.0 buffer and milk averaged approximately 10.5 degrees C and were not significantly different among strains ($P < 0.05$). The z-values in pH 4.5 buffer and orange juice averaged 12.9 and 13.9 degrees C, respectively, significantly ($P < 0.05$) higher than those obtained in milk or in pH 7.0 buffer. The significance of this difference was driven by large differences among a few strains. The z-values for *B. anthracis* strain Pasteur were twice as high in the acid media than in the neutral media. This study confirms that *B. anthracis* spores are not unusually heat resistant and that spores from validated *Bacillus* species are appropriate surrogates for thermal resistance studies.

Muller LM, Gorter KJ, Hak E, Goudzwaard WL, Schellevis FG, Hoepelman AI, Rutten GE (2005). Increased risk of common infections in patients with type 1 and type 2 diabetes mellitus. *Clin Infect Dis.* 1;41(3):281-8.

BACKGROUND: Clinical data on the association of diabetes mellitus with common infections are virtually lacking, not conclusive, and often biased. We intended to determine the relative risks of common infections in patients with type 1 and type 2 diabetes mellitus (DM1 and DM2, respectively). **METHODS:** In a 12-month prospective cohort study conducted as part of the Second Dutch National Survey of General Practice, we compared 705 adult patients who had DM1 and 6712 adult patients who had DM2 with 18,911 control patients who had hypertension without diabetes. Outcome measures were medically attended episodes of infection of the respiratory tract, urinary tract, and skin

1 and mucous membranes. We applied multivariable and polytomous logistic regression
2 analysis to determine independent risks of infections and their recurrences in patients
3 with diabetes, compared with control patients. RESULTS: Upper respiratory infections
4 were equally common among patients with diabetes and control patients. Patients with
5 diabetes had a greater risk of lower respiratory tract infection (for patients with DM1:
6 adjusted odds ratio [AOR], 1.42 [95% confidence interval {CI}, 0.96-2.08]; for patients
7 with DM2: AOR, 1.32 [95% CI, 1.13-1.53]), urinary tract infection (for patients with
8 DM1: AOR, 1.96 [95% CI, 1.49-2.58]; for patients with DM2: AOR, 1.24 [95% CI, 1.10-
9 1.39]), bacterial skin and mucous membrane infection (for patients with DM1: AOR, 1.59
10 [95% CI, 1.12-2.24]; for patients with DM2: AOR, 1.33 [95% CI, 1.15-1.54]), and
11 mycotic skin and mucous membrane infection (for patients with DM1: AOR, 1.34 [95%
12 CI, 0.97-1.84]; for patients with DM2: AOR, 1.44 [95% CI, 1.27-1.63]). Risks increased
13 with recurrences of common infections. CONCLUSIONS: Patients with DM1 and DM2
14 are at increased risk for lower respiratory tract infection, urinary tract infection, and skin
15 and mucous membrane infection. Studies are warranted into management of such
16 infections in patients with diabetes.

17
18 Nishiura, H. (2007). "Time variations in the transmissibility of pandemic influenza in Prussia,
19 Germany, from 1918-19." Theor Biol Med Model 4: 20.

20 BACKGROUND: Time variations in transmission potential have rarely been examined
21 with regard to pandemic influenza. This paper reanalyzes the temporal distribution of
22 pandemic influenza in Prussia, Germany, from 1918-19 using the daily numbers of
23 deaths, which totaled 8911 from 29 September 1918 to 1 February 1919, and the
24 distribution of the time delay from onset to death in order to estimate the effective
25 reproduction number, R_t , defined as the actual average number of secondary cases per
26 primary case at a given time. RESULTS: A discrete-time branching process was applied
27 to back-calculated incidence data, assuming three different serial intervals (i.e. 1, 3 and 5
28 days). The estimated reproduction numbers exhibited a clear association between the
29 estimates and choice of serial interval; i.e. the longer the assumed serial interval, the
30 higher the reproduction number. Moreover, the estimated reproduction numbers did not
31 decline monotonically with time, indicating that the patterns of secondary transmission

varied with time. These tendencies are consistent with the differences in estimates of the reproduction number of pandemic influenza in recent studies; high estimates probably originate from a long serial interval and a model assumption about transmission rate that takes no account of time variation and is applied to the entire epidemic curve.

CONCLUSION: The present findings suggest that in order to offer robust assessments it is critically important to clarify in detail the natural history of a disease (e.g. including the serial interval) as well as heterogeneous patterns of transmission. In addition, given that human contact behavior probably influences transmissibility, individual countermeasures (e.g. household quarantine and mask-wearing) need to be explored to construct effective non-pharmaceutical interventions.

Peters, C. J., P. B. Jahrling, et al. (1987). "Experimental studies of arenaviral hemorrhagic fevers." Curr Top Microbiol Immunol **134**: 5-68.

Peters, C. J., D. Jones, et al. (1988). "Experimental Rift Valley fever in rhesus macaques." Arch Virol **99**(1-2): 31-44.

Rift Valley fever (RVF) is a major cause of human morbidity and mortality in endemic areas of sub-Saharan Africa and has the potential to cause epidemic disease in receptive areas world-wide. In this study, a RVF viral isolate from the 1977 Egyptian epidemic (ZH-501) inoculated intravenously into rhesus macaques caused a benign viremic infection in most, but resulted in the hemorrhagic fever syndrome in 20 per cent (3 of 15). Serious disease of this type has not previously been observed in nonhuman primates inoculated with RVF virus and may be a consequence of the viral strain used or the route of inoculation. Severe disease was accompanied by extensive liver necrosis, disseminated intravascular coagulation, and microangiopathic hemolytic anemia. We also attempted to

1 prevent RVF by passive transfer of serum from vaccinated rhesus monkeys (plaque-
2 reduction neutralization test titer 1:2,560). As little as 0.025 ml/kg prevented the
3 development of viremia in naive rhesus monkeys after subcutaneous inoculation of virus.
4 The monkey model should be helpful in understanding the pathogenesis and prevention
5 of human RVF.

6
7 Pratt, W. D., D. Wang, et al. "Protection of nonhuman primates against two species of Ebola
8 virus infection with a single complex adenovirus vector." Clin Vaccine Immunol **17**(4): 572-81.

9 Ebola viruses are highly pathogenic viruses that cause outbreaks of hemorrhagic fever in
10 humans and other primates. To meet the need for a vaccine against the several types of
11 Ebola viruses that cause human diseases, we developed a multivalent vaccine candidate
12 (EBO7) that expresses the glycoproteins of Zaire ebolavirus (ZEBOV) and Sudan
13 ebolavirus (SEBOV) in a single complex adenovirus-based vector (CAAdVax). We
14 evaluated our vaccine in nonhuman primates against the parenteral and aerosol routes of
15 lethal challenge. EBO7 vaccine provided protection against both Ebola viruses by either
16 route of infection. Significantly, protection against SEBOV given as an aerosol challenge,
17 which has not previously been shown, could be achieved with a boosting vaccination.
18 These results demonstrate the feasibility of creating a robust, multivalent Ebola virus
19 vaccine that would be effective in the event of a natural virus outbreak or biological
20 threat.

22 Qin, C., J. Wang, et al. (2005). "An animal model of SARS produced by infection of *Macaca*
23 *mulatta* with SARS coronavirus." J Pathol **206**(3): 251-9.

24 A new SARS animal model was established by inoculating SARS coronavirus (SARS-
25 CoV) into rhesus macaques (*Macaca mulatta*) through the nasal cavity. Pathological
26 pulmonary changes were successively detected on days 5-60 after virus inoculation. All
27 eight animals showed a transient fever 2-3 days after inoculation. Immunological,
28 molecular biological, and pathological studies support the establishment of this SARS
29 animal model. Firstly, SARS-CoV-specific IgGs were detected in the sera of macaques
30 from 11 to 60 days after inoculation. Secondly, SARS-CoV RNA could be detected in
31 pharyngeal swab samples using nested RT-PCR in all infected animals from 5 days after

1 virus inoculation. Finally, histopathological changes of interstitial pneumonia were found
2 in the lungs during the 60 days after viral inoculation: these changes were less marked at
3 later time points, indicating that an active healing process together with resolution of an
4 acute inflammatory response was taking place in these animals. This animal model
5 should provide insight into the mechanisms of SARS-CoV-related pulmonary disease and
6 greatly facilitate the development of vaccines and therapeutics against SARS.

7
8 Rabenau, H. F., J. Cinatl, et al. (2005). "Stability and inactivation of SARS coronavirus." Med
9 Microbiol Immunol **194**(1-2): 1-6.

10 The SARS-coronavirus (SARS-CoV) is a newly emerged, highly pathogenic agent that
11 caused over 8,000 human infections with nearly 800 deaths between November 2002 and
12 September 2003. While direct person-to-person transmission via respiratory droplets
13 accounted for most cases, other modes have not been ruled out. Faecal shedding is
14 common and prolonged and has caused an outbreak in Hong Kong. We studied the
15 stability of SARS-CoV under different conditions, both in suspension and dried on
16 surfaces, in comparison with other human-pathogenic viruses, including human
17 coronavirus HCoV-229E. In suspension, HCoV-229E gradually lost its infectivity
18 completely while SARS-CoV retained its infectivity for up to 9 days; in the dried state,
19 survival times were 24 h versus 6 days. Thermal inactivation at 56 degrees C was highly
20 effective in the absence of protein, reducing the virus titre to below detectability;
21 however, the addition of 20% protein exerted a protective effect resulting in residual
22 infectivity. If protein-containing solutions are to be inactivated, heat treatment at 60
23 degrees C for at least 30 min must be used. Different fixation procedures, e.g. for the
24 preparation of immunofluorescence slides, as well as chemical means of virus
25 inactivation commonly used in hospital and laboratory settings were generally found to
26 be effective. Our investigations confirm that it is possible to care for SARS patients and
27 to conduct laboratory scientific studies on SARS-CoV safely. Nevertheless, the agents
28 tenacity is considerably higher than that of HCoV-229E, and should SARS re-emerge,
29 increased efforts need to be devoted to questions of environmental hygiene.

1 Riley, S., C. Fraser, et al. (2003). "Transmission dynamics of the etiological agent of SARS in
2 Hong Kong: impact of public health interventions." Science **300**(5627): 1961-6.

3 We present an analysis of the first 10 weeks of the severe acute respiratory syndrome
4 (SARS) epidemic in Hong Kong. The epidemic to date has been characterized by two
5 large clusters-initiated by two separate "super-spread" events (SSEs)-and by ongoing
6 community transmission. By fitting a stochastic model to data on 1512 cases, including
7 these clusters, we show that the etiological agent of SARS is moderately transmissible.
8 Excluding SSEs, we estimate that 2.7 secondary infections were generated per case on
9 average at the start of the epidemic, with a substantial contribution from hospital
10 transmission. Transmission rates fell during the epidemic, primarily as a result of
11 reductions in population contact rates and improved hospital infection control, but also
12 because of more rapid hospital attendance by symptomatic individuals. As a result, the
13 epidemic is now in decline, although continued vigilance is necessary for this to be
14 maintained. Restrictions on longer range population movement are shown to be a
15 potentially useful additional control measure in some contexts. We estimate that most
16 currently infected persons are now hospitalized, which highlights the importance of
17 control of nosocomial transmission.

19 Rose, L. J., R. Donlan, et al. (2003). "Survival of *Yersinia pestis* on environmental surfaces."
20 Appl Environ Microbiol **69**(4): 2166-71.

21 The survival of two strains of *Yersinia pestis* (avirulent A1122 and virulent Harbin) on
22 the surfaces of four materials was investigated. Viability was evaluated with
23 epifluorescence microscopy by using the metabolic stain cyanoditoyl tetrazolium
24 chloride and plate counts. Small numbers of cells suspended in phosphate buffer survived
25 2 to 4 h after visible drying on stainless steel, polyethylene, or glass and beyond 48 h on
26 paper. Cells suspended in brain heart infusion broth (BHI) persisted more than 72 h on
27 stainless steel, polyethylene, and glass. Small numbers of cells suspended in BHI were
28 still viable at 120 h on paper. These data suggest that *Y. pestis* maintains viability for
29 extended periods (last measured at 5 days) under controlled conditions.

1 Sagripanti, J. L. and C. D. Lytle (2007). "Inactivation of influenza virus by solar radiation."
2 Photochem Photobiol **83**(5): 1278-82.

3 Influenza virus is readily transmitted by aerosols and its inactivation in the environment
4 could play a role in limiting the spread of influenza epidemics. Ultraviolet radiation in
5 sunlight is the primary virucidal agent in the environment but the time that influenza
6 virus remains infectious outside its infected host remains to be established. In this study,
7 we calculated the expected inactivation of influenza A virus by solar ultraviolet radiation
8 in several cities of the world during different times of the year. The inactivation rates
9 reported here indicate that influenza A virions should remain infectious after release from
10 the host for several days during the winter "flu season" in many temperate-zone cities,
11 with continued risk for reaerosolization and human infection. The correlation between
12 low and high solar virucidal radiation and high and low disease prevalence, respectively,
13 suggest that inactivation of viruses in the environment by solar UV radiation plays a role
14 in the seasonal occurrence of influenza pandemics.

16 Saile, E. and T. M. Koehler (2006). "Bacillus anthracis multiplication, persistence, and genetic
17 exchange in the rhizosphere of grass plants." Appl Environ Microbiol **72**(5): 3168-74.

18 Bacillus anthracis, the causative agent of anthrax, is known for its rapid proliferation and
19 dissemination in mammalian hosts. In contrast, little information exists regarding the
20 lifestyle of this important pathogen outside of the host. Considering that Bacillus species,
21 including close relatives of B. anthracis, are saprophytic soil organisms, we investigated
22 the capacity of B. anthracis spores to germinate in the rhizosphere and to establish
23 populations of vegetative cells that could support horizontal gene transfer in the soil.
24 Using a simple grass plant-soil model system, we show that B. anthracis strains
25 germinate on and around roots, growing in characteristic long filaments. From 2 to 4 days
26 postinoculation, approximately one-half of the B. anthracis CFU recovered from soil
27 containing grass seedlings arose from heat-sensitive organisms, while B. anthracis CFU
28 retrieved from soil without plants consisted of primarily heat-resistant spores. Co-
29 inoculation of the plant-soil system with spores of a fertile B. anthracis strain carrying the
30 tetracycline resistance plasmid pBC16 and a selectable B. anthracis recipient strain
31 resulted in transfer of pBC16 from the donor to the recipient as early as 3 days

1 postinoculation. Our findings demonstrate that *B. anthracis* can survive as a saprophyte
2 outside of the host. The data suggest that horizontal gene transfer in the rhizosphere of
3 grass plants may play a role in the evolution of the *Bacillus cereus* group species.

5 Salvaggio, M. R. and J. W. Baddley (2004). "Other viral bioweapons: Ebola and Marburg
6 hemorrhagic fever." Dermatol Clin **22**(3): 291-302, vi.

7 The term viral hemorrhagic fever refers to a clinical syndrome characterized by acute
8 onset of fever accompanied by nonspecific findings of malaise, prostration, diarrhea, and
9 headache. Patients frequently show signs of increased vascular permeability, and many
10 develop bleeding diatheses. The hemorrhagic fever viruses represent potential agents for
11 biologic warfare because of capability of aerosol transmission, high morbidity, and
12 mortality associated with infection, and ability to replicate in cell culture in high
13 concentrations. Herein we discuss the Filoviridae, the agents of Ebola and Marburg
14 hemorrhagic fevers.

19 Sertsou, G., N. Wilson, et al. (2006). "Key transmission parameters of an institutional outbreak
20 during the 1918 influenza pandemic estimated by mathematical modelling." Theor Biol Med
21 Model **3**: 38.

22 AIM: To estimate the key transmission parameters associated with an outbreak of
23 pandemic influenza in an institutional setting (New Zealand 1918). METHODS:
24 Historical morbidity and mortality data were obtained from the report of the medical
25 officer for a large military camp. A susceptible-exposed-infectious-recovered
26 epidemiological model was solved numerically to find a range of best-fit estimates for
27 key epidemic parameters and an incidence curve. Mortality data were subsequently
28 modelled by performing a convolution of incidence distribution with a best-fit incidence-
29 mortality lag distribution. RESULTS: Basic reproduction number (R_0) values for three
30 possible scenarios ranged between 1.3, and 3.1, and corresponding average latent period
31 and infectious period estimates ranged between 0.7 and 1.3 days, and 0.2 and 0.3 days

1 respectively. The mean and median best-estimate incidence-mortality lag periods were
2 6.9 and 6.6 days respectively. This delay is consistent with secondary bacterial
3 pneumonia being a relatively important cause of death in this predominantly young male
4 population. CONCLUSION: These R0 estimates are broadly consistent with others made
5 for the 1918 influenza pandemic and are not particularly large relative to some other
6 infectious diseases. This finding suggests that if a novel influenza strain of similar
7 virulence emerged then it could potentially be controlled through the prompt use of major
8 public health measures.

10 Sha, J., S. L. Agar, et al. (2008). "Braun lipoprotein (Lpp) contributes to virulence of yersiniae:
11 potential role of Lpp in inducing bubonic and pneumonic plague." *Infect Immun* **76**(4): 1390-
12 409.

13 Yersinia pestis evolved from Y. pseudotuberculosis to become the causative agent of
14 bubonic and pneumonic plague. We identified a homolog of the Salmonella enterica
15 serovar Typhimurium lipoprotein (lpp) gene in Yersinia species and prepared lpp gene
16 deletion mutants of Y. pseudotuberculosis YPIII, Y. pestis KIM/D27 (pigmentation locus
17 minus), and Y. pestis CO92 with reduced virulence. Mice injected via the intraperitoneal
18 route with 5 x 10⁷ CFU of the Deltalpp KIM/D27 mutant survived a month, even
19 though this would have constituted a lethal dose for the parental KIM/D27 strain.
20 Subsequently, these Deltalpp KIM/D27-injected mice were solidly protected against an
21 intranasally administered, highly virulent Y. pestis CO92 strain when it was given as five
22 50% lethal doses (LD₅₀). In a parallel study with the pneumonic plague mouse model,
23 after 72 h postinfection, the lungs of animals infected with wild-type (WT) Y. pestis
24 CO92 and given a subinhibitory dose of levofloxacin had acute inflammation, edema, and
25 masses of bacteria, while the lung tissue appeared essentially normal in mice inoculated
26 with the Deltalpp mutant of CO92 and given the same dose of levofloxacin. Importantly,
27 while WT Y. pestis CO92 could be detected in the bloodstreams and spleens of infected
28 mice at 72 h postinfection, the Deltalpp mutant of CO92 could not be detected in those
29 organs. Furthermore, the levels of cytokines/chemokines detected in the sera were
30 significantly lower in animals infected with the Deltalpp mutant than in those infected
31 with WT CO92. Additionally, the Deltalpp mutant was more rapidly killed by

1 macrophages than was the WT CO92 strain. These data provided evidence that the
2 Deltalpp mutants of yersiniae were significantly attenuated and could be useful tools in
3 the development of new vaccines.

13 Stephenson, E. H., E. W. Larson, et al. (1984). "Effect of environmental factors on aerosol-
14 induced Lassa virus infection." J Med Virol **14**(4): 295-303.

15 Previous studies suggested that the most frequent means of transmission of Lassa virus
16 was by either direct or indirect contact with infectious material. Aerosol stability and
17 respiratory infectivity of the Josiah strain of Lassa virus were assessed to determine the
18 effect of environmental factors on aerosol-induced infection. The stability of the virus in
19 aerosol, particularly at low relative humidity (30% RH), plus the ability of the virus to
20 infect guinea pigs and monkeys via the respiratory route emphasize the potential for
21 aerosol transmission of Lassa virus. Biological half-lives at both 24 and 32 degrees C
22 ranged from 10.1 to 54.6 min, and were sufficient for aerosol dispersion of virus to
23 considerable distances in natural situations. Infectivity of Lassa virus in small particle
24 aerosol was demonstrated in outbred guinea pigs and cynomolgus monkeys using
25 dynamic aerosol equipment. Monkeys exposed to inhaled doses to 465 PFU were
26 infected and died. The median infectious dose (ID50) for guinea pigs was 15 PFU, yet a
27 definitive median lethal aerosol dose (LD50) could not be established. Organ tropism of
28 aerosol-induced Lassa virus infections in outbred guinea pigs was similar to that
29 previously reported for inbred guinea pigs infected by subcutaneous inoculation.

Tamrakar, S. B. and C. N. Haas (2008). "Dose-response model for Lassa virus." Human and Ecological Risk Assessment **14**: 742-752.

This article develops dose-response models for Lassa fever virus using data sets found in the open literature. Dose-response data were drawn from two studies in which guinea pigs were given subcutaneous and aerosol exposure to Lassa virus. In one study, six groups of inbred guinea pigs were inoculated subcutaneously with doses of Lassa virus and five groups of out-bred guinea pigs were similarly treated. We found that the out-bred subcutaneously exposed guinea pig did not exhibit a dose-dependent trend in response. The inbred guinea pigs data were best fit by an exponential dose-response model. In a second study, four groups of out-bred guinea pigs were exposed to doses of Lassa virus via the aerosol route. In that study, aerosol diameter was less than 4.5 μm and both mortality and morbidity were used as endpoints. The log-probit dose-response model provided a somewhat better fit than the Beta-Poisson model for data with mortality as the endpoint, but the Beta-Poisson is considered the best fit model because it can be derived using biological considerations. Morbidity data were best fit with an exponential dose-response model.

5 Turnbull, P. C. B. (1998). Guidelines for the surveillance and control of anthrax in humans and
6 animals. E. a. o. C. D. World Health Organization, Surveillance and Control. Geneva, World
7 Health Organization: 1-106.

8
9 Vasconcelos, D., R. Barnewall, et al. (2003). "Pathology of inhalation anthrax in cynomolgus
10 monkeys (*Macaca fascicularis*).*" Lab Invest* **83**(8): 1201-9.

11 Anthrax is considered a serious biowarfare and bioterrorism threat because of its high
12 lethality, especially by the inhalation route. Rhesus macaques (*Macaca mulatta*) are the
13 most commonly used nonhuman primate model of human inhalation anthrax exposure.
14 The nonavailability of rhesus macaques necessitated development of an alternate model
15 for vaccine testing and immunologic studies. This report describes the median lethal dose
16 (LD(50)) and pathology of inhalation anthrax in cynomolgus macaques (*Macaca*
17 *fascicularis*). Gross and microscopic tissue changes were reviewed in 14 cynomolgus
18 monkeys that died or were killed after aerosol exposure of spores of *Bacillus anthracis*
19 (Ames strain). The LD(50) and 95% confidence intervals were 61800 (34000 to 110000)
20 colony-forming units. The most common gross lesions were mild splenomegaly, lymph
21 node enlargement, and hemorrhages in various organs, particularly involving the
22 meninges and the lungs. Mediastinitis, manifested as hemorrhage or edema, affected 29%
23 of the monkeys. Microscopically, lymphocytolysis occurred in the intrathoracic lymph
24 nodes and spleens of all animals, and was particularly severe in the spleen and in
25 germinal centers of lymph nodes. Hemorrhages were common in lungs, bronchial lymph
26 nodes, meninges, gastrointestinal tract, and mediastinum. These results demonstrate that
27 the Ames strain of *B. anthracis* is lethal by the inhalation route in the cynomolgus
28 macaque. The LD(50) of the Ames strain of *B. anthracis* was within the expected
29 experimental range of previously reported values in the rhesus monkey in an aerosol
30 challenge. The gross and microscopic pathology of inhalation anthrax in the cynomolgus
31 monkey is remarkably similar to that reported in rhesus monkeys and humans. The results

of this study are important for the establishment of an alternative nonhuman primate model for evaluation of medical countermeasures against inhalational anthrax.

Viboud, C., T. Tam, et al. (2006). "Transmissibility and mortality impact of epidemic and pandemic influenza, with emphasis on the unusually deadly 1951 epidemic." *Vaccine* **24**(44-46): 6701-7.

There are important gaps in our current understanding of the influenza virus behavior. In particular, it remains unclear why some inter-pandemic seasons are associated with unusually high mortality impact, sometimes comparable to that of pandemics. Here we compare the epidemiological patterns of the unusually deadly 1951 influenza epidemic (A/H1N1) in England and Wales and Canada with those of surrounding epidemic and pandemic seasons, in terms of overall mortality impact and transmissibility. Based on the statistical and mathematical analysis of vital statistics and morbidity epidemic curves in these two countries, we show that the 1951 epidemic was associated with both higher mortality impact and higher transmissibility than the 1957 and 1968 pandemics. Surprisingly in Liverpool, considered the 'epicenter' of the severe 1951 epidemic, the mortality impact and transmissibility even surpassed the 1918 pandemic.

Wallinga, J. and P. Teunis (2004). "Different epidemic curves for severe acute respiratory syndrome reveal similar impacts of control measures." *Am J Epidemiol* **160**(6): 509-16.

Severe acute respiratory syndrome (SARS) has been the first severe contagious disease to emerge in the 21st century. The available epidemic curves for SARS show marked differences between the affected regions with respect to the total number of cases and epidemic duration, even for those regions in which outbreaks started almost simultaneously and similar control measures were implemented at the same time. The authors developed a likelihood-based estimation procedure that infers the temporal pattern of effective reproduction numbers from an observed epidemic curve. Precise estimates for the effective reproduction numbers were obtained by applying this estimation procedure to available data for SARS outbreaks that occurred in Hong Kong, Vietnam, Singapore, and Canada in 2003. The effective reproduction numbers revealed that epidemics in the various affected regions were characterized by markedly similar

disease transmission potentials and similar levels of effectiveness of control measures. In controlling SARS outbreaks, timely alerts have been essential: Delaying the institution of control measures by 1 week would have nearly tripled the epidemic size and would have increased the expected epidemic duration by 4 weeks.

Wang, W. and S. Ruan (2004). "Simulating the SARS outbreak in Beijing with limited data." J Theor Biol **227**(3): 369-79.

We propose a mathematical model to simulate the SARS outbreak in Beijing. The model consists of six subpopulations, namely susceptible, exposed, quarantined, suspect, probable and removed, as China started to report SARS cases as suspect and probable separately from April 27 and cases transferred from suspect class to probable class from May 2. By simplifying the model to a two-compartment suspect-probable model and a single-compartment probable model and using limited data, we are able to simulate the SARS outbreak in Beijing. We estimate that the reproduction number varies from 1.0698 to 3.2524 and obtain certain important epidemiological parameters.

Wang, X. W., J. S. Li, et al. (2005). "Study on the resistance of severe acute respiratory syndrome-associated coronavirus." J Virol Methods **126**(1-2): 171-7.

In this study, the persistence of severe acute respiratory syndrome-associated coronavirus (SARS-CoV) was observed in feces, urine and water. In addition, the inactivation of SARS-CoV in wastewater with sodium hypochlorite and chlorine dioxide was also studied. In vitro experiments demonstrated that the virus could only persist for 2 days in hospital wastewater, domestic sewage and dechlorinated tap water, while 3 days in feces, 14 days in PBS and 17 days in urine at 20 degrees C. However, at 4 degrees C, the SARS-CoV could persist for 14 days in wastewater and at least 17 days in feces or urine. SARS-CoV is more susceptible to disinfectants than *Escherichia coli* and f2 phage. Free chlorine was found to inactivate SARS-CoV better than chlorine dioxide. Free residue chlorine over 0.5 mg/L for chlorine or 2.19 mg/L for chlorine dioxide in wastewater ensures complete inactivation of SARS-CoV while it does not inactivate completely *E. coli* and f2 phage.

1 Warfield, K. L., S. B. Bradfute, et al. (2009). "Development and characterization of a mouse
2 model for Marburg hemorrhagic fever." J Virol **83**(13): 6404-15.

3 The lack of a mouse model has hampered an understanding of the pathogenesis and
4 immunity of Marburg hemorrhagic fever (MHF), the disease caused by marburgvirus
5 (MARV), and has created a bottleneck in the development of antiviral therapeutics.
6 Primary isolates of the filoviruses, i.e., ebolavirus (EBOV) and MARV, are not lethal to
7 immunocompetent adult mice. Previously, pathological, virologic, and immunologic
8 evaluation of a mouse-adapted EBOV, developed by sequential passages in suckling
9 mice, identified many similarities between this model and EBOV infections in nonhuman
10 primates. We recently demonstrated that serially passaging virus recovered from the liver
11 homogenates of MARV-infected immunodeficient (SCID) mice was highly successful in
12 reducing the time to death in these mice from 50 to 70 days to 7 to 10 days after
13 challenge with the isolate MARV-Ci67, -Musoke, or -Ravn. In this study, we extended
14 our findings to show that further sequential passages of MARV-Ravn in
15 immunocompetent mice caused the MARV to kill BALB/c mice. Serial sampling studies
16 to characterize the pathology of mouse-adapted MARV-Ravn revealed that this model is
17 similar to the guinea pig and nonhuman primate MHF models. Infection of BALB/c mice
18 with mouse-adapted MARV-Ravn caused uncontrolled viremia and high viral titers in the
19 liver, spleen, lymph node, and other organs; profound lymphopenia; destruction of
20 lymphocytes within the spleen and lymph nodes; and marked liver damage and
21 thrombocytopenia. Sequencing the mouse-adapted MARV-Ravn strain revealed
22 differences in 16 predicted amino acids from the progenitor virus, although the exact
23 changes required for adaptation are unclear at this time. This mouse-adapted MARV
24 strain can now be used to develop and evaluate novel vaccines and therapeutics and may
25 also help to provide a better understanding of the virulence factors associated with
26 MARV.

28 Weber, D. J. and W. A. Rutala (2001). "Risks and prevention of nosocomial transmission of rare
29 zoonotic diseases." Clin Infect Dis **32**(3): 446-56.

30 Americans are increasingly exposed to exotic zoonotic diseases through travel, contact
31 with exotic pets, occupational exposure, and leisure pursuits. Appropriate isolation

precautions are required to prevent nosocomial transmission of rare zoonotic diseases for which person-to-person transmission has been documented. This minireview provides guidelines for the isolation of patients and management of staff exposed to the following infectious diseases with documented person-to-person transmission: Andes hantavirus disease, anthrax, B virus infection, hemorrhagic fevers (due to Ebola, Marburg, Lassa, Crimean-Congo hemorrhagic fever, Argentine hemorrhagic fever, and Bolivian hemorrhagic fever viruses), monkeypox, plague, Q fever, and rabies. Several of these infections may also be encountered as bioterrorism hazards (i.e., anthrax, hemorrhagic fever viruses, plague, and Q fever). Adherence to recommended isolation precautions will allow for proper patient care while protecting the health care workers who provide care to patients with known or suspected zoonotic infections capable of nosocomial transmission.

Weber, T. P. and N. I. Stilianakis (2008). "Inactivation of influenza A viruses in the environment and modes of transmission: a critical review." *J Infect* **57**(5): 361-73.

OBJECTIVES: The relative importance of airborne, droplet and contact transmission of influenza A virus and the efficiency of control measures depends among other factors on the inactivation of viruses in different environmental media. **METHODS:** We systematically review available information on the environmental inactivation of influenza A viruses and employ information on infectious dose and results from mathematical models to assess transmission modes. **RESULTS:** Daily inactivation rate constants differ by several orders of magnitude: on inanimate surfaces and in aerosols daily inactivation rates are in the order of 1-10(2), on hands in the order of 10(3). Influenza virus can survive in aerosols for several hours, on hands for a few minutes. Nasal infectious dose of influenza A is several orders of magnitude larger than airborne infectious dose. **CONCLUSIONS:** The airborne route is a potentially important transmission pathway for influenza in indoor environments. The importance of droplet transmission has to be reassessed. Contact transmission can be limited by fast inactivation of influenza virus on hands and is more so than airborne transmission dependent on behavioral parameters. However, the potentially large inocula deposited in

1 the environment through sneezing and the protective effect of nasal mucus on virus
2 survival could make contact transmission a key transmission mode.

3
4 Wilkening, D. A. (2006). "Sverdlovsk revisited: modeling human inhalation anthrax." Proc Natl
5 Acad Sci U S A **103**(20): 7589-94.

6 Several models have been proposed for the dose-response function and the incubation
7 period distribution for human inhalation anthrax. These models give very different
8 predictions for the severity of a hypothetical bioterror attack, when an attack might be
9 detected from clinical cases, the efficacy of medical intervention and the requirements for
10 decontamination. Using data from the 1979 accidental atmospheric release of anthrax in
11 Sverdlovsk, Russia, and limited nonhuman primate data, this paper eliminates two of the
12 contending models and derives parameters for the other two, thereby narrowing the range
13 of models that accurately predict the effects of human inhalation anthrax. Dose-response
14 functions that exhibit a threshold for infectivity are contraindicated by the Sverdlovsk
15 data. Dose-dependent incubation period distributions explain the 10-day median
16 incubation period observed at Sverdlovsk and the 1- to 5-day incubation period observed
17 in nonhuman primate experiments.

18
19 Won, W. D. and H. Ross (1966). "Effect of diluent and relative humidity on apparent viability of
20 airborne *Pasteurella pestis*." Appl Microbiol **14**(5): 742-5.

21 Airborne *Pasteurella pestis* (A-1122) at low humidities [20 to 50% relative humidity
22 (RH)] exhibited exponential decay when either 1% peptone or Heart Infusion Broth
23 (HIB) was used as the diluent in the viable assay system. At higher RH values (65 and
24 87%), however, the 1% peptone diluent adversely affected the viability assay. In contrast,
25 HIB as diluent was remarkably effective in demonstrating a higher number of viable cells
26 in aerosols held at high RH values. Similarly, with HIB as diluent, aerosols were shown
27 to contain viable cells during 90 min of observation; with 1% peptone, viability was not
28 detectable after 20 min in the airborne state.

30 Wong, K. T., I. Grosjean, et al. (2003). "A golden hamster model for human acute Nipah virus
31 infection." Am J Pathol **163**(5): 2127-37.

1 A predominantly pig-to-human zoonotic infection caused by the novel Nipah virus
2 emerged recently to cause severe morbidity and mortality in both animals and man.
3 Human autopsy studies showed the pathogenesis to be related to systemic vasculitis that
4 led to widespread thrombotic occlusion and microinfarction in most major organs
5 especially in the central nervous system. There was also evidence of extravascular
6 parenchymal infection, particularly near damaged vessels (Wong KT, Shieh WJ, Kumar
7 S, Norain K, Abdullah W, Guarner J, Goldsmith CS, Chua KB, Lam SK, Tan CT, Goh
8 KJ, Chong HT, Jusoh R, Rollin PE, Ksiazek TG, Zaki SR, Nipah Virus Pathology
9 Working Group: Nipah virus infection: Pathology and pathogenesis of an emerging
10 paramyxoviral zoonosis. *Am J Pathol* 2002, 161:2153-2167). We describe here a golden
11 hamster (*Mesocricetus auratus*) model that appears to reproduce the pathology and
12 pathogenesis of acute human Nipah infection. Hamsters infected by intranasal or
13 intraperitoneal routes died within 9 to 29 days or 5 to 9 days, respectively. Pathological
14 lesions were most severe and extensive in the hamster brain. Vasculitis, thrombosis, and
15 more rarely, multinucleated endothelial syncytia, were found in blood vessels of multiple
16 organs. Viral antigen and RNA were localized in both vascular and extravascular tissues
17 including neurons, lung, kidney, and spleen, as demonstrated by immunohistochemistry
18 and in situ hybridization, respectively. Paramyxoviral-type nucleocapsids were identified
19 in neurons and in vessel walls. At the terminal stage of infection, virus and/or viral RNA
20 could be recovered from most solid organs and urine, but not from serum. The golden
21 hamster is proposed as a suitable model for further studies including pathogenesis
22 studies, anti-viral drug testing, and vaccine development against acute Nipah infection.

28
29 Yetter, R. A., S. Lehrer, et al. (1980). "Outcome of influenza infection: effect of site of initial
30 infection and heterotypic immunity." *Infect Immun* **29**(2): 654-62.

1 An infection established throughout the total respiratory tract of mice with a highly lung
2 adapted influenza virus (H0N1) led to death from viral pneumonia. The 50% lethal dose
3 (LD(50)) was approximately the same as the 50% infectious dose (ID(50)). An infection
4 with the same virus initiated in the nasal mucosa spread to the trachea and lungs over a 3-
5 to 5-day period but was not lethal except at very high infecting doses. The LD(50) was
6 30,000 times the ID(50). Mice that had recovered from a prior infection with
7 A/PC/73(H3N2) demonstrated enhanced recovery (heterotypic immunity) when
8 challenged with A/PR/8/34(H0N1). Heterotypically immune mice infected while
9 anesthetized with this potentially lethal virus stopped shedding virus from the nose,
10 trachea, and lungs by day 7 and recovered. Heterotypically immune mice, infected
11 awake, stopped shedding virus from the nose by day 5, and, in fact, the virus did not
12 spread to the trachea or lungs. Thus, some of the variation in the severity of influenza
13 infections may be explained by two factors: the site of initial infection and previous
14 infection with heterotypic influenza virus.

15
16 Yip, C., W. L. Chang, et al. (2007). "Possible meteorological influence on the severe acute
17 respiratory syndrome (SARS) community outbreak at Amoy Gardens, Hong Kong." J Environ
18 Health **70**(3): 39-46.

19 The largest community outbreak of Severe Acute Respiratory Syndrome (SARS)
20 occurred in the Amoy Gardens residential estate in Hong Kong, in March and April of
21 2003. It affected more than 300 residents, or 1.7 percent of the total Amoy Gardens
22 population. An airborne pathway has been hypothesized as a possible mode for the spread
23 of the disease. If that hypothesis is correct, meteorological factors may have played a
24 contributory role; the virus-laden aerosols may have been transported between apartment
25 blocks by the ambient wind, low mixing heights may have prevented the efficient
26 dispersion of the aerosols, and a fall in temperature may have fostered the survival of the
27 virus or increased the susceptibility of the exposed population. This information, used in
28 combination with weather forecasts available several days ahead from meteorological
29 services, should be useful for mitigation considerations in the unlikely event of a similar
30 occurrence.

1 Zaas, A. K., M. Chen, et al. (2009). "Gene expression signatures diagnose influenza and other
2 symptomatic respiratory viral infections in humans." Cell Host Microbe **6**(3): 207-17.

3 Acute respiratory infections (ARIs) are a common reason for seeking medical attention,
4 and the threat of pandemic influenza will likely add to these numbers. Using human viral
5 challenge studies with live rhinovirus, respiratory syncytial virus, and influenza A, we
6 developed peripheral blood gene expression signatures that distinguish individuals with
7 symptomatic ARIs from uninfected individuals with >95% accuracy. We validated this
8 "acute respiratory viral" signature-encompassing genes with a known role in host defense
9 against viral infections-across each viral challenge. We also validated the signature in an
10 independently acquired data set for influenza A and classified infected individuals from
11 healthy controls with 100% accuracy. In the same data set, we could also distinguish viral
12 from bacterial ARIs (93% accuracy). These results demonstrate that ARIs induce changes
13 in human peripheral blood gene expression that can be used to diagnose a viral etiology
14 of respiratory infection and triage symptomatic individuals.

15
16 Zhang, Z. (2007). "The outbreak pattern of SARS cases in China as revealed by a mathematical
17 model." Ecological Modelling **201**: 420-426.

18 Since it first appeared in China's Guangdong Province, Severe Acute Respiratory
19 Syndrome (SARS) has caused serious damages to many parts of the world, especially
20 Asia. Little is known about its epidemiology. We developed a modified discrete SIR
21 model including susceptible individuals, non-hospitalized SARS persons; hospitalized
22 patients, cured hospital patients, and those who have died due to SARS infection.
23 Here, we demonstrate the effective reproduction number is determined by infection rates
24 and infectious period of hospitalized and non-hospitalized SARS patients. Both infection
25 rate and the effective reproductive number of the SARS virus are significantly negatively
26 correlated with the total number of cumulative cases, indicating that the control measures
27 implemented in China are effective, and the outbreak pattern of accumulative SARS
28 cases in China is a logistic growth curve. We estimate the basic reproduction number R_0
29 of SARS virus is 2.87 in mainland of China, very close to the estimations in Singapore
30 and Hong Kong.

1 Zhou, G. and G. Yan (2003). "Severe acute respiratory syndrome epidemic in Asia." Emerg
2 Infect Dis **9**(12): 1608-10.

3 We analyzed the dynamics of cumulative severe acute respiratory syndrome (SARS)
4 cases in Singapore, Hong Kong, and Beijing using the Richards model. The predicted
5 total SARS incidence was close to the actual number of cases; the predicted cessation
6 date was close to the lower limit of the 95% confidence interval.

H.2 EXPERT PANEL BIOGRAPHICAL SKETCHES AND ORIENTATION CALL MATERIALS

Expert Panel; Orientation call materials

Arturo Casadevall, MD, PhD is the Leo and Julia Forchheimer Professor of Microbiology & Immunology at the Albert Einstein College of Medicine of Yeshiva University in the Bronx, New York. He is Chairman of the Department of Microbiology and Immunology and served as Director of the Division of Infectious Diseases at the Montefiore Medical Center at the Albert Einstein College of Medicine from 2000-2006. Dr Casadevall received both his MD and PhD (biochemistry) degrees from New York University in New York, New York. Subsequently, he completed internship and residency in internal medicine at Bellevue Hospital in New York, New York. Later he completed subspecialty training in Infectious Diseases at the Montefiore Medical Center and Albert Einstein College of Medicine. Dr. Casadevall major research interests are in fungal pathogenesis and the mechanism of antibody action. In the area of Biodefense Dr. Casadevall has an active research program to understand the mechanisms of antibody-mediated neutralization of Bacillus anthracis toxins. He has authored over 410 scientific papers. Dr. Casadevall was elected to membership in the American Society for Clinical Investigation, the American Academy of Physicians, and the American Academy of Microbiology. He was elected a fellow of the American Academy for the Advancement of Science and has received numerous honors including the Solomon A Berson Medical Alumni Achievement Award in Basic Science from the NYU School of Medicine, the Maxwell L. Littman Award (mycology award), the Rhoda Benham Award from Medical Mycology Society of America, and the Kass Lecture of the Infectious Disease Society of America. Dr. Casadevall is an editor of Infection and Immunity and serves in the editorial board of the Journal of Clinical Investigation and the Journal of Experimental Medicine. He is Editor-in-Chief of mBio, the first NIH open access general journal. He has served in numerous NIH committees including those that drafted the NIAID Strategic Plan and the Blue Ribbon Panel on Biodefense Research. He was a member of the National Academy Committee that reviewed the FBI Amerithrax Investigation. He is currently a member of the National Science Advisory Board for Biosecurity and co-chairs the NIAID Board of Scientific counselors.

1 Since he joined the AECOM faculty in 1992 Dr. Casadevall has mentored dozens of graduate
2 students, postdoctoral fellows, and junior faculty. Many of his trainees have gone on to have
3 highly successful careers in science and several have currently AECOM faculty. From 2000-2006
4 Dr. Casadevall was director of the Division of Infectious Diseases at AECOM-Montefiore and
5 oversaw the expansion of its research program. He is highly regarded as a teacher and was
6 elected to the Davidoff Society. In 2001 Dr. Casadevall received the Samuel M. Rosen
7 outstanding teacher award and in 2008 he was recognized the American Society of
8 Microbiology with the William Hinton Award for mentoring scientists from underrepresented
9 groups. Dr. Casadevall has organized numerous symposia and conference and was the Chair of
10 the Program committee of the Infectious Disease Society of America in 2006. Dr. Casadevall
11 has taken a national leadership role in postgraduate education and chairs the Career
12 Development committee of the American Society of Microbiology.

13
14 **Charles N. Haas, PhD** is the L.D. Betz Professor of Environmental Engineering and head of the
15 Department of Civil, Architectural and Environmental Engineering, at Drexel University, where
16 he has been since 1991. He directs the Drexel Engineering Cities Initiative. He also has an
17 adjunct appointment in the Department of Emergency Medicine of the Drexel University
18 College of Medicine. He received his BS (Biology) and MS (Environmental Engineering) from the
19 Illinois Institute of Technology and his PhD in Environmental Engineering from the University of
20 Illinois at Urbana-Champaign. He has served on the faculties of Rensselaer Polytechnic Institute
21 and the Illinois Institute of Technology prior to joining Drexel. He co-directs the USEPA/DHS
22 University Cooperative Center of Excellence – Center for Advancing Microbial Risk Assessment
23 (CAMRA). He is a fellow of the American Academy for the Advancement of Science, the Society
24 for Risk Analysis, and the American Academy of Microbiology. He is a Board Certified
25 Environmental Engineering Member by eminence of the American Academy of Environmental
26 Engineers. For over 30 years, Professor Haas has specialized in the assessment of risk from and
27 control of human exposure to pathogenic microorganisms, and in particular the treatment of
28 water and wastewater to minimize microbial risk to human health. Professor Haas has served
29 on numerous panels of the National Research Council.. He is a past member of the Water

1 Science and Technology Board of the National Academies, and is on the US EPA Board of
2 Scientific Counselors.

3
4 **Jim LeDuc, PhD** is the director of the Galveston National Laboratory (GNL) located on the
5 campus of the University of Texas Medical Branch in Galveston, Texas. He formerly served as
6 the GNL's Deputy Director (2008-2010) and Associate Director for Program Development (2006-
7 2008). He also currently serves as the Director for Global Health in the Institute for Human
8 Infections and Immunity and holds the inaugural Robert E. Shope, MD and John S. Dunn
9 Distinguished Chair in Global Health.

10
11 Dr. LeDuc relocated to UTMB in late 2006 from the Centers for Disease Control and Prevention
12 (CDC) in Atlanta, Georgia, where he was the Influenza Coordinator. He also served as Director,
13 Division of Viral and Rickettsial Diseases (2000-2005), coordinating research activities,
14 prevention initiatives and outbreak investigations for viral and rickettsial pathogens of global
15 importance, including viral hemorrhagic fevers, influenza and other respiratory infections,
16 childhood viral diseases, and newly emerging diseases such as SARS. He served as the Associate
17 Director for Global Health (1996-2000) in the Office of the Director, National Center for
18 Infectious Diseases at CDC, and was a Medical Officer in charge of arboviruses and viral
19 hemorrhagic fevers at the World Health Organization in Geneva, Switzerland (1992-1996). He
20 also held leadership positions during a 23-year career as a U.S. Army officer in the medical
21 research and development command, with assignments in Brazil, Panama and at various
22 locations in the United States, including the Walter Reed Army Institute of Research and the
23 U.S. Army Medical Research Institute of Infectious Diseases. His professional career began as a
24 field biologist working for the Smithsonian Institution in West Africa.

25
26 He is a member of various professional organizations, has published over 200 scientific articles
27 and book chapters, and is well recognized as an expert in virus diseases, biodefense and global
28 health. Dr. LeDuc is a native of southern California and earned his masters and doctoral

degrees from the University of California at Los Angeles. He and his wife Maryellen reside in Galveston and have three grown children and five grandchildren.

Alison O'Brien, PhD received her B.A. in Biology and Bacteriology from The University of California at Davis in 1969. She graduated Phi Beta Kappa. She then trained as a medical technologist for one year and worked for two years in bacteriology, chemistry, and hematology sections of diagnostic laboratories. She received her Ph.D. in Pathogenic Bacteriology from the Department of Medical Microbiology at The Ohio State University in 1976. She was awarded graduate student research awards from the College of Letters and Science in 1975 and 1976. Her graduate research project focused on the role of the *Staphylococcus aureus* delta toxin in the pathogenesis of staphylococcal enterocolitis. In 1976, Dr. O'Brien was awarded a National Research Council postdoctoral fellowship to study a newly described toxin of *Shigella*. Her project was conducted under the sponsorship of Dr. Samuel Formal at the Walter Reed Army Institute, Washington, D.C. In 1978, Dr. O'Brien became an Assistant Professor of Microbiology at Uniformed Services University of the Health Sciences (USUHS). She was promoted to an Associate Professor in 1981, a Professor in 1985, and Chair of Microbiology and Immunology in 1996. Dr. O'Brien's research areas include: the pathogenic mechanisms of Shiga toxin-producing *E. coli*, the contributions of Cytotoxic Necrotizing Factor and Hemolysins to infections caused by Uropathogenic *E. coli*, and development of therapeutics against *Bacillus anthracis* and *B. cereus*. Her research has been funded by the National Institutes of Health (NIH), the United States Department of Agriculture, and the Agency for International Development. She also serves as the Editor in Chief of one of the major journals in pathogenesis, *Infection and Immunity*, and as a member of the U.S. Department of Agriculture's National Advisory Committee on Microbiological Criteria for Foods. She was a member of the NIH Bacteriology and Mycology Study Section 1 and the Chair of the Food and Drug Administration (FDA) Advisory Panel on Vaccines and Related Projects. She previously served as President of the American Society for Microbiology.

Jean Patterson, PhD is currently Chairman of the Department of Virology and Immunology at the Southwest Foundation for Biomedical Research (SFBR). Her major research interests are the molecular biology of viruses infecting protozoan parasites, transcription of bunyaviruses, mechanisms of action of antiviral agents, and therapeutics and vaccine development for biodefense agents. She is the author or coauthor of more than 75 peer-reviewed publications. Dr. Patterson holds the E.M. Stevens Chair for

Biomedical Research and is an Adjunct Professor in the Department of Microbiology at the University of Texas Health Science Center at San Antonio (UTHSCSA). Before joining the Foundation, she was an Associate Professor in the Department of Microbiology and Molecular Genetics, Harvard Medical School, Boston, Massachusetts. Other prior positions include Scientific Associate, Department of Medicine (Infectious Diseases), Children's Hospital, Boston, Massachusetts; Assistant Professor of Microbiology and Molecular Genetics, Harvard Medical School, Boston, Massachusetts; and Instructor, Department of Microbiology and Molecular Genetics, Harvard Medical School. Dr. Patterson is a reviewer for the *Journal of Virology*; *Virology*; *Journal of General Virology*; *Molecular and Biochemical Parasitology*; *Experimental Parasitology*; *Antiviral Research*; and the American Institute for Biological Sciences. In addition, she is a member of the Study Group on Protozoal Viruses of the International Committee on Taxonomy of Viruses and numerous National Biodefense Analysis and Countermeasures Center panels. Dr. Patterson has more than 20 years of teaching experience, primarily at the University of Notre Dame and Harvard Medical School, and most recently at the UTHSCSA. She is a member of the design team that completed the construction of a 36,000 square-foot laboratory building that holds 12 Biosafety Level 2, three Biosafety Level 3, and one Biosafety Level 4 laboratories at SFBR. She also serves as a consultant for the development of the Montana BSL4 laboratory facility.

C. J. Peters, MD received his B.A. degree (summa cum laude) in chemistry at Rice University, Houston, TX in 1962 and his M.D. degree from Johns Hopkins, Baltimore, M.D. (alpha omega alpha) in 1966. After being on the Parkland Hospital, Dallas, TX internal medicine house staff for two years he became a NIAID Research Associate at the Middle America Research Unit in the Canal Zone. He extended past his two year obligation for a total of 5 years and acquired an interest in tropical diseases, chronic virus infections, arenaviruses, and ecological determinants of disease transmission. He then went to the University of California in San Diego to finish his internal medicine training and become board certified. Subsequently he spent 3 years as an immunology fellow at the Scripps Clinic and Research Foundation.

\

From 1977-1991 Dr. Peters was at the U.S.Army Medical Research Institute for Infectious Diseases where he began working as a research scientist and later became Division Director and Deputy Commander. While there he worked with biothreats, biodefense, and emerging diseases, particularly hemorrhagic fevers. In 1992 he moved to the Centers for Disease Control and Prevention where he was head of Special Pathogens Branch in the National Center of Infectious Diseases and was involved in

1 epidemiological investigations of hemorrhagic fevers and other emerging infections. He moved to the
2 University of Texas Medical Branch in 2001, where he is professor of Pathology and of Microbiology and
3 Immunology as well as being Director for Biodefense of the Center for Biodefense and Emerging
4 Infectious Diseases.

5
6 Some of the emerging infectious diseases he has been closely involved with are Rift Valley fever virus,
7 arenavirus hemorrhagic fevers, Ebola virus, Nipah virus, and hantavirus pulmonary syndrome. Because
8 of the aerosol infectiousness of many of these agents they are commonly implicated as causing
9 laboratory infections and suspected as potential agents of bioterrorism or large scale biological warfare.
10 He has published more than 300 scientific articles, reviews, and chapters. He has served on numerous
11 committees, including NAS committees on emerging microbial threats and misuse of biotechnology.

12
13 His current research interests are Rift Valley fever biology and vaccines, Phlebovirus pathogenesis, SARS
14 coronavirus, and monoclonal antibodies for therapy. Peters is deeply involved in qualifying a live-
15 attenuated vaccine for human licensure and a related vaccine for domestic animal use.

16
17 **Wayne Thomann, PhD** is Director of Occupational and Environmental Safety at Duke University Medical
18 Center. He is also Assistant Clinical Professor in the Division of Occupational and Environmental
19 Medicine, Department of Community and Family Medicine, and Assistant Professor in the Nicholas
20 School of the Environment and Earth Sciences. Dr. Thomann received B.S. and M.S. degrees in
21 microbiology from Florida Atlantic University in Boca Raton, Florida. He received his doctor of public
22 health degree from the School of Public Health at the University of North Carolina at Chapel Hill. He has
23 been researching the identification and control of bioaerosols for more than 20 years and is a member
24 of ASHRAE Standard 62.1 Committee on Ventilation for Indoor Air Quality. He teaches graduate courses
25 in occupational health and safety at the Duke University Nicholas School of the Environment and Earth
26 Sciences and lectures extensively about indoor air quality.

Expert Panel on H1N1

Teleconference

April 8, 2010

10:00 – 10:30 AM

Phone Number: 1-888-552-2815 Passcode: 149213

AGENDA

10:00 AM Welcome and Roundtable Introductions

Sam Bozzette, M.D., Ph.D., Consultant to NIH, Professor of Medicine,

University of California at San Diego, Senior Natural Scientist,

The RAND Corporation

Adi Gundlapalli, M.D., Ph.D., M.S., Assistant Professor, Departments of Internal

Medicine, Pathology and Biomedical Informatics, University of Utah

School of Medicine

10:10 AM Development of the Supplementary Risk Assessment of the National Emerging
Infectious Diseases Laboratories at Boston University Medical Center

10:15 AM Goals for Expert Consultation

10:20 AM Review of the Delphi Process

10:25 AM Questions and Discussion

10:30 AM Adjourn

Expert Consultation for the Risk Assessment of the National Emerging Infectious Diseases Laboratory at Boston University

Orientation Call

8 April 2010

NEIDL RA Expert Consultation

1

1

Background: Lab Capacity

- 2002: BSL-4/3 laboratory space deemed insufficient for biodefense
- 2003: Funding awarded for 2 national labs
 - Galveston National Laboratory
 - BSL-3 operational now
 - BSL-4 operational soon
 - National Emerging Infectious Diseases Laboratories at Boston University (NEIDL)
 - construction started in 2006
 - 98+% complete but not operational

8 April 2010

NEIDL RA Expert Consultation

2

2

Background: NEIDL

- Difficulties with Environmental Impact Statements
 - Found inadequate in state and federal courts
- Supplemental Risk Assessment performed
 - Unfavorably reviewed by a National Research Council committee
- New risk assessment being performed
 - Contractor is TetraTech
 - Guidance from a NIH Blue Ribbon Panel
- RA divided into 3 elements
 - Threat assessment
 - Risk and amount of exposure
 - Initial and secondary infections

8 April 2010

NEIDL RA Expert Consultation

3

1

Goals for Consultation

- Modeling exposure requires estimates of atmospheric decay
 - Half-life under specified conditions
- Estimating infections requires estimates of dose-response and transmissibility
 - Dose-response: amount needed to infect specific proportions of specific populations (ID10, ID50, ID90)
 - Transmissibility: average number of infections transmitted by an infected person in a susceptible population (R_o)

8 April 2010

NEIDL RA Expert Consultation

4

2

Modified Delphi Method

- Efficiently gains consensus
- Gives all a voice
- Our implementation:
 - Review of provided information
 - Voting
 - Feedback:
 - aggregated group results
 - your own individual responses
 - Discussion at single meeting
 - voting
 - Feedback and re-voting

8 April 2010

NEIDL RA Expert Consultation

5

Example of Questionnaire: Dose-Response for Infection

		Number	x	Power (of 10)
1. <i>B. anthracis</i>	ID50	5,000	x	
	ID10	1	x	2
	ID90	5	X	4
2. <i>F. tularensis</i>	ID50		x	
	ID10		x	
	ID90		x	
3. <i>Y. pestis</i>	ID50		x	
	ID10		x	
	ID90		x	
4. SARS virus	ID50		x	
	ID10		x	
	ID90		x	
5. 1918 Influenza virus	ID50		x	
	ID10		x	
	ID90		x	

8 April 2010

NEIDL RA Expert Consultation

6

2

Example of Questionnaire: Vulnerability

1. How much more vulnerable to infection do you judge a child younger than 5 to be?
Please enter a percentage Percent more vulnerable
2. How much more vulnerable to infection do you judge a person older than 65 to be?
Please enter a percentage Percent more vulnerable
3. How much more vulnerable to infection do you judge a person with diabetes to be?
Please enter a percentage Percent more vulnerable
4. How much more vulnerable to infection do you judge a person with HIV/AIDS to be?
Please enter a percentage Percent more vulnerable

8 April 2010

NEIDL RA Expert Consultation

7

Example of Questionnaire: Transmissibility

	Estimated Range for Ro	Do you concur with this estimate? (enter Y or N)
1. <i>Y. pestis</i>	1 – 2.5	<input type="text" value="Y"/>
2. SARS virus	<input type="text"/>	<input type="text"/>
3. 1918 Influenza virus	<input type="text"/>	<input type="text"/>
4. Rift Valley Fever virus	<input type="text"/>	<input type="text"/>
5. Ebola virus	<input type="text"/>	<input type="text"/>

H.3 QUESTIONNAIRE

Paper Version of Questionnaire

1

Infectivity and Decay Expert Consultation

Round 1 Voting

Please enter last name:

Thank you for agreeing to participate in this exercise. In formulating your answers to the questions below, you should draw on the material provided, other relevant information known to you, discussions with other panel members and colleagues, and (especially) your own judgment. Note that there are 2 sections and 5 pages to this questionnaire.

Section 1: Infectivity

The purpose of this section is to estimate the dose-response curve for infection with agents being evaluated as part of the NEIDL Risk Assessment. It is necessary for you to fill all of the fields in this section, even if you are extremely uncertain about a particular response.

Part A: For each organism, we are asking you to make three dose estimates: the minimum number of organisms necessary to infect 50% of susceptible individuals, or the ID50; the minimum number of organisms necessary to infect 10% of susceptible individuals, or the ID10; and the minimum number or organisms necessary to infect 90% of susceptible individuals, or the ID90.

For this set of questions, you may enter a single digit in the "Number" field and a power of 10 in the "Power" field. For example, 10,000 would be entered as '1' in the Number field and '4' in the Power field, 500,000 would be '5' in the Number field and '5' in the Power field, and 20 would be '2' in the Number field and '1' in the Power field. Alternatively, you may enter your entire estimate in only the "Number" field, leaving the "Power" field blank.

		Number	x	Power (of 10)
1. <i>B. anthracis</i>	ID50	<input type="text"/>	x	<input type="text"/>
	ID10	<input type="text"/>	x	<input type="text"/>
	ID90	<input type="text"/>	x	<input type="text"/>

Number	x	Power (of 10)
--------	---	---------------

2. <i>F. tularensis</i>	ID50	<input type="text"/>	x	<input type="text"/>
	ID10	<input type="text"/>	x	<input type="text"/>
	ID90	<input type="text"/>	x	<input type="text"/>

		Number	x	Power (of 10)
3. <i>Y. pestis</i>	ID50	<input type="text"/>	x	<input type="text"/>
	ID10	<input type="text"/>	x	<input type="text"/>
	ID90	<input type="text"/>	x	<input type="text"/>

		Number	x	Power (of 10)
4. Andes hantavirus	ID50	<input type="text"/>	x	<input type="text"/>
	ID10	<input type="text"/>	x	<input type="text"/>
	ID90	<input type="text"/>	x	<input type="text"/>

		Number	x	Power (of 10)
5. Ebola virus	ID50	<input type="text"/>	x	<input type="text"/>
	ID10	<input type="text"/>	x	<input type="text"/>
	ID90	<input type="text"/>	x	<input type="text"/>

		Number	x	Power (of 10)
6. Marburg virus	ID50	<input type="text"/>	x	<input type="text"/>
	ID10	<input type="text"/>	x	<input type="text"/>
	ID90	<input type="text"/>	x	<input type="text"/>

		Number	x	Power (of 10)
7. Junin virus	ID50	<input type="text"/>	x	<input type="text"/>
	ID10	<input type="text"/>	x	<input type="text"/>
	ID90	<input type="text"/>	x	<input type="text"/>

		Number	x	Power (of 10)
8. Lassa fever virus	ID50	<input type="text"/>	x	<input type="text"/>

	ID10		x	
	ID90		x	

		Number	x	Power (of 10)
9. Nipah virus	ID50		x	
	ID10		x	
	ID90		x	

		Number	x	Power (of 10)
10. Rift Valley fever virus	ID50		x	
	ID10		x	
	ID90		x	

		Number	x	Power (of 10)
11. Russian spring-summer encephalitis virus	ID50		x	
	ID10		x	
	ID90		x	

		Number	x	Power (of 10)
12. SARS virus	ID50		x	
	ID10		x	
	ID90		x	

		Number	x	Power (of 10)
13. 1918 influenza virus	ID50		x	
	ID10		x	
	ID90		x	

Part B. In this part, we are asking for your concurrence with estimates of infectivity that we have derived from the literature. The measure of infectivity that we are using is R_0 , or the average number of infections that would arise from each infected person in a susceptible population.

	Estimated Base Value for Ro	Do you concur with this estimate? (enter Y or N)
1. <i>Y. pestis</i>	1.3	<input type="text"/>
2. Ebola virus	1.5	<input type="text"/>
3. Rift Valley fever virus	1.2	<input type="text"/>
4. SARS virus	3.0	<input type="text"/>
5. 1918 influenza virus	3.0 (1.5-4)	<input type="text"/>

Part C. In this part, we are asking you to estimate how much *more* vulnerable to disease and death that certain compromised subgroups are likely to be. The groups are the very young, the very old, those with diabetes, those with HIV infection, and women who are pregnant.

We will not be asking for separate values for each organism, but for a factor to apply to all. Specifically, we are asking you to make 4 judgments for each group: vulnerability to bacterial disease, vulnerability to viral disease, mortality from bacterial disease, and mortality from viral disease.

For these question, please enter a number corresponding to the percentage increase in vulnerability. For example, if your judgment is 10% more vulnerable, enter "10."

How much more vulnerable do you judge the following to be?

To disease	To mortality
---------------	-----------------

1. A child younger than 5?	(Please enter a percentage)	Bacteria		
		Viruses		

2. An adult older than 65?	(Please enter a percentage)		To disease	To mortality
		Bacteria		
		Viruses		

3. A person with diabetes?	(Please enter a percentage)		To disease	To mortality
		Bacteria		
		Viruses		

4. A person with HIV infection?	(Please enter a percentage)		To disease	To mortality
		Bacteria		
		Viruses		

5. A pregnant woman?	(Please enter a percentage)		To disease	To mortality
		Bacteria		
		Viruses		

Section 2: Atmospheric Decay

The purpose of this section is to develop estimates of the stability in the atmosphere of the 13 agents being evaluated as part of the as part of the NEIDL Risk Assessment. As above, it is necessary for you to fill all of the fields in this section, even if you are extremely uncertain about a particular response.

For each organism, we are asking you to make two estimates: one for the half-life in a cold humid night and another for a hot sunny dry day.

For this set of questions, please enter your estimate, in minutes, of the nighttime and daytime half-life of viable organisms in the fields below. For example, if you estimate that the number of virulent organisms would be halved every quarter hour, you would enter "15" minutes. Note that we are not asking you to estimate the viability of *B. anthracis* spores.

	Cold humid night	Hot dry sunny day
1. <i>B. anthracis</i>	Indefinite	Indefinite

	Cold humid night (minutes)	Hot dry sunny day (minutes)
2. <i>F. tularensis</i>	<input type="text"/>	<input type="text"/>

	Cold humid night (minutes)	Hot dry sunny day (minutes)
3. <i>Y. pestis</i>	<input type="text"/>	<input type="text"/>

	Cold humid night (minutes)	Hot dry sunny day (minutes)
4. Andes hantavirus	<input type="text"/>	<input type="text"/>

	Cold humid night (minutes)	Hot dry sunny day (minutes)
5. Ebola virus	<input type="text"/>	<input type="text"/>

	Cold humid night (minutes)	Hot dry sunny day (minutes)
6. Marburg virus	<input type="text"/>	<input type="text"/>

	Cold humid night (minutes)	Hot dry sunny day (minutes)
7. Junin virus	<input type="text"/>	<input type="text"/>

	Cold humid night (minutes)	Hot dry sunny day (minutes)
8. Lassa fever virus	<input type="text"/>	<input type="text"/>

	Cold humid night (minutes)	Hot dry sunny day (minutes)
9. Nipah virus	<input type="text"/>	<input type="text"/>

	Cold humid night (minutes)	Hot dry sunny day (minutes)
10. Rift Valley fever virus	<input type="text"/>	<input type="text"/>

	Cold humid night (minutes)	Hot dry sunny day (minutes)
11. Russian spring-summer encephalitis virus	<input type="text"/>	<input type="text"/>

	Cold humid night (minutes)	Hot dry sunny day (minutes)
12. SARS virus	<input type="text"/>	<input type="text"/>

	Cold humid night (minutes)	Hot dry sunny day (minutes)
13. 1918 influenza virus	<input type="text"/>	<input type="text"/>

H.5 ROUND 2 MEETING AGENDA AND RESULTS

Face-to-Face Meeting Agenda and Results of Round 2

Expert Consultation on Infectiousness of Organisms
Studied in the NEIDL Risk Assessment

May 18, 2010

Doubletree Hotel and Executive Meeting Center
Ballroom – Section B

Teleconference Number 1-866-647-1048 Passcode 6488095

Draft Agenda

10:00 AM Welcome and Roundtable Introductions

*Sam Bozzette, M.D., Ph.D., Consultant to NIH, Professor of Medicine and of
International Relations, University of California San Diego*

10:15 AM Discussion on Dose Response

*Sam Bozzette, M.D., Ph.D.,
Wiley A. Schell, Associate Professor in Medicine, Duke University Medical Center*

11:30 AM Vote

12:00 PM Discussion on Transmissibility (Ro)

*Adi Gundlapalli, M.D., Ph.D., M.S., Assistant Professor, Departments of Internal
Medicine, Pathology and Biomedical Informatics, University of Utah
School of Medicine*

I. Medically Vulnerable Subpopulations

I.1 Introduction

The public and State and Federal Courts have expressed an interest in the demographic and health information regarding the community surrounding the NEIDL (Mahmoud 2008). To augment the environmental justice analysis presented in Chapter 10, this RA takes into account Medically Vulnerable Subpopulations (MVSP) in the communities surrounding the urban, suburban, and rural sites.

Vulnerability is a key concept in environmental justice (National Environmental Justice Advisory Council (U.S.) 2004). Vulnerability and susceptibility are often used interchangeably in the lay literature (US Environmental Protection Agency 2009). In reviewing the definitions for these terms, a suitable definition of the term *vulnerability* for this RA is provided by the NEJAC (National Environmental Justice Advisory Council (U.S.) 2004). In a report on the proposed framework for environmental justice and cumulative risk assessment, the Council addresses the concept of vulnerability: “A subpopulation is vulnerable if it is more likely to be adversely affected by a stressor than the general population.” Vulnerability, in general, results from susceptibility/sensitivity, differential exposure, differential preparedness, or differential ability to recover.

The EPA, in their framework for a cumulative risk assessment, defines those that are *susceptible* as those who exhibit “greater or lesser biological response to exposure” (US Environmental Protection Agency 2003). Further, the susceptible are “those who are significantly more liable than the general population to be affected by a stressor due to life stage (e.g., children, the elderly, or pregnant women), genetic polymorphisms (e.g., the small but significant percentage of the population who have genetic susceptibilities), prior immune reactions (e.g., individuals who have been “sensitized” to a particular chemical), disease state (e.g., asthmatics), or prior damage to cells or systems (e.g., individuals with damaged ear structures due to prior exposure to toluene, making them more sensitive to damage by high noise levels).”

Extending the NEJAC and EPA framework for the purposes of this RA, the “stressors” under study are the pathogens. In general, when a pathogen comes into contact with a human (host), the outcome of that host-pathogen interaction is determined by characteristics of the pathogen and of the host (Osterholm et al. 2010). Key characteristics of the pathogen in this interaction include infectivity, pathogenicity, and virulence. Key host factors are those that influence the likelihood of infection and the occurrence and severity of disease, such as age at the time of exposure to the pathogen; co-existing chronic non-infectious

diseases; immune status at the time of infection, such as immunization status; immune deficiency, such as that due to chronic diseases, drugs, or other pathogens (e.g., HIV); gender; and genetic make-up. Important issues in the host-pathogen interaction are the route of transmission of the pathogen and the amount of pathogen to which the host is exposed.

Combining the NEJAC framework of vulnerability and the EPA definition of “susceptible” with these principles of host-pathogen interactions, this RA defines an MVSP as a group of individuals with a particular characteristic that have, in the event of exposure to a pathogen, an increased likelihood of disease from the pathogen and/or increased likelihood of death attributable to the disease.

An important point to note is that of the 13 pathogens, the entire population (general and MVSP) of the three sites could be considered susceptible to 12 of the pathogens (excluding 1918 H1N1 influenza virus). This assumption is based on the fact that none of these 12 pathogens are endemic to the area and, as such, the population would not have had an opportunity for exposure and development of immunity to those pathogens. Furthermore, even if relevant vaccines for these pathogens were available for the public, no one is likely to have been vaccinated. In the case of 1918 H1N1 influenza virus, it is likely that, apart from the children, others, especially those who have received the annual influenza vaccine or the 2009 pandemic vaccine, would have a measure of pre-existing immunity to influenza viruses. Based on the recent experience with 2009 H1N1 pandemic, this may reduce their susceptibility to the 1918 H1N1 influenza virus (Johns et al. 2010; Manicassamy et al. 2010; Medina et al. 2010). The exception is for pregnant women, who, based on observational data, appear to be more susceptible to and experience worse outcomes from pandemic influenza (Mosby et al. 2011; Rasmussen et al. 2011). So, in summary, for 12 of the pathogens, the entire population is considered susceptible. Among MVSPs, though there are no controlled studies, it is conservatively assumed that this susceptibility is further increased.

This appendix reviews the choice of specific medically vulnerable subpopulations for this RA, the methods and data sources used to derive estimates of those populations, the derivation of estimates of differential susceptibility to pathogens under study for the subpopulations, a general description of the effect of the pathogen/disease on underlying medical vulnerabilities, and the use of subpopulation data in the estimates of initial infection and secondary transmission modeling.

I.2 Choice of Medically Vulnerable Subpopulations for Risk Analysis

As noted in the definition of “susceptible” above, MVSPs are a diverse group of individuals in the community. In general, these are the very young, the very old, and those with chronic conditions such as diabetes, heart disease, respiratory conditions (e.g., asthma), and those with genetic polymorphisms/immuno-compromised states (e.g., solid-organ and bone-marrow transplants), those undergoing chemotherapy for cancer, and pregnant women. Further, the EPA considers those who are sensitized by a reaction to a chemical or stressor to be vulnerable to another stressor.

The criteria for considering a specific MVSP for this RA are: (1) the condition should be relevant in a bio-medical sense and confer increased susceptibility to a pathogen, such as those under study for this RA (bacteria and viruses); and (2) reliable estimates of the subpopulation should be available from federal, state, and local government sources that could be cited. Using these criteria, the following groups were considered:

1. Children younger than 5 years
2. Adults older than 65 years
3. Those with diabetes
4. Those with HIV/AIDS
5. Pregnant women.

Those excluded from this RA, as there are no data linking medical vulnerability in these subpopulations to a direct increase in susceptibility to pathogens (from the examples from EPA given above), are those with prior immune reactions and those with prior damage to cells or systems. Those with asthma were also excluded as there is no known direct association of asthma with increased susceptibility to infections from the pathogens considered in this RA. On the other hand, the diseases caused by the pathogens, especially those associated with respiratory disease such as influenza, may exacerbate asthma. This has been shown in children during the recent 2009 H1N1 influenza pandemic, where even secondary pneumonia has been noted (Dawood et al. 2010; Dawood et al. 2010; Dawood et al. 2011).

A further subset was excluded as there are no area-wide estimates available for these subpopulations from the urban, suburban, and rural sites: those with genetic predisposition (genetic polymorphisms) to infections; those with other immune-compromised states, such as those with solid-organ and bone-marrow transplants; and those undergoing chemotherapy for cancer. This exclusion may result in an

underestimation of the proportion of MVSPs in the populations at the three sites. However, this underestimation is considered not significant based on the small numbers of these subpopulations. For example, according to the Organ Procurement and Transplantation Network website (Health Resources and Services Administration 2011), the number of solid-organ transplants in the Commonwealth of Massachusetts averaged 761 for the years 2008-2010; for the corresponding period in the State of New Hampshire, there were an average of 55 such transplants.

I.3 Methods and Data Sources for Derivation of Estimates of MVSP

Internet searches were performed in September 2010 (and updated for census data in August 2011) on federal, state, and local government websites for reliable and reproducible estimates of MVSP in the three alternative sites considered in this RA. The three sites are: (1) Urban – BUMC BioSquare Research Park in Boston, Suffolk County, Massachusetts; (2) Suburban – Tyngsborough, Middlesex County, Massachusetts; and (3) Rural – Sargent Center in Peterborough and Hancock, Hillsborough County, New Hampshire (Table 1).

General estimates of census data were obtained from the U.S. Census with the latest estimates for towns available as 2005-2009 American Community Survey 5-Year Estimates (US Census Bureau 2010). Population estimates for the U.S., the States of Massachusetts and New Hampshire, and the City of Boston were available for 2008 from the U.S. Census Bureau. Census data for Tyngsborough Township in Middlesex County, Massachusetts, and the Townships of Peterborough and Hancock in Hillsborough County, New Hampshire, were available as estimates for the years 2005-2009. Population data for the zip code 02118 (Boston) were available only for the year 2000 from the U.S. Census Bureau.

Data on prevalence of diabetes were obtained from the CDC for national and race-based data (Centers for Disease Control 2010) and county-level data (Centers for Disease Control 2010). State-level data were obtained from the Department of Health of the Commonwealth of Massachusetts (Commonwealth of Massachusetts 2010); prevalence data of HIV/AIDS were obtained from the Department of Health of the Commonwealth of Massachusetts (Commonwealth of Massachusetts 2010; Commonwealth of Massachusetts 2010) and the State of New Hampshire (New Hampshire Department of Health and Human Services 2010).

The estimate of 1% for the subpopulation of pregnant women in any area was derived in the calculations of influenza morbidity and mortality among pregnant women by CDC authors (Jamieson et al. 2009;

- 1 Siston et al. 2010). The 1% estimates are a reasonable match with the “resident births” recorded in the
- 2 areas under study for the years listed as reported by the Commonwealth of Massachusetts
- 3 (Commonwealth of Massachusetts 2010) and the State of New Hampshire (New Hampshire Department
- 4 of Health and Human Services 2010).

I.3.1 Differential Susceptibility to Infection among MVSP

Members of the MVSPs studied in this RA are considered to be at increased risk of some infectious diseases and also of death due to some infectious diseases. For example, children are at increased risk of respiratory infections, particularly respiratory syncytial virus and influenza (Munoz 2002); the elderly are at increased risk of some infections (Crossley et al. 1996; Liang et al. 2007); diabetics are at increased risk of some infections in general due to disturbances in several compartments of the immune system (Calvet et al. 2001; Rajagopalan 2005; Gupta et al. 2007); and those with HIV, especially advanced AIDS are at risk of many common infections due to a profound immune deficiency (Duse 1999; Gordon 2004; Corti et al. 2009).

Pregnant women are considered to be immune-suppressed and are at high risk of adverse events from seasonal and pandemic influenza (Jamieson, Honein et al. 2009; Siston, Rasmussen et al. 2010; Mosby et al. 2011; Rasmussen, Kissin et al. 2011). Seasonal-influenza related hospitalization rates from selected acute cardiopulmonary conditions were found to be nearly five-fold higher in pregnant women in the third trimester (Neuzil et al. 1998). With respect to pandemic influenza, the historical mortality rates of pregnant women have been noted to be in the range of 20–51% for the 1918 and 1957 influenza pandemics (Callaghan et al. 2010). In reviewing observations from the 2009 H1N1 influenza pandemic, pregnancy was associated with an increased risk of hospitalization, intensive care unit admission, and death (Mosby, Rasmussen et al. 2011). Pregnant women were disproportionately represented in hospitalizations and deaths; pregnancy-specific mortality rates were not provided.

The published literature often qualitatively refers to these observations and provides quantitative estimates of increase in susceptibility for small cohorts of patients; these estimates may not be generalizable to the entire population. The observation remains that members of the MVSP are at increased risk, and quantitative estimates of those increases are not generally available for infectious diseases. It should be noted that much less observational data are available for the pathogens under study in this RA. A review of the pathogens is provided in Chapter 3, and the limited references to increased susceptibility (and a few for decreased susceptibility) ascribed to these pathogens to specific MVSPs (if available) are presented in Table 2.

In the absence of quantitative estimates, the differential susceptibility of the MVSPs to infectious diseases caused by the 13 pathogens was (1) qualitatively described from a representative review of the published literature and (2) estimated from elicitation from an expert panel (Expert Elicitation on Organisms Studied in the NEIDL Risk Assessment, Appendix H).

Qualitative Description of Differential Susceptibility among MVSPs

The evidence for differential susceptibility among MVSPs to the 13 pathogens is limited in the literature for a majority of the pathogens. The published references to increased susceptibility (and in rare cases, decreased susceptibility) are provided in Chapter 3 with the description of the pathogens. These are summarized in Table 2.

Table 2: Differential Susceptibility as Noted in the Published Literature among Members of Medically Vulnerable Subpopulations to the 13 Pathogens under Study in the RA (for details see Chapter 4). The ▲ mark indicates a report of increased susceptibility to the pathogen in terms of disease and/or death; conversely, the ▼ mark indicates decreased susceptibility to the pathogen. Shaded cells indicate that there are no pertinent data available to support differential susceptibility.

I.3.2 Estimates of Differential Susceptibility among MVSP to Pathogens

In the absence of quantitative data of the differential susceptibility of MVSPs to infectious diseases caused by the 13 pathogens from the published literature, estimates were generated from the expert panel elicitation conducted by the NIH.

As noted in the Final Delphi Report (Appendix H), the goal of the expert panel elicitation was to obtain estimates of the degree of increased vulnerability to infection and to severe disease that could be used as a starting point for analyses of differential health effects. The experts were instructed to provide general estimates of increased vulnerability to infections by either pathogenic bacteria or viruses (Tables 3a-b).

Table 3a: Estimates of Increased Vulnerability to Disease for MVSPs studied in this RA (Source: Expert Elicitation on Organisms Studied in the NEIDL Risk Assessment, Appendix H)

Disease (% increase in vulnerability)		Median	Low	High	Geometric Mean

	Viruses	15%	5%	25%	13%
HIV	Bacteria	30%	10%	40%	26%
	Viruses	30%	10%	40%	28%
Pregnancy	Bacteria	5%	0%	30%	3%
	Viruses	5%	2%	50%	8%

Table 3b: Estimates of Increased Vulnerability to Death for MVSPs studied in this RA (Source: Expert Elicitation on Organisms Studied in the NEIDL Risk Assessment, Appendix H)

Death (% increase in vulnerability)		Median	Low	High	Geometric Mean
Young	Bacteria	10%	5%	20%	11%
	Viruses	10%	5%	20%	12%
Older	Bacteria	10%	5%	50%	14%
	Viruses	15%	5%	50%	16%
Diabetes	Bacteria	10%	5%	25%	10%
	Viruses	10%	5%	25%	10%
HIV	Bacteria	25%	10%	30%	22%
	Viruses	25%	10%	30%	22%
Pregnancy	Bacteria	5%	1%	20%	5%
	Viruses	4%	1%	20%	5%

I.3.3 Impact of Pathogen on Underlying Medical Vulnerabilities

In general, any disease condition has an effect on the human host. In the case of the 13 pathogens, the diseases caused are often aggressive and are generally expected to result in high morbidity and mortality in all populations.

Infectious diseases in general are considered to have an adverse impact on the health of the young and the elderly, thus contributing to increased morbidity and mortality. Blood sugar control in diabetic patients is disrupted in those who are experiencing active infections; thus diabetes is adversely impacted by the disease. HIV/AIDS may also be adversely impacted by another infectious disease. Pregnant women often experience pre-term birth or loss of the pregnancy when they experience a serious insult such as an infectious disease caused by a pathogen under this study. Asthma is often triggered by respiratory infections; it is plausible that a person who has been infected by one of the respiratory pathogens would have an asthma attack as a result of the infection. A recent report on the association of seasonal and pandemic influenza on children with asthma in the U.S. concludes that children with asthma experience pneumonia more frequently and are admitted to the intensive care unit more often as compared to children without asthma (Dawood, Kamimoto et al. 2011). The risk of respiratory failure and death was not increased. Children experienced exacerbations of asthma due to influenza. For all these adverse impacts on the underlying medical vulnerability, there are no specific data or methods to allow for quantifying the adverse impact.

I.3.4 Use of MVSP Data

The estimates of the MVSP among the populations at the three NEIDL sites and the estimates of increased susceptibility to disease and death caused by the pathogens are used in generating (1) estimates of initial infection after exposure to a pathogen, and (2) secondary transmission modeling of spread of disease in the community, as described below.

I.3.5 Estimates of Initial Infection

There are two categories of individuals who are affected in the scenarios of loss of biocontainment and exposure to a pathogen, namely the laboratory worker and members of the public.

I.3.6 Laboratory Worker

In general, for the loss of biocontainment scenarios analyzed for this RA, the number of laboratory workers exposed to the pathogen as a result of the release is 1 -4 workers. The laboratory workers will not

be younger than 5 years of age and are unlikely to be older than 65 years. It is likely that pregnant laboratory workers would be assigned duties other than working with BSL-3 and BSL-4 pathogens. The possibility remains that the laboratory worker could be a member of the diabetic or HIV/AIDS subpopulations. The estimates of initial infection could be adjusted based on the possibility of the laboratory worker being a member of one of the MVSPs. The challenge lies in making an assumption regarding the health status of the laboratory worker in order to estimate the probability that he/she has diabetes or HIV/AIDS. In this setting, this RA assumes that the laboratory worker is a healthy adult.

I.3.7 Members of the Public

Under release scenarios in which members of the public are directly exposed to a pathogen from a release event, it is possible that the average susceptibility profile of the local population at the three sites could result in site differences in the average probability of initial infection per person at the same level of exposure. To quantify this potential difference, populations of the five MVSPs described above are examined in this RA.

The baseline dose-response curves, derived in the dose-response appendix (Appendix J), are assumed to reflect characteristics of a heterogeneous population containing members of the five groups to some extent. The question of interest is whether the relative difference in the population profiles near the three sites has an effect on the comparative risk of initial infections occurring from scenarios in which members of the public are exposed. The following assumptions are made in order to investigate quantitatively this possibility: (1) a given dose response curve being assumed for a particular pathogen is relevant for an average U.S. population; (2) the probability that a given exposed individual is a member of an MVSP is equal to the portion of the local population that is a member of that MVSP; and (3) the average probability of infection when an individual from one of the MVSPs inhales a given number of organisms is higher than the probability for an individual who is not a member of any of the MVSPs. The increase in this probability is calculated as follows: if person A is more susceptible to infection than person B by X% (e.g., 20%), it is assumed that the probability of person A being infected at a particular dose is the same as the probability of person B being infected at a dose that is X% higher (e.g., 20% higher; for more details, see Appendices J and K).

The potential implications of these assumptions on rates of initial infections among MVSPs at the three sites are assessed in the initial infections appendix.

I.4 Secondary Transmission Modeling

Differential susceptibility also has potential implications for affecting the average number of transmissions from an infected individual interacting with a susceptible population that includes members of MVSPs. As defined in the secondary transmission chapters and appendices, the population-wide reproductive number is the average number of transmissions per infected individual. In the context of considering the effect of vulnerable portions of the susceptible sub-population, the reproductive number is considered a product of two components: (1) the average number of contacts per infected individual, and (2) the average probability of transmission per contact .

Under this framework, one can consider the portion of the average number of contacts that is likely to represent contacts with individuals in each subpopulation (based on the portion of the available contacts that are members of the subpopulation) and then how the probability of transmission per contact would change based on the differential susceptibility of that subpopulation.

The general estimates of the reproductive number that are used for this RA were based on transmission data from real outbreaks among populations that contained some portion of individuals with increased susceptibility. In this sense, the effect of differential susceptibility is already incorporated into the reproductive values being used. However, as this RA is concerned with specific populations for which data on subpopulations are available, it was determined to be appropriate to include a framework for adjusting values of the reproductive number based on how the local population characteristics may differ from a typical population.

The following assumptions are made: (1) for a given scenario, the base case value for the reproductive number is relevant for a population containing portions of each subpopulation that are in line with their overall frequency in the total U.S. population; (2) the probability that any given contact of an infectious individual is a member of a given MSVP is equal to the portion of the local population that is a member of that MVSP; (3) the average probability of transmission when an infectious individual contacts a member of an MVSP is higher than the probability resulting from contact with an individual who is not a member of the MVSPs (the percentage increase in this probability is assumed to be equal to the percentage increase of susceptibility relevant for the particular pathogen and subpopulation); (4) the MVSP identity of each simulated individual is not tracked in the secondary transmission modeling; and (5) potential differences in transmission *from* infected individuals belonging to different MVSPs are not considered.

The implications of these assumptions on quantitative estimates of site differences in transmission are assessed in the secondary transmission appendix (Appendix L).

J. Dose-Response Relationships

J.1 Introduction

Dose-response assessment is used to estimate the relationship between a dose, or amount of pathogen to which a potential host is exposed, to a given response such as the establishment of infection, morbidity, or mortality. For this risk assessment (RA), dose-response assessment is an important component in converting estimates of the frequency and amount of exposure to a pathogen from the event sequence analysis to estimates of initial infection for the health effects analysis.

When a potential host is exposed to a dose containing one or more infectious microorganisms (virions or bacterial cells), there is a probability that the microorganism(s) will replicate or multiply in the host and cause an infection, possibly leading to disease. There is also a probability that the microorganisms will die off or be eliminated by the host's immune system before infection can be established. The outcome after a given exposure depends on characteristics of both the pathogen and the host. For each pathogen, this RA considers evidence for the ability of doses of various sizes to infect humans, and, because a dose of a given size might affect one human differently from another, this RA also considers the potential variability in susceptibility in heterogeneous populations.

J.2 Methodology

Dose-response is assessed by estimating a functional relationship between the amount of exposure, or dose, and the probability of that dose resulting in a response of interest in a randomly chosen individual from a given population. This section describes the general methodology for assessing the relationship between dose and response for each pathogen.

J.2.1 Responses to Exposure

An exposure can result in no detectable response if the initial organisms to which the host is exposed die off, are eliminated from the host, cannot attach to host cells because of lack of or imperfect receptor sites, or are inactivated by the host's immune system. Otherwise, the following potential responses are considered:

Infection "Invasion and multiplication of microorganisms in body tissues" (Dorland's). A dose resulting in infection is termed an infectious dose (ID), and a dose resulting in infection of a human is termed a human infectious dose (HID). An infection might or might not result in symptomatic disease or subsequent death, but exposure to and infection by the

microorganism may produce antibodies in the infected host that can be detected by appropriate serodiagnostic tests.

Morbidity “The condition of being diseased or morbid” (Dorland’s); for the purposes of this RA, that refers to disease attributable to infection with the pathogen.

Mortality Death of a host; for the purposes of this RA, it refers to death attributable to the disease caused by the pathogen. A dose resulting in death is termed a lethal dose (LD).

Infection caused by a pathogen in humans is the response of interest at this stage of the RA. Infection is a prerequisite for morbidity and mortality, which are considered in a subsequent section as estimates of the percentage of infections that eventually lead to symptomatic disease and death, respectively. Infection is an important response to consider because it is also a prerequisite for potential secondary transmission. It is important to note that for certain pathogens, secondary transmission can occur in the absence of clinically evident symptoms in the primary case at the time transmission occurs.

J.2.2 Routes of Exposure

The following routes of exposure have been considered in this RA:

Inhalation A route of exposure whereby a person inhales droplets or aerosolized particles containing one or more pathogenic microorganisms into the lungs (BMBL 2009).

Ingestion A route of exposure whereby a person is exposed to a pathogen via ingestion of a liquid or solid contaminated with a pathogen or by contaminated hand-to-mouth exposure (BMBL 2009).

Direct contact A route of exposure whereby a person is exposed to a pathogen directly to the skin (potentially broken), eye, or mucous membrane. (BMBL 2009)

Puncture A route of exposure whereby microorganisms are placed below the outermost layer of the skin through a mechanical means such as a syringe needle or other sharp object (BMBL 2009).

Animal-related exposure A route of exposure which combines animal-related elements of the other routes and that involves exposure to infectious particles from animals (e.g., mammals or arthropods) via bites, scratches, as well as airborne dispersal that could result from such sources as sneezes and saliva. Note that BMBL does not distinguish those animal-related mechanisms as a separate route, but they

are separated here because an animal has the potential to produce exposure via all routes.

Each pathogen has a natural route of infection that is dependent on the biology of the pathogen, natural reservoirs, and typical modes of transmission. In a laboratory setting such as the National Emerging Infectious Diseases Laboratories (NEIDL), some experiments would attempt to simulate the natural route of infection, but it is possible that events occurring during culturing, manipulating, transporting, and storing the pathogen could lead to potential exposures that differ from those that would occur naturally. In such circumstances, it is possible that exposure to a pathogen in a laboratory setting from a route different from its natural route of exposure could result in an infection. *For this RA, it is assumed that any route of exposure resulting from a NEIDL-related event could potentially lead to infection in the exposed individual.*

The probability of infection resulting from a given dose of a pathogen can vary according to the route of exposure. The above routes of infection are considered on a pathogen-by-pathogen basis. Generally speaking, the bulk of the dose-response assessment focuses on the inhalation route of exposure, for the following reasons. Some of the most important event sequences for this RA result in inhalational exposure, and most of the relevant animal dose-response data for many of the pathogens were derived from inhalational exposures. Other routes of exposure are considered, as appropriate, for each pathogen and compared with the estimates generated for dose-response by the inhalational route.

J.2.3 Potentially Exposed Groups

The results of each event sequence analysis are provided in terms of exposures for one or more of the following groups.

Laboratory worker	People working in the biocontainment area where the event might be initiated.
Facility worker	People working in the NEIDL but not in the biocontainment area where the event under consideration occurs. For example, they might work in other laboratories or in administrative areas.
Public	Any person outside the NEIDL-controlled perimeter, specifically referring to the population in the surrounding communities.

For the dose-response assessment, estimates of the probabilities of human infection if exposure occurs are assumed to be equal across all three groups, with the following exceptions.

- Vaccine status—As part of training and preparation for work in a high biocontainment laboratory, it is possible that laboratory workers working with certain pathogens for which a vaccine is available would have received that vaccine to prevent infection. The vaccines might or might not be available to facility workers or the general public. That possibility is considered on a pathogen-by-pathogen basis.
- Post-exposure prophylaxis—The above three groups would possibly have differential access to prophylactic regimens, if available, after being exposed. The availability and effectiveness of medication or vaccine prophylaxis are discussed on a pathogen-by-pathogen basis. Note that many of the release scenarios examined in this RA assume that the incident leading to the release is either undetected or unreported. In such situations, the issue of post-exposure prophylaxis might not be applicable.
- Population susceptibility—Because of inherent heterogeneity in the population with respect to age, immune status, and co-morbid or preexisting complicating conditions, the above three groups likely differ in average susceptibility to infection and in heterogeneity of susceptibility among group members. Those differences might or might not be uniform between members of the public near the three sites compared in this RA. In some cases, where relative susceptibility estimates for a specific population are available, adjustments to dose-response estimates are made.

J.2.4 Quantification of Exposure and Dose-Response

As described in the event sequence analyses, the manner in which exposure estimates are quantified varies by pathogen because estimates of the concentration of pathogens that would be used at the NEIDL are generated from sources that measure pathogen concentration using a variety of metrics. The literature and information available for dose-response assessment also exhibits a variety of measurement techniques used to quantify doses to which potential hosts are exposed. To translate estimates of exposure to estimates of infection probability, the units of exposure or dose must be reconciled, which sometimes requires assumptions for converting one unit of measure to another. Those assumptions are specified on a pathogen-by-pathogen basis.

J.2.5 Dose-Response Modeling

The relationship between the dose received and the probability of infection can be quantified using mathematical dose-response models. A dose-response model takes the form of a mathematical function that uses as input a quantity measuring an expected dose to which an individual is exposed and provides as output an estimate of the probability of infection that would result from that expected dose. Equivalently, the output can be considered to represent the proportion of individuals from a population estimated to become infected from the given expected dose.

Dose-response models are particularly important in estimating the probability of infection after a low initial dose. Many of the event sequences investigated in this RA lead to estimates of exposure to a small dose, sometimes on the order of a single virion or bacterial cell, and experimental data on the effects of such a low dose are scarce or non-existent. The effects of higher doses are better understood, and dose-response models are used to extrapolate information of the effects of higher doses to that of lower doses. That is, the models use information about the height and shape of the dose-response curve in regions where estimates are available, in conjunction with an assumed functional form, to then extend the curve into lower regions where estimates are needed. The assumed functional form varies from model-to-model, sometimes leading to different extrapolated estimates from the same dose-response information. For this RA, three different model forms were considered as described in the following section.

J.2.5.1 Description of Candidate Dose-Response Models

Let d be the dose received, generally quantified as the expected number of organisms with potential to infect a human in the dose. Here and throughout, it should be noted that the general term *organisms*, when referring to doses of exposure, means either bacterial cells or virions. Then, let $p(d)$ be the probability of infection if dose d is received. The mathematical function $p(d)$ describes a dose-response curve. In the literature, dose-response information is often specified as a point or points on a dose-response curve in the form ID_x , where ID stands for infectious dose and x is a number from 0 to 100 representing the percentage chance of infection. In the $p(d)$ formulation, $p(ID_x) = x/100$; for example, the ID_{50} would result in a probability of infection of 0.5.

Three different mathematical forms for the function $p(d)$ are considered, all of which are commonly used in the literature to quantify dose-response relationships for infectious pathogens. They are the exponential model, the log-probit model, and the beta Poisson model.

Exponential model

The exponential model assumes the probability of infection is given by the functional form

$$p(d) = 1 - e^{-rd}. \quad (1)$$

The single parameter r is a constant defined as the probability that infection is established by a single organism. A single organism establishing infection means that the organism produces descendants in the host that survive to contribute to a sustained population in the host. In that sense, the exponential model is an example of a *single hit* model. The model assumes that multiple organisms act independently in the host. That is, the probability that any one organism in the initial dose produces descendants in an eventual infection is independent of the size of the dose. If the exact number of organisms in the dose is known, the overall probability of infection is simply the complement to the probability that none of the organisms establish infection, or $p(d) = 1 - (1 - r)^d$. The exponential model assumes that there is some uncertainty in the size of the dose. Specifically, it assumes that d is the expected value for the number of organisms in the dose, and the true value varies according to a Poisson distribution with mean d .

The exponential model is appealing because of its simplicity and its basis in clear biological assumptions. The fact that it requires only one parameter means that a single point defines the entire curve. For example, if the ID_{50} is known, then $r = (\ln 2)/ID_{50}$, and the probability of infection for any dose is defined. A drawback to the exponential model is that it does not assume heterogeneity among organisms or hosts; that is, the probability r is the same for every organism in a dose and also does not change from host to host. Nonetheless, the exponential model has had some success in describing data (e.g., Haas 2002; Tamrakar 2008; Watanabe 2010; Wilkening 2006), and there is merit in choosing a relatively simple model when there is no compelling evidence that a more complicated model would be significantly more accurate.

Log-probit model

The log-probit model assumes the probability of infection is given by the functional form

$$p(d) = \Phi \left(m \ln \left(\frac{d}{ID_{50}} \right) \right). \quad (2)$$

Here, ID_{50} is a constant parameter referring to the dose at which there is a 50% chance of infection (i.e., $p(ID_{50}) = 0.5$), and m is a second constant parameter called the probit slope. The function Φ is the cumulative distribution function for the standard normal distribution, and \ln is the natural logarithm. Traditionally, the base-10 logarithm was used in the formula, but using the natural logarithm achieves the

same purpose and results in a model that is easily transformed for purposes of curve fitting in a manner consistent with the other two models.

The model was first developed (Bliss 1934) as a convenient method for transforming experimental data into approximately linear form so that regression could more easily be done by hand. The method was popularized for use in applications to toxicology (Finney 1947) and has since become the traditional model used in toxicological risk assessment. The model is still used despite the fact that its originally espoused advantage (ease of hand calculation) is no longer relevant with the advancement of computer technology. Some authors (e.g., Tamrakar 2008) have argued that the log-probit model is not a preferred choice because it is not based on any clear assumptions about biological mechanisms for the establishment of infection. Also, when the probit slope parameter is low, the log-probit model often predicts much higher probability of infection at low doses than other models (Haas 2002), which might lead to unrealistically high estimates of risk under scenarios in which many individuals receive a small dose. Still, data on probability of infection are sparse (particularly for low doses), so researchers are sometimes unable to demonstrate conclusively that the log-probit model is a worse predictor than other models. Some have argued that the log-probit model is an appropriate model when the host population is heterogeneous (e.g., Wilkening 2006); for example, if each potential host has a tolerance (a dose that is just sufficient for establishing infection), and the variation in tolerances across the population is adequately captured by the lognormal distribution, then the log-probit model may be justified (Finney 1947).

Beta Poisson model

The beta Poisson model assumes the probability of infection is given by the functional form

$$p(d) = 1 - \left(1 + \frac{d}{\beta}\right)^{-\alpha}. \quad (3)$$

Here, α and β are constant parameters. The derivation of the beta Poisson model (Furumoto 1967) begins with assumptions similar to those for the exponential model. It begins with the same *single-hit* framework, assuming that organisms act independently. Again, under those assumptions, if the exact dose d is known and if the probability r of a single organism establishing infection is constant, the probability of infection would be given as $p(d) = 1 - (1 - r)^d$. The beta Poisson model, like the exponential model, assumes that the dose d is a random Poisson-distributed variable with mean d , and additionally assumes that the probability r varies according to a beta distribution with parameters α and β . Specifically, the probability density function $f(r)$ describing the beta distribution for r is given by¹

$$f(r) = \frac{\Gamma(\alpha+\beta)}{\Gamma(\alpha)\Gamma(\beta)} r^{\alpha-1} (1-r)^{\beta-1}. \quad (4)$$

¹In equation (4), Γ refers to the Gamma function, defined $\Gamma(z) = \int_0^\infty t^{z-1} e^{-t} dt$

Those assumptions alone lead to a dose-response model with a complicated functional form involving the Kummer confluent hypergeometric function (see Haas 1999). The simpler beta Poisson formula above is an approximation to the exact formula, and the approximation is valid when $\beta \gg 1$ and $\beta \gg \alpha$.² Note that, because of that approximation, the beta Poisson model is not technically a single-hit model (Teunis 2000). It was decided that use of the simpler formula was suitable for the purposes of this RA.

The beta Poisson model is appealing in that it is a simple model based on well-defined assumptions about both the biological mechanisms of establishing infection and heterogeneity between organisms and/or hosts. There has been some success in using the model to fit experimental data (Tamrakar 2008; Huang 2010).

Some dose-response models are in the literature that are not among the three listed in this section. Many are more complicated models with several parameters that are difficult to specify accurately in the absence of a rich set of data, and, therefore, are not necessarily more accurate than a simpler model. Some have argued that threshold dose-response models should be considered in the context of risk assessment (Coleman et al. 2008). Threshold dose-response models (often referred to as *nonlinear* models) assume that there is a dose level below which the probability of infection drops non-smoothly or even drops to zero. The three models from the previous section all result in non-zero estimates of infection probability at any dose no matter how low. Threshold models are not considered for the following reasons.

- The assumption of a threshold dose may be nonconservative (i.e., could underestimate the risk) at doses below the threshold, especially when the model is applied to a population that includes individuals who might be severely immunocompromised or have a lung condition that severely hampers the ability to clear pathogens from the lungs after inhalation.
- The three models considered do allow for the possibility of very small probabilities of infection at low doses, with certain choices of parameter values. For example, the log-probit model with a high probit slope parameter results in a *threshold-like* dose-response curve that is steep, i.e., estimates a quick drop in the infection probability as the dose decreases (Wilkening 2006). If dose-response data exhibit evidence of a steep decline in infection probability as doses decrease, then the log-probit model, at least, could account for this observation.

Assumptions about the spatial distribution of organisms in a dose is another potentially important feature of dose-response models. For example, in an aerosol containing some number of organisms, some of the

² The symbol “ \gg ” means “is much greater than.”

aerosolized, respirable particles might contain more organisms than others because of the effect of clumping. Then, if exposure occurs among a group of individuals, some individuals could randomly inhale more organisms than others because of a heterogeneous spatial distribution in the aerosol. That possibility is modeled explicitly by the exponential and beta Poisson dose-response models, which assume a Poisson-distributed number of organisms around the expected dose. It is possible that actual distributions of doses for pathogens modeled in this RA would be more highly dispersed than the Poisson distribution, leading to higher probabilities for above-average sized doses, although there is generally very little data to support using an alternate assumption. The log-probit model does not explicitly assume a given heterogeneous distribution of doses in a sample of organisms. It is assumed that any uncertainties arising from applying the log-probit model to exposure estimates for aerosols with a heterogeneous spatial distribution are small compared with the overall uncertainty of the dose-response analyses.

J.2.5.2 Evaluation of Dose-Response Models

For this RA, the three models described in the previous section were evaluated in light of the dose-response data and information available in the literature for each of the pathogens. In some cases, researchers have applied one or more of the three models to human dose-response information and/or to experimental data from exposed animals that have been proposed as suitable models for human infection. In these studies, parameters for a particular model were chosen such that the predictions of the model differ from the observations from experiments as little as possible. An appropriate model would produce a dose-response curve with both an appropriate position (for example, the numerical value of the ID₅₀) and an appropriate shape (the steepness of the curve, or how fast the probability of infection increases as the dose increases). The models found in the literature for each pathogen were evaluated, and, in some cases, models were fit to published experimental data that had not previously been fit to one or more of the models considered here. The techniques used for fitting models to published data are described in Section J.3, in conjunction with each data set to which they were applied, as the procedure can vary because of the details of each data set.

In addition, the three dose-response models were used to fit curves to the information obtained from the expert panelists who were asked via the Delphi method to provide ID estimates (Bozzette 2010). The process for fitting curves to the expert-provided values is described in the following section. In this context, the three models were evaluated and compared with each other in terms of their ability to match as closely as possible to the estimates provided by each expert for each pathogen.

J.2.5.3 Fitting Dose-Response Models to Expert-Provided Values

As part of the Delphi process, each expert provided a set of three ID's (ID_{10} , ID_{50} , and ID_{90}) corresponding to three points on a theoretical dose-response curve for each pathogen. Each set of numbers provided by the experts for each pathogen was evaluated separately against the three dose-response models. Because the three dose-response models that were used are one- or two-parameter models, it might not be possible to fit a curve exactly to a set of three points. Instead, an optimization procedure was used for each model to choose parameter values that result in a dose-response curve that comes as close as possible to fitting the three points, using criteria described as follows.

First, the models were rewritten with the probability, p , as the independent variable and the natural logarithm of the dose, $\ln(d)$, as the dependent variable:

$$\text{Exponential model: } \ln(d) = \ln(1/r) + \ln(-\ln(1 - p))$$

$$\text{Log-probit model: } \ln(d) = \ln(ID_{50}) + \frac{1}{m} \Phi^{-1}(p) \quad (5)$$

$$\text{Beta Poisson model: } \ln(d) = \ln(\beta) + \ln[(1 - p)^{-1/\alpha} - 1]$$

The reason for setting p as the independent variable is that the experts were given values of p (0.1, 0.5, and 0.9) for which to predict the corresponding dose, and therefore it is natural to evaluate the models as predictors of the dose given the probability. The reason for setting the logarithm of the dose as the dependent variable (rather than the dose itself) is to avoid putting too much weight on errors at the higher probability levels, where the dose predictions can be many orders of magnitude higher than doses at lower probability.

For each set of three points, optimal values for model parameters were calculated using least-squares optimization. Specifically, the optimal parameter values are those that minimize the sum of the squared differences between the log-dose values predicted by the model and the log of the dose values predicted by the expert. Specific optimization procedures used for each of the three models are described as follows.

Exponential model fitting

To simplify the exponential model,

$$\ln(d) = \ln(1/r) + \ln(-\ln(1 - p)), \quad (6)$$

the three (p, d) data pairs from each expert were transformed into (x, y) pairs according to

$$x = \ln(-\ln(1 - p)) \quad \text{and} \quad y = \ln(d), \quad (7)$$

and the parameter a_1 was introduced as

$$a_1 = \ln(1/r). \quad (8)$$

Then, the exponential model has the linear form

$$y = a_1 + x, \quad (9)$$

for which the optimal value for the parameter a_1 was calculated using the `lm` (linear model) function in R (version 2.9.2) for linear least-squares fitting.

Log-probit model fitting

To simplify the log-probit model,

$$\ln(d) = \ln(\text{ID}_{50}) + \frac{1}{m} \Phi^{-1}(p) \quad (10)$$

the three (p, d) data pairs from the expert were transformed into (x, y) pairs according to

$$x = \Phi^{-1}(p) \quad \text{and} \quad y = \ln(d), \quad (11)$$

and the parameters a_2 and a_3 were introduced as

$$a_2 = \ln(\text{ID}_{50}) \quad \text{and} \quad a_3 = \frac{1}{m}. \quad (12)$$

Then, the log-probit model has the linear form

$$y = a_2 + a_3 x, \quad (13)$$

for which the optimal value for the parameters a_2 and a_3 were calculated using the `lm` function in R (version 2.9.2) for linear least-squares fitting.

Beta Poisson model fitting

To simplify the beta Poisson model,

$$\ln(d) = \ln(\beta) + \ln[(1 - p)^{-1/\alpha} - 1], \quad (14)$$

the three (p, d) data pairs from the expert were transformed into (x, y) pairs according to

$$x = (1 - p)^{-1} \quad \text{and} \quad y = \ln(d), \quad (15)$$

and the parameters a_4 and a_5 were introduced as

$$a_4 = \ln(\beta) \quad \text{and} \quad a_5 = 1/\alpha. \quad (16)$$

Then, the beta Poisson model has the nonlinear form

$$y = a_4 + \ln(x^{a_5} - 1), \quad (17)$$

for which the optimal values for the parameters a_4 and a_5 were calculated using the `nls` function in R (version 2.9.2) for nonlinear least-squares fitting, which uses the Gauss–Newton algorithm (see Fletcher 1987). For some of the data sets, the `nls` function did not find a solution because the Gauss–Newton algorithm did not converge. It was determined that in every case for which convergence did not occur, the optimal values of α and β were unbounded. That is, as α and β increase (along the curve defining the optimal relationship between α and β), the fit improves indefinitely. However, as the parameters become very large, the improvement in the fit caused by further increasing α and β becomes infinitesimal. In this case, an alternate procedure was used to determine estimates for α and β , in which the parameters were changed step-by-step until the dose-response curve at one step was the same as the curve from the previous step, within a small tolerance.

J.2.5.4 Comparison of Dose-Response Model Fits to Expert-Provided Values

The relative success of the three dose-response models in fitting each of set of three points was compared using the Bayesian information criterion (BIC) (Schwarz 1978), which is a criterion used for selecting among models with different numbers of parameters. The beta Poisson and log-probit models each have one more parameter than the exponential model, which gives them an advantage in their ability to fit the data, but additional parameters can result in overfitting. For example, many different three-parameter models could fit all three points exactly but could give very different predictions for interpolated or extrapolated points away from the data points themselves, and, therefore, use of a particular three-parameter model could be misleading. The BIC evaluates the fit of each model using the likelihood (the probability density of the data at the best-fit model parameter(s)) and also includes a penalty term that increases for a higher number of parameters.

The BIC is calculated using

$$\text{BIC} = -2\ln(L) + k\ln(n), \quad (18)$$

where L is the likelihood for the optimized model ($\ln(L)$ is calculated using the R function `logLik` on the results of the objects produced by the `lm` and `nls` functions used for curve fitting), k is the number of parameters (1 for exponential and 2 for log-probit and beta Poisson), and n is the number of data points (3 for all models). According to this criterion, the model with the lowest value of BIC is the preferred model. Note that some of the three-point sets fit perfectly to the log-probit model, and in these cases the BIC is negative infinity. For comparing models, the conservative assumption was made to eliminate a curve from consideration only if its BIC number was more than six greater than that of another curve. According to one source (Raftery 1995), a difference of more than six constitutes strong evidence that the model with the higher value can be rejected in favor of the other. The results are generated as ΔBIC values, calculated by taking the difference between the BIC value and the lowest of the three BIC values for each set of points. A ΔBIC of zero means the corresponding model scored the lowest, and a ΔBIC greater than six led to the elimination of that model from consideration.

For each pathogen, one or more dose-response curves from each expert was left in consideration after eliminating curves according to the BIC. The eliminated curves from each expert can be considered models that, when compared to the retained model(s), do not adequately represent the estimates provided by that expert. Given the importance of the choice of curve in determining risk and the fact that the experts did not reach consensus, it was decided not to choose a representative expert or a particular dose-response model for purposes of this RA. Instead, each expert's curve or set of curves was given equal weight in estimating the probability of infection. If more than one curve was left in consideration for a particular expert, each curve was given equal weight in determining the probability estimations from that expert. Because there were eight experts, if a single curve was left in consideration for an expert, that curve was weighted with 1/8 probability. If two curves were left in consideration for an expert, each of those curves was weighted with 1/16 probability. If all three curves remained for an expert, each of those curves was weighted with 1/24 probability. In that way, a distribution was defined for the probability of infection given any particular dose.

J.2.6 Synthesis of Dose-Response Information

For each pathogen, the qualitative and quantitative information was synthesized to provide a range of estimates for the probability of infection at doses of exposure that might occur as a result of NEIDL-related events. Two sets of quantitative estimates are provided for each pathogen:

1. A literature-based dose-response estimate, consisting of one of the three models described in Section J.2.5.1 along with a point estimate and uncertainty range for the parameter value(s) associated with that model.
2. A range of dose-response estimates derived from the expert-provided values, consisting of a distribution that includes all three models with fitted parameter values as described in Section J.2.5.4.

The two alternate ranges of estimates were compared, especially for low doses at which most of the exposure estimates for the event sequences occur. In some cases, the literature-based range is more conservative (estimates higher risk) than the expert-based range, and in other cases the opposite is true. All results are presented and the differences discussed in conjunction with each pathogen.

Both distributions of infection probabilities derived from the dose-response models presented in this appendix are applied to the exposure estimates in the initial infections calculation packages associated with each relevant event sequence. The uncertainty in the probability of infection described by the distributions of dose-response curves contributes to the overall uncertainty in the estimate of risk posed by each event sequence. The relative contribution of the dose-response uncertainty compared to other sources of uncertainty is evaluated in sensitivity analyses performed in conjunction with each event sequence.

J.3 Results

This section documents the dose-response assessment for each of the 13 pathogens.

J.3.1 *Bacillus anthracis*

Bacillus anthracis (*B. anthracis*) is a bacterial organism that causes anthrax and has caused infection in humans in both natural and laboratory settings, as described in Chapter 3 and Appendix C. This section synthesizes the available dose-response information and derives a range of dose-response estimates to be applied to the exposure results from each of the event sequence analyses.

J.3.1.1 Routes of Exposure

Natural routes of human exposure for *B. anthracis* are cutaneous, inhalational, and gastrointestinal. From a release in or from a laboratory, possible routes of exposure could be inhalation, ingestion, direct contact, puncture, or animal-related (nonhuman primates [NHP] or rodents). The inhalational route is the focus of

the remainder of this assessment. Other routes of exposure in the laboratory and the ID for those other routes as compared to the inhalational route are addressed in the description of specific scenarios such as needlestick exposure or exposure to skin/mucous membranes.

J.3.1.2 Vaccine and Prophylaxis

There is an FDA-licensed pre-exposure vaccine for anthrax with the trade name BioThrax®, also called Anthrax Vaccine Absorbed (AVA), produced by Emergent BioSolutions, Inc., Rockville, Maryland. Centers for Disease Control and Prevention (CDC)-reported guidelines (CDC 2000, 2002) state that pre-exposure use of this vaccine should be based on quantifiable risk of exposure and recommend the vaccine for workers in settings in which repeated exposure to aerosolized *B. anthracis* spores might occur, including certain laboratory workers. Those guidelines do not recommend the vaccine for members of the general population who do not engage in work that places them at risk for repeated exposures. The vaccine would not prevent infection with *B. anthracis* cells as defined in this RA, but rather is designed to promote immune responses in the vaccinated host that effectively neutralize the toxins produced by *B. anthracis* bacteria that cause anthrax disease (Joellenbeck 2002). A precursor to the available vaccine was estimated to be 92.5 percent effective in preventing anthrax disease in a placebo-controlled field study involving at-risk mill workers (Brachman 1962).

For non-vaccinated individuals who might have been exposed to aerosolized *B. anthracis* spores, the CDC recommends the following post-exposure prophylaxis: 60 days of selected oral antibiotics in conjunction with a 3-dose regimen of BioThrax AVA vaccine, a combination that has proven effective in NHPs exposed to *B. anthracis* (CDC 2000). Antibiotics taken by exposed individuals might prevent infection if applied before inhaled spores germinate and reproduce, while the vaccine could promote an immune response to neutralize disease-causing toxins originating from active *B. anthracis* cells.

For this RA, it is assumed that most NEIDL laboratory workers assigned to work with *B. anthracis* in biosafety level (BSL)-3 labs would have received the anthrax vaccine before a potential exposure event. As noted above, the available vaccine does not prevent infection with *B. anthracis* organisms, so the dose response estimates for laboratory worker infection is assumed to be unaffected. However, vaccinated laboratory workers who become infected would have a low (less than about 10 percent based on the literature) probability of developing anthrax disease. It is also likely that recognized and reported mishaps in the laboratory involving *B. anthracis* would result in potentially exposed workers receiving the recommended prophylactic regimen, which could reduce the probability of both infection and disease. However, this RA focuses on laboratory incidents that are most likely to be undetected, in which case

1 prophylaxis would likely not be administered early enough to prevent infection. Those assumptions have
2 no impact on the estimated risk posed by laboratory workers to the public, as *B. anthracis* is not
3 transmissible person-to-person by the inhalational route, whether or not a primary case develops
4 symptomatic disease. One possible exception to the direct person-to-person transmission of *B. anthracis*
5 would be carriage of spores on a laboratory worker's skin or clothing that could transfer to a contact and
6 cause skin disease (WHO 2008; Freedman 2002), but this potential scenario is not relevant to the issue of
7 prophylaxis for inhalational anthrax.

8
9 It is possible that some members of the public in the vicinity of NEIDL would have received the anthrax
10 vaccine because of their occupation (e.g., military personnel). However, those individuals likely make up
11 a small percentage of the general public, so it is conservatively assumed that no members of the public
12 would be vaccinated against anthrax before potential exposures from a NEIDL-related release. If
13 exposures occurred in the general public, it is possible that prophylactic treatment, if administered in time,
14 would prevent infection and/or disease that would otherwise have occurred. This possibility would be
15 more likely for exposed individuals experiencing a long incubation period. Those issues are discussed in
16 more detail in the sections of this RA related to potential health consequences of specific events resulting
17 in direct public exposure.

18 19 **J.3.1.3 Dose-Response Information from the Literature**

20 This section consists of a review and discussion of selected literature and information relating to the
21 probabilistic estimates of infection for humans exposed to a given number of *B. anthracis* spores via the
22 inhalational route. The literature review was performed according to the methodology outlined in Chapter
23 3. This section concludes with a summary of the procedure for dose-response modeling of *B. anthracis* to
24 be used in this RA, in light of the pathogen information and discussion provided here.

25 26 **Human data and evidence**

27 There are very little experimental, quantitative data for human exposures to *B. anthracis*. Data exist from
28 human experimentation in Japan during World War II, but the experiments were done via subcutaneous
29 and oral routes, not inhalational. The resulting data (Harris 1999) have been difficult to interpret and
30 difficult to reconcile with epidemiological knowledge of subcutaneous infections (WHO 2008). Those
31 data are not considered further.

32
33 Semi-quantitative data exist for exposure of non-vaccinated industrial workers handling animal products
34 contaminated with *B. anthracis* in the early-mid 1900s. That historical evidence suggests that the

infection rate for humans exposed in this setting is very low, especially for inhalational anthrax, as most of the infections that did occur were cutaneous (WHO 2008). Workers in one mill were shown to be inhaling hundreds of spores daily with not a single infection documented (Dahlgren 1960). In a recent, detailed analysis of this study and others, the authors concluded that 600 spores or fewer would not be expected to cause disease in healthy humans and advocated the use of 600 spores as a threshold to use in risk assessments (Cohen 2007). However, it is possible that the industrial workers had developed resistance to infection from repeated low-level exposure, that there were undiagnosed cases, and/or that infections would result from low-dose exposures among members of a population with unusual susceptibility (Brachman 1966).

In another historical event, *B. anthracis* spores were accidentally released from a facility in Sverdlovsk in the former Soviet Union in 1979, causing infections in both humans and animals downwind of the facility. One study (Meselson 1994) tabulated 77 likely human cases, 66 resulting in death. Doses inhaled by the infected individuals are not known, and it is also not known how many spores were released from the facility. However, that study and others include estimates of human dose-response information using atmospheric data on the day the release likely occurred, the likely locations of the infected individuals when they were exposed, and epidemiology of the tabulated cases.

Meselson et al. (1994) calculated that the attack rate at a ceramics factory 2.8km downwind of the Sverdlovsk release was approximately 1–2 percent (18 out of about 1,500 employees infected, including 10 out of 450 employees working in a single unpartitioned building). That suggests that the average dose received at that distance would have been roughly the ID₁ or ID₂ for humans. They applied lower and upper limit ID₂ estimates of 9 spores and about 1,300 spores to calculate that the weight of material released from the facility was between a few milligrams to nearly one gram.

Wilkening et al. (2006) analyzed the Sverdlovsk case data and applied a series of theoretical dose-response models. They determined that both the spatial (distance from release) and temporal (incubation period, assumed to vary with dose) distribution of cases are consistent with dose-response curves that are less steep, i.e., curves that estimate a gradual decrease in the probability of infection as the dose decreases. They conclude that the data contraindicate dose-response functions that assume a threshold of infection, such as the extreme case of a step function, which assumes a dose below which no one is infected and above which everyone is infected and is the steepest possible curve. This conclusion that gradual curves perform better than threshold-like curves holds regardless of the exact dose numbers assumed. Under an assumption of 8,600 spores as the ID₅₀, the two best of the tested models predict ID₁₀

of 110 and 1,300 spores. Those low-dose results are dependent on the assumption of the ID₅₀ value; much different values are accommodated by adjusting the number of spores released, which is a fitted parameter in the models.

Summary of human data and evidence:

- No human experimental data are available for inhalational anthrax.
- Non-vaccinated industrial workers were shown to be inhaling hundreds of spores daily with infections occurring very rarely.
- *B. anthracis* spores released from a facility in Sverdlovsk in 1979 caused dozens of human infections in the nearby community; spatial and temporal distributions of the documented cases are consistent with less steep, non-threshold-like dose-response curves.

NHP data

Glassman (1966) reports on data from unpublished work performed by Jemski in which 1,236 cynomolgus monkeys (*Macaca fascicularis*) were exposed to aerosols of *B. anthracis*. The data showed an LD₅₀ of 4,130 spores (95 percent confidence interval 1,980 to 9,630) and were fit to a log-probit model resulting in a probit slope of 0.667 probits per log dose (95 percent confidence interval 0.520 to 0.818). Extrapolation under the log-probit model assumptions, with LD₅₀ of 4,130 and probit slope of 0.667, results in LD₁₀ of 50 spores, LD₂ of 3 spores, and LD₁ of 1 spore. The raw data from the experiments are not presented, and it cannot be determined if any of the monkeys were exposed to low doses and, if so, if any of those doses proved fatal. Furthermore, without the full data set it is not possible to evaluate whether alternate dose-response models would have fit the data better than the log-probit model, which has been outperformed by other models in fitting other data sets (Haas 2002). For example, if the exponential model had been applied with the same LD₅₀ of 4,130 spores, extrapolations result in LD₁₀ of 628 spores, LD₂ of 120 spores and LD₁ of 60 spores.

Brachman et al. (1966) collected data from exposures of cynomolgus monkeys (*M. fascicularis*) to contaminated air from a goat hair mill. They reported that exposure to about 1,000 *B. anthracis*-bearing particles over a 5-day period resulted in approximately 10 percent mortality, and exposure to 3,500 to 5,500 particles resulted in approximately 20–25 percent fatality. Haas (2002) analyzed the original data using a more sophisticated quantitative procedure and derived an exponential model providing a good fit to the daily risk of mortality. Applying the fitted exponential model parameter and associated 95 percent likelihood-based confidence interval gives the following results: LD₅₀ of 27,000 (18,000–41,000), LD₁₀ of 4100 (2,700–6,300), LD₂ of 780 (530–1,200), and LD₁ of 390 (260–600). It should be noted that, in this

case, the average daily exposures ranged from 198 to 1041 *B. anthracis*-bearing particles, so the derived LD₁ and LD₂ estimates are in the range of the data points and not extrapolations from results at much higher doses.

Druett et al. (1953) exposed rhesus monkeys (*Macaca mulatta*) to aerosols of *B. anthracis* spores resulting in a range of inhaled doses estimated between about 70,000 to 400,000 spores. They reported an estimated LD₅₀ of 45,000 spores, which was derived from a log-probit regression. Haas (2002) reanalyzed the data set and determined that the log-probit model did not provide an improved fit over the exponential model, which results in the following estimates (with 95 percent likelihood-based confidence intervals): LD₅₀ of 96,800 (70,700–136,000), LD₁₀ of 14,700 (10,800–20,700), LD₂ of 2,820 (2,060–3,960), and LD₁ of 1,400 (1,030–1,970).

Haas (2002) synthesized and discussed the results from the above three NHP studies (Druett 1953; Brachman 1966; Glassman 1966) and determined that the exponential model can describe dose-response to inhalational anthrax in NHPs, and that low doses are predicted to produce a low, but nonzero, risk of disease. He states that other studies publishing different dose-response relationships do not provide the data necessary to evaluate the basis for the differences.

Summary of NHP data:

- A report on results from exposure of 1,236 cynomolgus monkeys gave an estimated LD₅₀ of 4,130 spores and a fitted parameter for the log-probit dose-response model. The full data set is not published, so it is not possible to evaluate whether low-dose extrapolations based on those results are appropriate.
- For a different data set on exposure of cynomolgus monkeys to relatively low doses, an exponential dose-response model with an LD₅₀ estimate of 27,000 spores was determined to provide an adequate fit.
- For a data set on exposure of rhesus monkeys to relatively high doses, an exponential model was selected from among alternate dose-response models, providing an LD₅₀ estimate of 96,800 spores.

Table J–1a displays the above results and also compares low-dose estimates derived from the three models. The results are displayed down to LD_{0.01}, which represents the expected dose at which the mortality rate is estimated to be 1 in 10,000 (0.01 percent). Fractional doses (less than one) can be interpreted as an average dose over a population of potentially exposed individuals in which some

individuals would receive a dose of zero. The variation in actual doses received across individuals is modeled by the Poisson distribution. For example, an LD₁ of 0.5 would mean that if a population were exposed to an average dose of 0.5 per individual, a 1 percent mortality rate would be expected. In this example, a Poisson-distributed dose with average 0.5 means that approximately 61 percent would receive no dose, 30 percent of individuals would receive a dose of one organism, and 9 percent would receive two or more organisms.

Table J–1a. LD estimates (with 95% confidence intervals) for NHPs from *B. anthracis* dose-response models from the literature

Set	Animal	Model	LD ₅₀	LD ₁₀	LD ₁	LD _{0.1}	LD _{0.01}
A	<i>Macaca fascicularis</i> (Glassman 1966)	LP	4130 spores (1980–9630)	50 (14–110)	1 (0.1–6)	0.1 (0.005–0.7)	0.01 (0.0003–0.1)
B	<i>Macaca fascicularis</i> (Brachman 1966, Haas 2002)	Exp	27000 spores (18000–41000)	4100 (2700–6300)	390 (260–600)	38 (26–60)	3.8 (2.6–6.0)
C	<i>Macaca mulatta</i> (Druett 1953, Haas 2002)	Exp	96800 spores (71000–140000)	14700 (11000–21000)	1400 (1000–2000)	140 (100–200)	14 (10–20)

Each LD_x result refers to the expected inhaled dose estimated to result in death of x% of exposed animals. For example, LD_{0.01} refers to the dose estimated to result in death of 0.01%, or one in ten thousand animals. For the models, LP = log-probit and Exp = exponential. For data set A, the 95% confidence interval for LD₅₀ was reported in the cited paper, and the intervals for LD_x, x < 50, were calculated using the reported best-fit LD₅₀ and varying the probit slope by the interval reported in the paper. For data sets B and C, the 95% confidence intervals are likelihood-based. The model fit to Set B was chosen as the literature-based model for this RA, as described in Section J.3.1.4.

J.3.1.4 Literature-Based Dose-Response Estimate

This section consists of a discussion of the dose-response data, evidence, and published models for *B. anthracis* outlined in the previous section and provides the literature-based dose-response estimate to be used for this RA.

The body of human evidence with regard to inhalational anthrax suggests that humans have a moderate level of resistance to infection (WHO 2008), given the relative rarity of human cases among animal workers who likely inhaled spores repeatedly. Those cases that have occurred among humans could be the result of inhalation of an unusually high number of spores, rather than rare low-dose infections from the tail end of a probability distribution (Cohen 2007; Coleman 2008). Researchers making that argument recommend that risk assessments include discussion of the possibility that there is a threshold to human infection below which the probability of infection drops nonlinearly (Coleman et al. 2008).

1 However, another possible explanation for rare human cases is that some of those individuals did inhale
2 low doses and became infected because they were unusually susceptible to disease because of an
3 immunocompromised or pulmonary condition. About the human cases after the Sverdlovsk release, a
4 World Health Organization anthrax report (WHO 2008) states, “many of those who succumbed had
5 predisposing respiratory illness.” The Cohen and Whalen (2007) paper, in which the authors recommend
6 600 spores as an appropriate threshold to human infection to use in risk assessments, states, “an exposure
7 of 600 spores per day would not be expected to cause disease in a healthy individual who is not
8 egregiously predisposed to anthrax or lung disease, or is immuno-compromised.” Because the dose-
9 response relationships developed for this RA are being applied to populations containing
10 immunocompromised and potentially predisposed individuals, it was determined that applying that
11 threshold would not be appropriate.

12
13 The study of Wilkening et al. (2006) of the Sverdlovsk data gives further support to the decision to avoid
14 applying threshold-like dose-response relationships to a general population. They demonstrated that the
15 distribution of cases is better explained by dose-response curves that are less steep, such as those
16 produced by exponential models or log-probit models with a lower probit slope. Objections to the
17 Wilkening results seem to focus criticism on the numerical results presented for potential probabilities of
18 infection at low doses (Cohen 2007; Coleman 2008) and do not speak to the result regarding the shape of
19 the dose-response curve, which holds regardless of the numerical ID values assumed. Given that the
20 Sverdlovsk incident is the historical event most similar to the large-scale release scenario analyzed for
21 this RA, it was determined that the application of dose-response curves similar in shape to those retained
22 by Wilkening et al. (2006) would be appropriate.

23
24 *In the absence of human data to further refine potential quantitative dose-response models, experimental*
25 *studies involving NHPs provide the best available data from which to gain insights into potentially*
26 *appropriate dose-response relationships for humans.* A number of assumptions are required to apply
27 results from NHP data to an analysis of risk to humans. The data from the studies above tabulated the
28 response of death to generate estimates of LD or lethal dose, which is assumed to be equivalent to ID or
29 infectious dose because the monkeys in the experiments did not receive treatment to combat infection and
30 pulmonary anthrax is nearly always fatal if untreated. There might be species differences in susceptibility
31 to infection between the NHPs tested and humans. In the case of the Brachman (1966) study, the
32 cynomolgus monkeys were exposed to spores from a factory where humans worked, and some monkeys
33 died from exposure to average daily doses less than 600 spores, which was the threshold below which
34 humans did not become infected as determined by Cohen and Whalen (2007). Therefore, it is surmised

1 that applying a dose-response relationship derived from cynomolgus monkeys to humans would be
2 conservative and would not underestimate the risk to humans. Such a model might significantly
3 overestimate risk to humans, but the possibility that the estimates are relevant to human susceptibility
4 cannot be fully ruled out in the absence of human data.

5
6 Log-probit regressions were traditionally performed to fit experimental monkey data to a dose-response
7 curve (Druett 1953; Glassman 1966). These log-probit curves have been used to extrapolate probabilities
8 of infection at doses much lower than were actually used in the experiments, often resulting in estimated
9 probabilities of infection that are controversially high at doses of just one or a few spores. There appears
10 to be no evidence that a monkey has ever developed infection after inhaling such a low dose.

11 Furthermore, there is no compelling reason to place faith in extrapolations from the log-probit model,
12 which is not based on any assumed mechanisms of infection or on any proven assumptions about the
13 heterogeneity of susceptibility in monkeys. It appears to have been used primarily because of tradition
14 and because it provided a convenient transformation through which regressions could easily be done by
15 hand before the advent of statistical computing.

16
17 Haas (2002) evaluated alternatives to the log-probit model in light of the best available NHP data from
18 the literature and concluded that the exponential model, which tends to estimate a significantly lower
19 probability of infection at low doses than the log-probit model, performed better. For example, the log-
20 probit model published by Glassman (1966) dramatically over-predicted the risk of mortality
21 demonstrated by monkeys in the Brachman (1966) study, which were subjected to relatively low doses.
22 The exponential fit to the Brachman data derived by Haas (2002) adequately described the data. Given the
23 fact that the monkeys in the Brachman study were exposed to much lower doses than in other studies, it
24 was determined that a model fitting these data offers the most potential insight into what the response of
25 humans to low doses might be.

26
27 In addition to being the best-fit model to the Brachman data, the exponential model is consistent with the
28 result from Wilkening (2006), in that the shape of the exponential curve over a range of doses is
29 consistent with the spatial and temporal distribution of human cases observed after the Sverdlovsk
30 release. Furthermore, the exponential model is appealing because it can be derived from assumptions
31 about the mechanisms of the establishment of infection in the lungs, a general approach advocated by
32 several authors (e.g., Brookmeyer 2005; Gutting 2008; Coleman et al. 2008).

The exponential model assumes that the probability p of infection given an expected inhalation of d spores is given by $p = 1 - e^{-rd}$, where r is the fitted exponential parameter equal to 2.6×10^{-5} . The statistical uncertainty with respect to this parameter value in light of the data can be assessed using different techniques. The likelihood-based confidence interval presented in Table J–1a is an estimate based on assuming that properties of the likelihood of various parameter values in light of the data are well approximated by the χ^2 distribution. An alternative approach is to use a bootstrap procedure (Haas 1999), in which randomized bootstrap replicates of the data set are created and fit to the model to create a simulated uncertainty distribution of the parameter value. This technique creates a set of parameter values that can be sampled when conducting the uncertainty analysis for the overall initial infections risk analysis. When applied to the Brachman data, the bootstrap distribution of the r value results in an estimated 95 percent confidence interval of $(1.5 \times 10^{-5} \text{ to } 4.7 \times 10^{-5})$, which is slightly wider than the likelihood-based interval and therefore potentially more likely to contain the true value. For those reasons, the bootstrap distribution is applied for uncertainty analysis of this model for this RA.

At an expected dose of 600 spores, the chosen literature-based model estimates a probability of infection at about 1.5 percent (95 percent confidence range 0.9 to 2.8 percent). This estimate would appear to run counter to the conclusion by Cohen and Whalen (2007) that 600 spores can be used as threshold in risk analysis. For example, a risk assessment estimating a 1 percent infection rate for visitors to a contaminated building would likely not conclude that building is safe for the general public. However, closer examination of the authors' statements reveals that the 600 spore threshold is recommended for healthy individuals. It is not unreasonable to conservatively assume that 1 to 3 percent of a general population might be unusually predisposed or immunocompromised such that exposure to 600 spores or less could result in infection where it did not for populations of mill workers.

J.3.1.5 Dose-Response Estimates Derived from Expert Panel

In the procedure described in Section J.2.5.4, dose-response curves were fit to the ID_{10} , ID_{50} , and ID_{90} estimates provided by each expert on the Delphi panel. The results of this model fitting procedure are displayed in Table J–1b, including which curves were retained from each expert according to the BIC. Fourteen curves were retained for application in this RA, and plots of those curves are shown in Figure J–1. ID estimates provided by the retained curves are shown in Table J–1c.

Table J-1b: Dose-response model fitting for *Bacillus anthracis*

Expert	ID ₁₀ ID ₅₀ ID ₉₀	Exp. model	Log-probit model		Beta Poisson Model		$\Delta\text{BIC}^{\text{Exp}}$	$\Delta\text{BIC}^{\text{Lp}}$	$\Delta\text{BIC}^{\text{BP}}$
		r	m	ID ₅₀	α	β			
1	100 5,000 50,000	8.8×10^{-5}	0.66	6,300	1.3	9.3×10^3	5.2	0	1.7
2	4,000 30,000 100,000	2.4×10^{-5}	0.80	23,000	1.1×10^1	4.2×10^5	1.1	8.9	0
3	400 10,000 200,000	5.9×10^{-5}	0.41	9,300	5.1×10^{-1}	2.3×10^3	18.1	0	10.1
4	1,000 10,000 100,000	5.5×10^{-5}	0.56	10,000	8.9×10^{-1}	8.2×10^3	N/A	Exact	N/A
5	400 10,000 100,000	7.5×10^{-5}	0.46	7,400	6.5×10^{-1}	3.3×10^3	8.1	0	2.9
6	1,000 10,000 100,000	5.5×10^{-5}	0.56	10,000	8.9×10^{-1}	8.2×10^3	N/A	Exact	N/A
7	200 8,000 10,000	2.2×10^{-4}	0.66	2,500	3.5	1.4×10^4	0	1.7	1.0
8	500 8,000 300,000	5.2×10^{-5}	0.40	11,000	4.6×10^{-1}	2.1×10^3	17.1	6.6	0

Fitted parameters for three dose-response models to each set of three data points from each expert panelist. Optimal parameter values were rounded to two significant figures. ΔBIC is the Bayesian Information Criterion value relative to the lowest value in that row, where a lower value indicates that the model better represents the available information. Bolded values in the BIC columns indicate that the model for that column was kept in consideration for representing the data provided by the expert panelist in that row, and grey values indicate that the model was eliminated from consideration, generally because its value was more than six greater than the lowest BIC value in that row. ^a indicates that the beta Poisson model fit produced a curve virtually identical to the exponential model, so it was redundant to keep it in consideration. *Exact* entries indicate that the Log-probit model fit the expert panelist values in that row exactly (which results in a BIC value of negative infinity), so the other two models in that row are not applied (N/A). Abbreviations: Exp = Exponential model; Lp = Log-probit model; BP = Beta Poisson model.

Figure J-1

Plot of all dose-response curves retained from fitting models to the information provided by the experts as part of the Delphi process, used to estimate probability of infection for each dose. Solid curves are weighted with 1/8 probability; dashed curves are weighted with 1/16 probability; dotted curves are weighted with 1/24 probability.

Table J–1c. Results for retained expert-derived *B. anthracis* dose-response models

Expert	Model	ID ₅₀	ID ₁₀	ID ₁	ID _{0.1}	ID _{0.01}
1	Exp	7,900	1,200	110	11	1.1
	LP	6,300	890	180	56	22
	BP	6,700	800	73	7.3	0.73
2	Exp	29,000	4,400	420	41	4.1
	BP	28,000	4,200	400	39	3.9
3	LP	9,300	420	33	5.2	1.1
4	LP	10,000	1,000	150	39	13
5	LP	7,400	470	49	9.5	2.4
	BP	6,300	580	51	5.1	0.51
6	LP	10,000	1,000	150	39	13
7	Exp	3,200	480	46	4.6	0.46
	LP	2,500	360	72	23	8.6
	BP	3,000	420	39	3.9	0.39
8	BP	7,300	540	46	4.5	0.45
Median (Min–Max)		8600 org. (2500–29000)	690 (360–4400)	73 (33–420)	10 (3.9–56)	2.4 (0.39–22)

Results are listed for the models that were retained after applying the Bayesian information criterion for model comparison. Each ID_x result refers to the expected inhaled dose estimated to result in infection of x% of exposed individuals. For example, ID_{0.01} refers to the dose estimated to result in infection of 0.01%, or one in ten thousand individuals. The medians were calculated after weighing each of the eight experts equally and weighing each model equally within each expert if more than one was retained. Abbreviations: org. = organisms, Exp = exponential, LP = log-probit and BP = beta Poisson.

Note that the estimates derived from Expert 2 are close to the estimates derived from the chosen dose-response model from the literature. That can be explained by the fact that the expert was an author of the study in which the literature-based model was found and was of the opinion that this model is applicable to humans.

J.3.1.6 Other Considerations

It is possible that different strains of *B. anthracis* would have differing levels of infectivity. It is not known which strains would be studied at the NEIDL, nor is it known which strains occurred at the animal factories referenced in Brachman et al. (1966) and Cohen and Whalen (2007), nor is it known what strain or strains were released from the facility at Sverdlovsk. Also, no particular strain or strains were specified to the expert panel members as part of the Delphi process. It is assumed that the uncertainty regarding infectivity of differing strains is captured within the overall uncertainty range for the dose-response parameters.

The units of exposure for events analyzed in this RA for *B. anthracis* are in terms of CFU (colony-forming units), which is assumed to measure the expected number of infectious units with potential to reproduce when inhaled. CFU is not a measure of the absolute number of live cells in a sample, because individual cells may aggregate or clump to form one colony. The exposures reported in Brachman et al. (1966) are in terms of *B. anthracis*-bearing particles, which were quantified using calculations based on colony counts from collected air samples, so it is appropriate to apply the curve derived from these data. The expert panelists were asked to provide their ID estimates in terms of number of organisms. It is assumed that the expert values represent numbers of potentially infectious units, as estimated by CFU, and that it is appropriate to apply the curves derived from their estimates to the exposure estimates.

J.3.1.7 Summary of Approach

The following summarizes the two sets of dose-response estimates to be applied to exposure data for this RA. ID estimates for *B. anthracis* derived from these models are compared in Table J–1d .

- Literature-based dose-response model: the exponential model with parameter $r = 2.6 \times 10^{-5}$, as derived by Haas (2002) as a fit to low-dose NHP data reported by Brachman et al. (1966). Use a distribution of r values derived from bootstrap replicates of the data set, which results in a 95 percent range of $(1.5 \times 10^{-5} \text{ to } 4.7 \times 10^{-5})$, for uncertainty and sensitivity analyses.
- Range of dose-response models derived from the expert-provided values: the distribution of estimates shown in Table J–1c, with the model or set of models derived from each expert weighted equally.

Table J–1d. ID estimates and associated ranges for *B. anthracis*

Model	ID ₅₀	ID ₁₀	ID ₁	ID _{0.1}	ID _{0.01}
Literature-based	27,000 spores (15000–47000)	4,100 (2200–7100)	390 (210–680)	38 (21–68)	3.8 (2.1–6.8)
Expert-based	8,600 org. (2500–29000)	690 (360–4400)	73 (33–420)	10 (3.9–56)	2.4 (0.39–22)

Each ID_x result refers to the expected inhaled dose estimated to result in infection of x% of exposed humans. The literature-based ranges are the 95% intervals derived from the bootstrap parameter distribution; the actual range of values applied to the RA may be wider. The expert-based ranges are the minimum and maximum values from Table J–1c.

For each ID point displayed in Table J–1d, the expert-based range extends lower (higher risk) than the literature-based range. Both sets of estimates are applied to the exposure estimates in the initial infection

portions of this RA to determine the implications of each estimate for the overall risk posed by *B. anthracis*.

J.3.2 *Francisella tularensis*

Francisella tularensis (*F. tularensis*) is a bacterial organism that causes tularemia and has infected humans in both natural and laboratory settings as described in Chapter 3 and Appendix C. This section synthesizes the available dose-response information and derives a range of dose-response estimates to be applied to the exposure results from each of the event sequence analyses.

J.3.2.1 Routes of Exposure

The most common natural routes of exposure and infection with *F. tularensis* for humans include animal-related exposures such as insect bites and direct contact with infected blood or tissue from animals, as well as ingestion of contaminated food or water. Infection from inhaling contaminated dust is also possible. In the laboratory, it is assumed that infection is possible through any of the routes of exposure (inhalation, ingestion, direct contact, puncture, and animal-related). This section focuses on the inhalational route of exposure.

J.3.2.2 Vaccine and Prophylaxis

As of March 2011, none of the vaccines against tularemia that have been developed are approved by the U.S. Food and Drug Administration (FDA) (CDC 2011a). For this RA, it is assumed that no laboratory worker, facility worker, or member of the general public would be vaccinated against infection with *F. tularensis*. That is a conservative assumption because it is possible that some individuals (especially laboratory workers) would be partially protected from an administered vaccine that was previously available, a vaccine that might become FDA-approved in the future, or a vaccine that might be available before official FDA-approval, such as in the investigational new drug (IND) category. Currently, there is an IND vaccine against *F. tularensis* available for laboratory workers at any institution to request through the Special Immunizations Program at Ft. Detrick, MD (NRC 2011).

For individuals who have been exposed to aerosolized *F. tularensis* but are not yet showing symptoms, prophylactic treatment with antibiotics is recommended; for possible but unlikely exposures, increased vigilance for signs of fever and readiness to treat symptoms might be sufficient (WHO 2007). Antibiotics taken by exposed individuals may prevent infection if applied before symptoms appear. It is highly likely that recognized and reported mishaps in the laboratory involving *F. tularensis* would result in potentially exposed workers receiving the recommended prophylactic regimen, which could dramatically reduce the

probability of both infection and disease. However, this RA focuses on laboratory incidents that are most likely to be undetected, in which case prophylaxis would likely not be administered early enough to prevent infection. Those assumptions have no impact on the estimated risk posed by laboratory workers to the public, as *F. tularensis* is not transmissible person-to-person, whether or not a primary case develops symptomatic disease. If exposures occurred in the general public, it is possible that prophylactic treatment, if administered in time, would prevent infection and/or disease that would otherwise have occurred. This possibility would be more likely for exposed individuals experiencing a long incubation period. Those issues are discussed in more detail in the sections of this RA related to potential health consequences of specific events resulting in direct public exposure.

J.3.2.3 Dose-Response Information from the Literature

This section consists of a review and discussion of selected literature and information relating to the probabilistic estimates of infection for humans exposed to a given number of *F. tularensis* organisms via the inhalational route. The literature review was performed according to the methodology outlined in Chapter 3. This section concludes with a summary of the procedure for dose-response modeling of *F. tularensis* to be used in this RA, in light of the pathogen information and discussion provided here.

Human data and evidence

There is strong evidence that even small inhaled doses of *F. tularensis* can infect humans. The fact that infection of laboratory workers handling *F. tularensis* has been relatively common even in vaccinated employees, as referenced in Appendix C, suggests that this pathogen is highly infectious to humans and that relatively small inhaled doses might cause infection. Furthermore, data exist from published studies from the 1960s in which human volunteers were exposed to low inhaled doses of *F. tularensis* that resulted in subsequent infection and disease.

A study in which human volunteers were exposed to aerosolized doses (Saslaw 1961b) produced the following data: of 20 non-vaccinated men exposed, 16 (80 percent) subsequently developed disease symptoms and 4 (20 percent) did not. The raw data (Saslaw 1961b) are reproduced in Table J–2a, showing the dose inhaled by each of the 16 positive cases and 4 negative cases. Positive responses occurred after doses ranging from 10 to 52 organisms, and negative responses occurred after doses ranging from 10 to 45 organisms. Unless the measurement of the inhaled doses contained errors of a magnitude comparable to these ranges, the fact that the ranges overlap suggests that there is not a strict threshold to infection that applies to all humans.

Note that in a companion study (Saslaw 1961a), 12 non-vaccinated human volunteers were exposed to about 10 organisms of *F. tularensis* via intracutaneous inoculation on the right forearm, and all responded with local infection and eventually with mild to severe systemic disease. From that evidence, it is possible that the direct contact route of exposure results in a higher probability of infection than the inhalational route given the same dose. It is also possible that intracutaneous inoculation resulted in greater certainty that the intended and measured dose was received by each volunteer compared to the delivery of aerosols. Regardless, the inhalational route remains the focus of this dose response assessment, as inhalation of infectious particles is more likely to occur after a potential aerosol release from a NEIDL-related event. Direct contact exposure such as that which occurred in the study (Saslaw 1961a) would require organisms entering under a layer of skin of an exposed person, which would require exceptional circumstances to occur from an exposure to an aerosol. Scenarios in which individuals might be exposed to *F. tularensis* through a puncture or animal-related bite or scratch are considered separately in conjunction with the events relevant to those routes.

Table J–2a. Non-vaccinated human dose-response data (Saslaw 1961b) for *F. tularensis*

Challenge dose (organisms)	Number exposed	Number positive for disease
10	2	1
12	1	0
13	1	1
14	1	1
15	1	1
16	1	1
18	1	1
20	2	1
23	2	2
25	1	1
30	1	1
45	1	0
46	2	2
48	1	1
50	1	1
52	1	1

Tabulated from data presented in Saslaw et al. (1961b). The challenge dose was the measured number of inhaled organisms. Those showing symptoms of disease were deemed positive.

Another report (McCrumb 1961), also tabulated results for human volunteers exposed to aerosols of *F. tularensis*. All 10 non-vaccinated individuals exposed were subsequently positive for disease at doses of 20, 200, or 2000 organisms, as shown in Table J–2b.

Table J–2b. Non-vaccinated human dose-response data (McCrumb 1961) for *F. tularensis*

Challenge dose (organisms)	Number exposed	Number positive for disease
20	4	4
200	4	4
2,000	2	2

Tabulated from data presented in McCrumb (1961).
The challenge dose was the measured number of inhaled organisms. Those showing symptoms of disease were deemed positive.

In a third study of inhalational *F. tularensis* exposure of human volunteers (Sawyer 1966), subjects were exposed to aerosols that had been aged for 30, 60, 120, and 180 minutes. The study found that aerosols aged for more than 60 minutes resulted in significantly decreased infectivity, except at the highest doses. Aerosols aged 30 or 60 minutes resulted in five infections out of eight exposed to a dose of 150 inhaled organisms, two out of four at 350 organisms, and four out of four at 750 organisms.

Jones et al. (2005) pooled the human volunteer dose-response data from the three studies described above (Saslaw 1961b; McCrumb 1961; Sawyer 1966) into a single data set and fit dose response models to the data. They employed a non-parametric model function and two parametric functions, one based on the Weibull distribution (a two-parameter extension to the exponential model) and one based on the lognormal distribution (equivalent to the log-probit model). The authors used the latter two models to calculate extrapolated estimates of the probability of infection at lower doses, resulting in an estimate that 20 to 40 percent of a human population would become infected after inhaling a single *F. tularensis* organism.

Animal data and evidence

A recent study (Huang 2011) analyzed data sets from the literature for the responses of animals exposed to doses of *F. tularensis* and fit the data to mathematical dose response models. The study primarily focuses on data from monkeys (*Macaca mulatta*) exposed to variously sized aerosolized particles bearing *F. tularensis* (Day 1972). The smallest particles (2.1 μm) proved the most infectious, with doses between 5 and 65 organisms resulting in death of 14 out of 24 monkeys (see Table J–2c).

Table J–2c. Monkey (*Macaca mulatta*) dose-response data (Day 1972) for *F. tularensis*

Challenge dose (organisms)	Number exposed	Number of deaths
5	6	1
11	6	3
32	6	4
65	6	6

Data from Day and Berendt (1972) and analyzed in Huang and Haas (2011). The challenge dose was the measured number of inhaled organisms on 2.1µm particles.

Huang and Haas (2011) analyzed the data in table J–2c and fit them to time-dose-response models, which are extensions to dose-response models used to estimate the probability of infection by various times after initial exposure. The best-fit model for the smallest particle-size exposure data was the exponential model incorporating the Weibull distribution for time dependence. This model reduces to the exponential model described in Section J.2.5.1 for large times after exposure. The best fit exponential model parameter ($r = 0.056$) results in an estimated LD₅₀ of 12 organisms. The model estimates the probability of infection after an expected dose of one organism to be about 5 percent.

J.3.2.4 Literature-Based Dose Response Estimate

This section consists of a discussion of the dose-response data, evidence, and published models for *F. tularensis* outlined in the previous section and provides the literature-based dose-response estimate to be used for this RA.

The human dose-response data (Saslaw 1961b; McCrumb 1961; Sawyer 1966) described in the previous section provide evidence for the infectivity of low inhaled doses of *F. tularensis* in humans. Jones et al. (2005) fit these data to dose-response models that could be used to estimate probabilities of infection at even lower doses than were used in the original experiments. However, it was determined that the models provided by Jones et al. (2005) would not be appropriate for use in this RA for the following reasons.

- The data do not appear to be extensive enough to support dose-response model fitting, in that they do not reveal a statistically significant trend for increasing probability of infection with increasing dose. Specifically, a binomial regression model fit to the data does not produce a coefficient for the dose (or the logarithm of the dose) that is statistically significantly different than zero. Also, the Cochran-Armitage test of trend (Haas 1999) demonstrates that a null hypothesis of lack of

1 trend cannot be rejected. Those results do not mean that a dose-response trend does not exist for
2 humans; the data set is not large enough and/or does not consist of a wide enough range of doses
3 to allow an underlying trend to be revealed.

- 4 • The models used in Jones et al. (2005) do not provide a statistically acceptable fit to the data
5 according to a chi-squared test on the deviance (Haas 1999) at the given optimal parameter
6 values.
- 7 • The Weibull and lognormal models used by Jones et al. (2005) are not based on any assumed
8 biological mechanisms of infection or on any evidence that human susceptibility to infection
9 varies according to those underlying distributions.

10
11 Furthermore, it was determined that the results from one of the three human volunteer studies (Sawyer
12 1966) are not representative of exposure scenarios to be analyzed in this RA. In that study, the aerosols to
13 which the humans were exposed were aged for at least 30 minutes before exposure, whereas aerosols that
14 might be released in or from the NEIDL could reach a potential host substantially faster. For aerosols
15 aged 30 minutes, the study found that two of four humans inhaling 150 organisms and two of four
16 humans inhaling 350 organisms were not infected. While the fact that half the humans tolerated exposure
17 to such relatively high doses might be evidence that some humans are able to withstand a higher amount
18 of exposure, the results might also be explained by diminished infectivity of the aerosols due to aging.
19 Therefore, the application of these data to this RA could result in non-conservative conclusions
20 (underestimates of the risk).

21
22 The other two data sets (Saslaw 1961b; McCrumb 1961) shown in Tables J–2a and J–2b were pooled for
23 further analysis for this RA. The pooled data set also does not appear to be extensive enough to justify
24 dose-response model fitting on its own. Nevertheless, the human exposure data set can be analyzed in
25 conjunction with the NHP data and associated models. Namely, it can be tested whether or not the human
26 data set is consistent with a given NHP data set. The Day and Berendt (1972) monkey data set for the
27 smallest particle size and mortality response (Table J–2c) is an obvious candidate for comparison with the
28 human data, as both the range of doses applied and the proportion of subjects responding at similar doses
29 appear to be similar across the two data sets.

30
31 To confirm the apparent consistency between the Day and Berendt monkey data and the Saslaw et al. and
32 McCrumb human data, two different statistical procedures were applied. First, a binomial regression was
33 performed on the combined data set, employing coefficients for both the log-dose and a species factor

1 (monkey or human). The optimal coefficient for the species factor was not statistically significantly
2 different than zero (p-value approximately 0.2), which means the species of a randomly chosen individual
3 does not significantly influence a predictor for the probability of response at a given dose.

4
5 Second, a test was performed against a hypothesis that the two data sets come from a common dose-
6 response model. Specifically, as the monkey data were shown to be well fit by an exponential model
7 (Huang 2011), the hypothesis is that the human data set (for disease response) and the monkey data set
8 (for mortality response) come from an exponential dose-response model with the same parameter value
9 (the same value of r as described in Section J.2.5.1). The test is performed after fitting each of the two
10 individual data sets and also the combined data set using the method of maximum likelihood, which
11 chooses the optimal value of the exponential model parameter r that maximizes the probability of
12 observing each data set under the model. The results are shown in Table J–2d. The optimal value of r for
13 each data set is displayed along with a 95 percent confidence interval, which was generated using the
14 bootstrapping procedure described in Haas et al. (1999). The confidence intervals for each data set
15 overlap substantially.

16
17 To assess model fit acceptability, the optimal deviance (Haas 1999) for each model is shown and
18 compared to the upper 5th percentile of the χ^2 distribution with degrees of freedom equal to the number of
19 distinct doses in the data set minus the number of parameters in the exponential dose-response model (1).
20 A null hypothesis of fit acceptability cannot be rejected for any of the three data sets as each optimal
21 deviance is less than the corresponding χ^2 statistic. Finally, a procedure was performed to determine if the
22 data sets could be pooled, i.e., a test was performed on the hypothesis that the two data sets come from a
23 common dose-response model. If the difference between the optimal deviance for the combined data set
24 and the sum of the optimal deviances for the individual data sets is more than a given percentile of the χ^2
25 distribution with one degree of freedom, the hypothesis can be rejected (Haas 1999; Bartrand 2008;
26 Watanabe 2010). Table J–2d shows that pooling of data set A and B can be deemed acceptable under the
27 given statistical test.

Table J–2d. Model fitting for *F. tularensis* data sets

Data Set	Optimal r value (95% conf. interval)	Optimal Deviance	$\chi^2_{0.95, df}$	Acceptable fit?	Pooling acceptability test
A: Human (Saslaw 1961b; McCrumb 1961)	0.080 (0.040, 0.19)	$Y_A = 14$	28	YES	$Y_C - (Y_A + Y_B) = 1.6$ $\chi^2_{0.95, 1} = 3.8$ Acceptable to pool
B: Monkey (Day 1972)	0.047 (0.025, 0.11)	$Y_B = 1.3$	7.8	YES	
C: Pooled A and B	0.063 (0.040, 0.11)	$Y_C = 17$	33	YES	

Data set A shown in Tables J–2a and J–2b. Data set B shown in Table J–2c. Fit deemed acceptable if optimal deviance is less than the 95th percentile χ^2 statistic with degrees of freedom (df) equal to the number of dose points minus the number of model parameters: df = (17, 3, 21) for data sets (A, B, C), respectively. Pooling of data sets A and B to form data set C deemed acceptable if the difference between the optimal deviance for data set C and the sum of the optimal deviances for data sets A and B is less than the 95th percentile χ^2 statistic with one degree of freedom (df).

Given the results of the statistical comparison between the two data sets, the pooled data set C was determined to be appropriate to use as the basis for a literature-based model to use for application to human infection for this RA. The possibility that a different dose-response model other than the exponential model provides an improved fit the pooled data set was tested. The beta-Poisson model does not decrease the deviance from Y_C (shown in Table J–2d) enough to justify the additional parameter according to the χ^2 test described in Haas (1999). Therefore, the exponential model fit to the pooled data set shown in Table J–2d is retained for use in this RA.

The ID estimates derived from the model fits to the three data sets listed in Table J–2d are displayed in Table J–2e.

Table J–2e. ID estimates from three *F. tularensis* data sets

Data Set	Model	ID ₅₀	ID ₁₀	ID ₁
A: Human (Saslaw 1961b; McCrum 1961)	Exp	8.7 org. (3.7–17)	1.3 (0.57–2.6)	0.13 (0.054–0.25)
B: Monkey (Day 1972)	Exp	15 org. (6.6–28)	2.2 (1.0–4.2)	0.21 (0.096–0.40)
C: Pooled A and B	Exp	11 org. (6.1–18)	1.7 (0.93–2.7)	0.16 (0.089–0.25)

Each ID_x result refers to the expected inhaled dose estimated to result in infection of *x*% of exposed individuals. The ranges in parentheses are 95% confidence intervals based on model fits to bootstrap replicates from each data set. Exp = exponential model; org. = organisms. The model fit to data set C was chosen as the literature-based model for this RA, as described in Section J.3.2.4.

J.3.2.5 Dose-Response Estimates Derived from Expert Panel

In the procedure described previously, dose-response curves were fit to the ID₁₀, ID₅₀, and ID₉₀ estimates provided by each expert on the Delphi panel. The results of this model-fitting procedure for *F. tularensis* are displayed in Table J–2f, including which models were retained from each expert according to the BIC. Fourteen curves were retained for application in this RA, and plots of those curves are shown in Figure J–2. ID estimates provided by the retained curves are shown in Table J–2g.

Table J-2f: Dose response model fitting for *Francisella tularensis*.

Expert	ID ₁₀ ID ₅₀ ID ₉₀	Exp. Model	Log-probit model		Beta Poisson model		$\Delta\text{BIC}^{\text{Exp}}$	$\Delta\text{BIC}^{\text{Lp}}$	$\Delta\text{BIC}^{\text{BP}}$
		r	m	ID ₅₀	α	β			
1	100 500 1,000	1.5×10^{-3}	1.11	370	1.0×10^5	6.7×10^7	1.3	0	2.4 ^a
2	2 12 41	5.5×10^{-2}	0.85	10	1.0×10^6	1.8×10^7	0	8.5	1.1 ^a
3	10 40 2,000	1.3×10^{-2}	0.86	43	2.2×10^1	1.7×10^3	7.4	0	8.5
4	5 10 100	3.2×10^{-2}	0.86	17	4.3	1.2×10^2	1	0	2
5	4 40 200	1.7×10^{-2}	0.66	32	1.6	6.6×10^1	6.4	3.2	0
6	4 40 400	1.4×10^{-2}	0.56	40	8.9×10^{-1}	3.3×10^1	N/A	Exact	N/A
7	10 50 1,000	7.0×10^{-3}	0.56	79	7.8×10^{-1}	5.2×10^1	5.0	0.8	0
8	20 50 200	9.4×10^{-3}	1.11	58	1.0×10^5	1.1×10^7	6.9	0	8

Fitted parameters for three dose response models to each set of three data points from each expert panelist. Optimal parameter values were rounded to two significant figures. ΔBIC is the Bayesian Information Criterion value relative to the lowest value in that row, where a lower value indicates that the model better represents the available information. Bolded values in the BIC columns indicate that the model for that column was kept in consideration for representing the data provided by the expert panelist in that row, and grey values indicate that the model was eliminated from consideration, generally because its value was more than six greater than the lowest BIC value in that row. ^a indicates that the Beta Poisson model fit produced a curve virtually identical to the exponential model, so it was redundant to keep it in consideration. *Exact* entries indicate that the Log-probit model fit the expert panelist values in that row exactly (which results in a BIC value of negative infinity), so the other two models in that row are not applied (N/A). Abbreviations: Exp = Exponential model; Lp = Log-probit model; BP = Beta Poisson model.

Figure J-2

Plot of all retained dose response curves used to estimate probability of infection for each dose. Solid curves were weighted with 1/8 probability; dashed curves were weighted with 1/16 probability; dotted curves were weighted with 1/24 probability.

Table J–2g. Results for retained expert-derived *F. tularensis* dose-response models

Expert	Model	ID ₅₀	ID ₁₀	ID ₁
1	Exp	460	70	6.7
	LP	370	120	46
2	Exp	12	1.9	0.18
3	LP	43	9.6	2.8
4	Exp	21	3.3	0.31
	LP	17	3.8	1.1
	BP	21	2.9	0.28
5	LP	32	4.5	0.91
	BP	35	4.4	0.41
6	LP	40	4.0	0.61
7	Exp	100	15	1.4
	LP	79	7.9	1.2
	BP	73	7.4	0.66
8	LP	58	18	7.2
Weighted Average (Min–Max)		42 org. (12–460)	6.0 (1.9–120)	1.0 (0.18–46)

Results are listed for the models that were retained after applying the Bayesian information criterion for model comparison. Each ID_x result refers to the expected inhaled dose estimated to result in infection of x% of exposed individuals. For example, ID_{0.01} refers to the dose estimated to result in infection of 0.01%, or one in ten thousand individuals. The medians were calculated after weighing each of the eight experts equally and weighing each model equally within each expert if more than one was retained. Abbreviations: org. = organisms, Exp = exponential, LP = log-probit and BP = beta Poisson.

Note that the estimates derived from Expert 2 are close to the estimates derived from the dose-response derived from the literature. That can be explained by the fact that this expert was an author of one of the studies on which the literature-based model was based and was of the opinion that the associated NHP data are applicable to humans.

J.3.2.6 Other Considerations

The data reported in Day and Berendt (1972) and modeled in Huang and Haas (2011) demonstrate that the infectivity of inhaled *F. tularensis* in NHPs can be highly dependent on the size of the aerosolized particles bearing the organisms, with smaller particles resulting in higher probability of infection. The results reported in Section J.3.2.3 are for the smallest particle size tested (2.1 µm), while 7.5-µm particles produced an estimated LD₅₀ roughly 44 times higher (Huang 2011). The human volunteer data referenced in Section J.3.2.3 were generated from exposures to aerosols with an average particle diameter of 0.7µ

(Saslaw 1961b). For this RA, exposure estimates are generally assumed to be relevant for particles less than 10 µm in diameter (see Chapter 4), which means that applying the results derived from exposures to only 2.1 µm or 0.7µm particles could significantly overestimate risk. However, it is possible that specific instances of aerosol releases might produce mostly small particles to which laboratory workers or members of the public could be exposed, so it was determined to be appropriate to conservatively assume that the infectivity from small particles is relevant for the events analyzed in this RA.

J.3.2.7 Summary of Approach

The following summarizes the two sets of dose-response estimates to be applied to exposure data for this RA. ID estimates derived from these models are compared in Table J–2h.

- Literature-based dose-response model: The exponential model with $r = 6.3 \times 10^{-2}$. Use a distribution of r values derived from bootstrap replicates of the pooled data set, which results in a 95 percent range of (3.9×10^{-2} to 1.1×10^{-1}), for uncertainty and sensitivity analyses.
- Range of dose-response models derived from the expert-provided values: the distribution of estimates shown in Table J–2g, with the model or set of models derived from each expert weighted equally.

Table J–2h. ID estimates and associated ranges for *F. tularensis*

Model	ID ₅₀	ID ₁₀	ID ₁
Literature-based	11 org. (6.1–18)	1.7 (0.93–2.7)	0.16 (0.089–0.25)
Expert-based	42 org. (12–460)	6.0 (1.9–120)	1.0 (0.18–46)

Each ID_x result refers to the expected inhaled dose estimated to result in infection of x% of exposed humans. The literature-based ranges are the 95% intervals derived from the bootstrap parameter distribution; the actual range of values applied to the RA may be wider. The expert-based ranges are the minimum and maximum values from Table J–2g. org. = organisms.

For each ID point displayed in Table J–2h, the literature-based range extends lower (higher risk) than the expert-based range. Both sets of estimates are applied to the exposure estimates in the initial infection portions of this RA to determine the implications of each estimate for the overall risk posed by *F. tularensis*.

J.3.3 *Yersinia pestis*

Yersinia pestis (*Y. pestis*) is a bacterial organism that causes plague and has infected humans in both natural and laboratory settings as described in Chapter 3 and Appendix C. This section synthesizes the available dose-response information and derives a range of dose-response estimates to be applied to the exposure results from each of the event sequence analyses.

J.3.3.1 Routes of Exposure

One natural route of exposure and infection in humans is animal-related through bites of infected fleas or bites or scratches from other infected animals. Those types of animal-related exposures can cause primary bubonic plague or, more rarely, primary septicemic plague. Another natural route of exposure and infection in humans is inhalation of droplets containing the bacteria, which can cause primary pneumonic plague. Inhalational exposure can occur from close contact with an animal or human having primary or secondary pneumonic plague (for references, see Chapter 3 and Appendix C).

Infections resulting from laboratory activities are assumed to be possible via inhalation, ingestion, direct contact, puncture, and animal-related (NHP, rodent, and insect) routes. The primary focus of this section is the inhalational route, in support of the events analyzed in this RA that lead to aerosol releases in the laboratory or outside the NEIDL. The inhalational route is especially important to consider for this RA because it could lead directly to the pneumonic form of plague, which in turn could lead to secondary transmission from an initially infected laboratory worker or member of the public. Infections from other routes of exposure would most likely lead to primary bubonic plague, which is not transmissible unless a severe or untreated case leads to secondary pneumonic plague. Non-inhalational routes of exposure and their potential consequences are considered separately and as needed in conjunction with relevant events.

J.3.3.2 Vaccine and Prophylaxis

Plague vaccines have been administered to high-risk workers in the past, but as of mid-2011, none were available for civilian use in the United States (CDC 2011b). For this RA, it is assumed that no potentially exposed laboratory worker, facility worker, or member of the general public would be vaccinated against infection with *Y. pestis*. That is a conservative assumption because it is possible that some individuals (especially laboratory workers) would be partially protected from an administered vaccine that was previously available, that could become FDA-approved in the near future, or that could be available before official FDA-approval, such as those classified as an IND.

For individuals who have possibly been exposed to aerosolized *Y. pestis* but are not yet showing symptoms, prophylactic treatment with antibiotics is recommended. Antibiotics taken by exposed individuals could prevent infection if applied before symptoms appear. It is highly likely that recognized and reported mishaps in the laboratory involving *Y. pestis* would result in potentially exposed workers receiving the recommended prophylactic regimen, which could dramatically reduce the probability of both infection and disease. However, this RA focuses on laboratory incidents that are most likely to be undetected, in which case prophylaxis would likely not be administered early enough to prevent infection. If exposures occurred in the general public, it is possible that prophylactic treatment, if administered in time, would prevent infection and/or disease that would otherwise have occurred. That possibility would be more likely for exposed individuals experiencing a long incubation period. Those issues are discussed in more detail within the sections of this RA related to potential health consequences of specific events resulting in direct public exposure.

J.3.3.3 Dose-Response Information from the Literature

Human evidence

No direct human dose-response data for *Y. pestis* are available in the literature. The infective dose for humans exposed to *Y. pestis* aerosols has been stated to be between 100–500 organisms (Franz et al. 1997), although it is unlikely that those numbers were derived from actual human data. Epidemiological information from human outbreaks of pneumonic plague have led to estimates of a low attack rate, with approximately 8 percent of close, unprotected contacts of symptomatic primary cases becoming secondarily infected (Begier 2006; Ratsitorahina 2000). That low attack rate could be interpreted as evidence that IDs for humans via inhalation are relatively high; alternatively, the low attack rate could be explained by the possibility that the primary cases did not produce a large number of aerosolized infectious particles that could be inhaled by their close contacts during their symptomatic period.

NHP data

In one study (Speck 1957), unimmunized rhesus monkeys (*Macaca mulatta*) were exposed to aerosolized *Y. pestis* in a cloud chamber with average doses ranging from 140 to 1,500,000 inhaled organisms (Table J–3a). In a recent study (Huang 2010), those data were fit to the exponential, log-probit, and beta Poisson dose-response models and the beta Poisson model with $\alpha = 6.5 \times 10^{-1}$ and $\beta = 8.0 \times 10^3$ (rounded to two significant figures) provided the best fit. The best-fit model provides an estimated LD₅₀ of 15,000 organisms, an LD₁₀ of 1,400 organisms, and an LD₁ of 120 organisms (rounded to two significant figures). The estimated LD₁ is close to the lowest dose to which monkeys were actually exposed; however, it should be noted that all eight monkeys exposed to an average dose of 140 organisms survived.

The lowest average dose that caused death of a monkey was 580 inhaled organisms (one death out of 19 exposed). It is also noteworthy that 2 of 14 monkeys survived without treatment after exposure to the highest average dose of 1,500,000 inhaled organisms.

Table J–3a. Monkey (*Macaca mulatta*) dose-response data (Speck 1957) for *Y. pestis*

Challenge Dose (organisms)	Number exposed	Number of deaths
140	8	0
580	19	1
1,500	21	1
5,800	15	4
23,000	33	19
63,000	25	21
200,000	33	32
500,000	14	12
1,500,000	14	12

Data from Speck and Wolochow (1957) and analyzed in Huang and Haas (2011). The challenge dose was the average number of inhaled organisms in each group.

Ehrenkranz and Meyer (1955) exposed unimmunized rhesus monkeys (*Macaca mulatta*) to intratracheal doses of *Y. pestis* ranging from 10 to up to 270 million organisms (Table J–3b). Two monkeys were exposed to the lowest dose of 10 organisms and both survived, while more than half (8 out of 12) died after exposure to the next lowest dose range of 120–170 organisms. It is again noteworthy that a small fraction of monkeys survived without treatment after exposure to doses several orders of magnitude higher than doses that were lethal to other monkeys.

Table J–3b. Monkey (*Macaca mulatta*) dose-response data (Ehrenkranz 1955) for *Y. pestis*

Challenge Dose (organisms)	Number exposed	Number of deaths
10	2	0
120–270	12	8
800–2,700	18	17
9,500–12,000	18	17
120,000–270,000,000	10	9

Data from Ehrenkranz and Meyer (1955). The challenge dose was the measured number of organisms delivered via intratracheal inoculation.

It appears that dose-response model fitting to the data in Table J–3b has not been attempted, most likely because the doses to which the monkeys were exposed are not reported precisely (particularly at the highest dose range). However, it is clear that the data suggest an LD₅₀ significantly lower than the LD₅₀ of about 15,000 organisms suggested by the Speck and Wolochow data. Speck and Wolochow (1957) include a discussion in their report about possible reasons for the different results in the two studies, which is presented in Section J.3.3.4.

J.3.3.4 Literature-Based Dose Response Estimate

This section consists of a discussion of the dose-response data, evidence, and published models for *Y. pestis* outlined in the previous section and provides the literature-based dose-response estimate to be used for this RA.

Without human dose-response data for *Y. pestis*, experimental studies involving NHPs provide the best available data from which to gain insights into potentially appropriate dose-response relationships for humans. Results from exposure of rhesus monkeys to aerosolized *Y. pestis* (Speck 1957) appear to be the only inhalational dose-response data that have been fit to dose response models (Huang 2010), and the beta Poisson model outperformed the other candidate models, producing estimated LD values shown in Table J–3c.

Another monkey data set (Ehrenkranz 1955) has not been fit to dose-response models but appears to suggest an LD₅₀ roughly two orders of magnitude lower than that estimated for the Speck and Wolochow data set (see Table J–3c). Such a significant difference can likely be explained by the fact that the two studies used different procedures for administering doses to the monkeys. In the Speck and Wolochow study, the monkeys inhaled aerosolized *Y. pestis* in a chamber, while in the Ehrenkranz and Meyer study,

the doses were delivered directly to each monkey's windpipe through intratracheal intubation. Of these two methods, inhalation of aerosolized *Y. pestis* is more consistent with types of exposure that might occur under events analyzed for this RA. Furthermore, the following passage from the discussion section of Speck and Wolochow (1957, pp. 65–67) is illuminating:

Other methods of inducing pneumonic infections, on the other hand, involve the artifacts of anaesthesia (and its effects on pulmonary physiology), intratracheal intubation where trauma may actually lead to submucosal injection, and instillation of fluid which may for some time supply the organisms with culture medium outside the normal defense mechanisms of the host. This seems especially significant with *Past. pestis* which is much more virulent when injected into tissue, and which multiplies enormously in the alveoli in the early stages of the pneumonic infection.

Because the method of delivery used in the Ehrenkranz and Meyer study might have significantly increased the ability of the *Y. pestis* organisms to reproduce in the early stages of infection beyond what would occur in a more natural inhalation scenario, it was determined that the model fit to the Speck and Wolochow data would be more appropriate to use as the literature-based dose-response assessment for this RA.

Table J–3c. LD estimates (with 95% confidence intervals) for NHPs from *Y. pestis* dose-response models from the literature

Set	Animal	Model	LD ₅₀	LD ₁₀	LD ₁	LD _{0.1}	LD _{0.01}
A	<i>Macaca mulatta</i> (Speck 1957; Huang 2010)	BP	15,000 org. (8,200–37,000)	1,400 (540–4100)	120 (45–370)	12 (4.5–37)	1.2 (0.45–3.7)
B	<i>Macaca mulatta</i> (Ehrenkranz 1955)	none	<≈ 300 org.				

Each LD_x result refers to the expected inhaled dose estimated to result in death of x% of exposed animals. For example, LD_{0.01} refers to the dose estimated to result in death of 0.01%, or one in ten thousand animals. BP = beta Poisson; org. = organisms. For data set A, the 95% confidence intervals are based on model fits to bootstrap replicates from the data set. For data set B, the data were not fit to a model and the LD₅₀ upper bound estimate is based on the result that 8 of 12 monkeys died from exposure to 120–270 organisms. The model fit to data set A was chosen as the literature-based model for this RA.

There are several possible objections to relying on the estimates for data set A in Table J–3c as estimates for probabilities of human infection:

- Speck and Wolochow (1957) acknowledge the difficulty of calculating the individual doses inhaled by each exposed monkey in their experiment and advise caution in drawing conclusions from quantitative results.
- Franz et al. (1997) state that the human *infective dose* for aerosolized *Y. pestis* is 100–500 organisms. The monkey data-based model (data set A) estimates 0.8 percent (0.3–3 percent) probability of infection at 100 organisms and 4 percent (1–10 percent) probability of infection at 500 organisms. While technically those estimates are consistent with the Franz et al. statement in that 100–500 organisms would be an ID for some humans, it is possible that Franz et al. were implying a range for the HID_{50} , in which case the monkey data-based estimates are non-conservative (estimate lower risk) by comparison. Other authors have used working estimates of about 100 organisms for the HID_{50} (e.g., Sabelnikov 2006). However, without knowing the basis for the estimates, it is impossible to judge whether they are based on relevant data or arguments that conflict with the results from data set A.
- It is not known if there are significant species differences between monkeys and humans with respect to susceptibility to infection with *Y. pestis*. The heterogeneity in susceptibility displayed by the monkeys in each cited experiment and captured by the beta Poisson dose-response model is notable; presumably a random population of humans would be relatively heterogeneous compared to a population of laboratory monkeys, so application of the beta Poisson model form is presumed to be appropriate. However, the specific probabilities of infection estimated at given doses by the model could overestimate or underestimate the risk of infection to humans. Evidence of low attack rates for close contacts of symptomatic human pneumonic plague patients (see Section J.3.3.3) might suggest that the probability of infection at low inhaled doses is relatively low for humans and consistent with the model estimates, but there are no direct data to support this.

J.3.3.5 Dose-Response Estimates Derived from Expert Panel

In the procedure described previously, dose-response curves were fit to the ID_{10} , ID_{50} , and ID_{90} estimates provided by each expert on the Delphi panel. The results of this model fitting procedure for *Y. pestis* are displayed in Table J–3d, including which models were retained from each expert according to the BIC. Seventeen curves were retained for application in this RA, and plots of those curves are shown in Figure J–3. ID estimates provided by the retained curves are shown in Table J–3e.

Table J–3d: Dose response model fitting for *Yersinia pestis*

Expert	ID ₁₀ ID ₅₀ ID ₉₀	Exp. model	Log-probit model		Beta Poisson Model		ΔBIC ^{Exp}	ΔBIC ^{Lp}	ΔBIC ^{BP}
		<i>r</i>	<i>m</i>	ID ₅₀	<i>α</i>	<i>β</i>			
1	100 500 5,000	8.8×10^{-4}	0.66	630	1.3	9.3×10^2	5.2	0	1.7
2	700 8,000 130,000	6.1×10^{-5}	0.49	9,000	6.6×10^{-1}	4.2×10^3	20.0	6.8	0
3	200 4,000 40,000	1.7×10^{-4}	0.48	3,200	6.9×10^{-1}	1.6×10^3	9.2	0	3
4	100 1,000 1,500	1.0×10^{-3}	0.95	530	1.0×10^5	9.6×10^7	0	3	1.1 ^a
5	200 5,000 30,000	1.8×10^{-4}	0.51	3,100	8.3×10^{-1}	2.2×10^3	4.1	0	1
6	400 4,000 40,000	1.4×10^{-4}	0.56	4,000	8.9×10^{-1}	3.3×10^3	N/A	Exact	N/A
7	100 100,000 1,000,000	2.6×10^{-5}	0.28	22,000	3.3×10^{-1}	1.5×10^3	4.3	0	2.5
8	250 4,000 30,000	1.8×10^{-4}	0.54	3,100	8.7×10^{-1}	2.4×10^3	7.1	0	1.2

Fitted parameters for three dose response models to each set of three data points from each expert panelist. Optimal parameter values were rounded to two significant figures. ΔBIC is the Bayesian Information Criterion value relative to the lowest value in that row, where a lower value indicates that the model better represents the available information. Bolded values in the BIC columns indicate that the model for that column was kept in consideration for representing the data provided by the expert panelist in that row, and grey values indicate that the model was eliminated from consideration, generally because its value was more than six greater than the lowest BIC value in that row. ^a indicates that the Beta Poisson model fit produced a curve virtually identical to the exponential model, so it was redundant to keep it in consideration. *Exact* entries indicate that the Log-probit model fit the expert panelist values in that row exactly (which results in a BIC value of negative infinity), so the other two models in that row are not applied (N/A). Abbreviations: Exp = Exponential model; Lp = Log-probit model; BP = Beta Poisson model.

Figure J-3

Plot of all retained dose response curves used to estimate probability of infection for each dose. Solid curves were weighted with 1/8 probability; dashed curves were weighted with 1/16 probability; dotted curves were weighted with 1/24 probability.

Table J–3e. Results for retained expert-derived *Y. pestis* dose-response models

Expert	Model	ID ₅₀	ID ₁₀	ID ₁	ID _{0.1}	ID _{0.01}
1	Exp	790	120	11	1.1	0.11
	LP	630	89	18	5.6	2.2
	BP	670	80	7.3	0.7	0.073
2	BP	7,700	720	64	6.3	0.63
3	LP	3,200	220	26	5.3	1.5
	BP	2,800	270	24	2.3	0.23
4	Exp	670	100	9.7	0.96	0.096
	LP	530	140	45	20	10
5	Exp	3,900	590	57	5.6	0.56
	LP	3,100	250	33	7.4	2.2
	BP	2,900	300	27	2.7	0.27
6	LP	4,000	400	61	16	5.0
7	Exp	27,000	4,100	390	39	3.9
	LP	22,000	220	5.0	0.32	0.034
	BP	11,000	580	47	4.6	0.46
8	LP	3,100	280	40	9.7	3.0
	BP	3,000	310	28	2.8	0.28
Weighted Average (Min–Max)		3100 org. (530–27000)	280 (80–4100)	37 (5.0–390)	5.6 (0.32–39)	0.63 (0.034–10)

Results are listed for the models that were retained after applying the Bayesian information criterion for model comparison. Each ID_x result refers to the expected inhaled dose estimated to result in infection of x% of exposed individuals. For example, ID_{0.01} refers to the dose estimated to result in infection of 0.01%, or one in ten thousand individuals. The medians were calculated after weighing each of the eight experts equally and weighing each model equally within each expert if more than one was retained. Abbreviations: org. = organisms, Exp = exponential, LP = log-probit and BP = beta Poisson.

J.3.3.6 Other Considerations

It is possible that different strains of *Y. pestis* would have differing levels of infectivity. The strain used in the study for the literature-based model was *I39L* (Speck 1957). It is not known which strains would be studied at the NEIDL, and no particular strain or strains were specified to the expert panel members as part of the Delphi process. It is assumed that the uncertainty regarding infectivity of differing strains is captured within the overall uncertainty range for the dose-response parameters.

The units of exposure for events analyzed in this RA for *Y. pestis* are in terms of CFU (colony-forming units), which is assumed to measure the expected number of infectious units with potential to reproduce when inhaled. CFU is not a measure of the absolute number of live cells in a sample, because individual cells may aggregate or clump to form one colony. This potential heterogeneous distribution of cells among airborne particles in a dose is accounted for by the beta Poisson dose-response model, which

assumes a Poisson-distributed number of organisms around the expected dose (see Section J.2.5.1). The exposures reported in Speck and Wolochow (1957) are in terms of *Y. pestis* organisms, which were quantified using calculations based on colony counts from collected air samples, so it is appropriate to apply the curve derived from these data.

The expert panelists were asked to provide their ID estimates in terms of number of organisms. It is assumed that the expert values represent numbers of potentially infectious units, as estimated by CFU, and that it is appropriate to apply the curves derived from their estimates to the exposure estimates.

J.3.3.7 Summary of Approach

The following summarizes the two sets of dose-response estimates to be applied to *Y. pestis* exposure data for this RA. ID estimates derived from these models are compared in Table J–3f.

- Literature-based dose-response model: The beta Poisson dose-response model with $\alpha = 6.5 \times 10^{-1}$ and $\beta = 8.0 \times 10^3$. Use a distribution of (α, β) pairs derived from bootstrap replicates of the pooled data set, for uncertainty and sensitivity analyses.
- Range of dose-response models derived from the expert-provided values: the distribution of estimates shown in Table J–3e, with the model or set of models derived from each expert weighted equally.

Table J–3f. ID estimates and associated ranges for *Y. pestis*

Model	LD ₅₀	LD ₁₀	LD ₁	LD _{0.1}	LD _{0.01}
Literature-based	15,000 org. (8200–36000)	1,400 (530–4000)	120 (44–370)	12 (4.4–37)	1.2 (0.44–3.7)
Expert-based	3,100 org. (530–27000)	280 (80–4100)	37 (5.0–390)	5.6 (0.32–39)	0.63 (0.034–10)

Each ID_x result refers to the expected inhaled dose estimated to result in infection of x% of exposed humans. The literature-based ranges are the 95% intervals derived from the bootstrap parameter distribution; the actual range of values applied to the RA may be wider. The expert-based ranges are the minimum and maximum values from Table J–3e. org. = organisms.

For each ID point displayed in Table J–3f, the expert-based range extends lower (higher risk) than the literature-based range. Both sets of estimates are applied to the exposure estimates in the initial infection portions of this RA to determine the implications of each estimate for the overall risk posed by *Y. pestis*.

J.3.4 1918 H1N1 Influenza Virus

1918 H1N1 influenza virus (1918 H1N1V) is a strain of influenza A virus that caused a worldwide human influenza pandemic in 1918–1919, as described in Chapter 3 and Appendix C. Descendent lineages of 1918 H1N1V persist naturally in the human population today but differ in pathogenicity from the 1918 parent virus (Taubenberger 2006). 1918 H1N1V was reconstructed in 2005 (Tumpey 2004) and has since been studied in laboratories. This section synthesizes the available dose-response information and derives a range of dose-response estimates to be applied to the exposure results from each of the event sequence analyses.

J.3.4.1 Routes of Exposure

The primary natural routes of exposure and infection for humans to influenza viruses, including 1918 H1N1V, are assumed to be inhalation of aerosols or droplets and direct contact through handling of contaminated fomites. Infections resulting from laboratory activities are assumed to be possible via inhalation, ingestion, direct contact, puncture, and animal-related (NHP and rodent) routes. The inhalational and direct contact (intranasal) routes are the primary focus of the dose-response assessment in this section. The ingestion route is assumed to require an equal or higher dose to achieve the same probability of infection as compared to the inhalational route. The puncture and animal-related routes are discussed separately in conjunction with the event sequences for which those routes are relevant.

J.3.4.2 Vaccine and Prophylaxis

No vaccine is available that is designed to protect specifically against 1918 H1N1V. Seasonal influenza vaccines are licensed by FDA and are available to laboratory workers and the general public on a yearly basis. The seasonal vaccine is updated each year to protect against strains predicted to be most common in the upcoming flu season, normally including a strain of H1N1 virus. The efficacy of any particular seasonal vaccine against 1918 H1N1V for humans is not known; however, there is evidence that individuals who had received previous seasonal vaccines were moderately protected against the 2009 H1N1 pandemic influenza virus (Johns 2010). In addition, the 2009 H1N1 pandemic influenza vaccine, which was included in the most recent 2010–2011 seasonal vaccine, was shown to be effective in protecting mice against 1918 H1N1V (Medina 2010). It is also to be noted that older individuals who had experienced prior influenza pandemics were at least partially protected from the 2009 H1N1 strain (Ikonen 2010).

Given the evidence above, it is possible that any laboratory worker or member of the general public who had received previous H1N1 vaccines or had recovered from an H1N1 virus infection would be at least

1 partially protected from infection after exposure to 1918 H1N1V. It is noted in Section J.3.4.3 that the
2 human dose-response data for influenza viruses are generally limited to individuals who were shown to
3 lack protective antibodies to the given strain before experimental exposure, which may contribute to
4 overestimating the probability of infection for a general population that likely includes individuals with
5 some level of protection. This issue is discussed further in the summary Section J.3.4.7. It is assumed the
6 experts who provided ID estimates for 1918 H1N1V (Section J.3.4.5) took into account their estimates for
7 portions of the population who may be partially protected, and no adjustments to the models derived from
8 their estimates are made. For laboratory acquired infection LAI scenarios, it is conservatively assumed
9 that laboratory workers would be protected due to past infections or immunizations with the same
10 probability as a random member of the general public. This assumption is conservative because it is likely
11 that a worker assigned to handle 1918 H1N1V would be especially encouraged to receive all available
12 influenza vaccinations.

13
14 Chemoprophylaxis with antiviral agents has been shown to be effective in preventing influenza illness
15 among individuals who were likely exposed and is recommended for individuals at high risk for
16 complications who have not been immunized and are likely to be exposed (CDC 2011c). It is likely that
17 recognized and reported mishaps in the laboratory involving 1918 H1N1V would result in potentially
18 exposed workers receiving antiviral medication, which may or may not be effective in preventing
19 infection or disease. However, this RA focuses on laboratory incidents that are most likely to be
20 undetected, in which case prophylaxis would likely not be administered early enough to prevent infection.
21 If exposures occurred in the general public, it is possible that prophylactic treatment, if administered in
22 time, would prevent infection and/or disease that would otherwise have occurred. This possibility might
23 be more likely for exposed individuals experiencing a long incubation period. These issues are discussed
24 in more detail within the sections of this RA related to potential health consequences of specific events
25 resulting in direct public exposure.

26 27 **J.3.4.3 Dose-Response Information from the Literature**

28 There are no direct human dose-response data for 1918 H1N1V. There are numerous data sets from
29 experimental human exposures to other strains of influenza virus, including H1N1 strains. Carrat et al.
30 (2008) performed an extensive literature search of human volunteer studies on influenza and reviewed
31 results reported in 71 papers, which were published between 1965 and 2005. They selected for statistical
32 analysis only those subgroups of volunteers who had been tested for antibodies and met criteria for being
33 considered unprotected from infection before exposure. The resulting data set represents 61 subgroups

consisting of 1009 participants challenged with given doses of influenza A/H1N1, A/H3N2, A/H2N2, or influenza B.

The dose-response data for human infection (Carrat 2008) for influenza A/H1N1, the strains that are presumably closest to 1918 H1N1V, are compiled in Table J–4a.

Table J–4a. Human volunteer dose-response data (Carrat 2008) for influenza A/H1N1

Challenge dose (log ₁₀ TCID ₅₀)	Number exposed	Number infected	Percent infected
4	21	17	81.0%
4.5	9	8	88.9%
5	103	91	88.3%
6	79	66	83.5%
6.4	28	26	92.9%
6.7	22	20	90.9%
7	207	198	95.7%

Data from Carrat et al. (2008); see references therein for source studies. The challenge doses listed are in units of base-10 logarithm (log₁₀) of the median tissue culture infective dose (TCID₅₀). The exposure route for all groups contained in this table was intranasal.

The lowest dose listed in Table J–4a is 10,000 TCID₅₀ (median tissue culture infective dose³), so these data provide only indirect information on the likely response of humans to exposure at much lower doses, for example, doses on the order of one TCID₅₀. The Carrat et al. (2008) literature review found only one study in which humans were exposed to very low doses (Alford 1966) via the inhalational route. The strain of influenza used in this study was influenza A/Bethesda/10/63 (H2N2). In the study, eleven volunteers who were previously unprotected from the virus (according to the protection criteria used by Carrat et al.) inhaled 1, 2, or 5 TCID₅₀ of the virus and six were subsequently infected. See Table J–4b for details.

³ In the terminology used for this RA, TCID₅₀ is termed CCID₅₀ (median cell culture infectious dose). In Section 3.4.3, the units as reported by the cited authors are retained. In future sections where the data are used for analysis, the term CCID₅₀ is used to maintain consistency with the rest of the RA.

Table J–4b. Unprotected human volunteer dose-response data (Alford 1966) for influenza A/H2N2

Challenge dose (TCID ₅₀)	Number exposed	Number infected
1	1	1
2	4	1
5	6	4

TCID₅₀ = median tissue culture infective dose

J.3.4.4 Literature-Based Dose-Response Estimate

This section consists of a discussion of the dose-response data and evidence for 1918 H1N1V and other strains of influenza virus outlined in the previous section and provides the literature-based dose-response estimate to be used for this RA.

The data in Table J–4a were tested for dose-response behavior (i.e., increasing probability of infection with increasing dose). The Cochran-Armitage test of trend concludes that a null hypothesis of lack of trend can be rejected ($p < 0.002$), which means that it is appropriate to attempt dose-response model fitting to these data (Haas 1999). The exponential, log-probit, and beta Poisson models were fit to the data using the method of maximum likelihood, which chooses optimal values that maximizes the probability of observing each data set under the model. The results are shown in Table J–4c. To assess model fit acceptability, the optimal deviance (Haas 1999) for each model is shown and compared to the upper 5th percentile of the χ^2 distribution with degrees of freedom equal to the number of distinct doses in the data set minus the number of parameters in the dose-response model. A null hypothesis of fit acceptability can be rejected for the exponential model as the optimal deviance is greater than the corresponding χ^2 statistic. Both the log-probit model and the beta Poisson model provide much improved fits over the exponential model and both model fits are deemed acceptable according to this statistical test. The log-probit model produces a fit with slightly lower deviance than the beta Poisson model.

Table J–4c. Model fitting for human volunteer influenza A/H1N1 data set

Model	Optimal parameter values	Optimal deviance	$\chi^2_{0.95, df}$	Acceptable fit?	ID ₅₀	ID ₁₀	ID ₁
Exp	$r = 1.2 \times 10^{-6}$	663	12.6	NO	-	-	-
LP	$m = 0.10$ $ID_{50} = 2.8$	5.9	11.1	YES	2.8 CCID ₅₀	1.2×10^{-5}	5.2×10^{-10}
BP	$\alpha = 0.17$ $\beta = 0.89$	6.2	11.1	YES	49 CCID ₅₀	0.75	0.054

CCID₅₀ = median cell culture infective dose; Exp = exponential; LP = log-probit; BP = Beta Poisson; df = degrees of freedom

The results in the last three columns of Table J–4c demonstrate that the choice of model has large implications for the estimated probability of infection at low doses. For example, the log-probit model produces an ID₁ eight orders of magnitude lower than the ID₁ produced by the beta-Poisson model. The low-dose experimental results shown in Table J–4b provide some insight into what might be a reasonable value for the ID₅₀, as six of eleven (54.5 percent) of unprotected humans were infected after inhalation of 1–5 CCID₅₀ of influenza virus. These data suggest that the log-probit fit to the H1N1 data, which produces an estimated ID₅₀ of 2.8 CCID₅₀, might be an appropriate model. However, the extremely low values for the ID₁₀ and ID₁ estimates of this log-probit model are not directly supported by any data. Furthermore, and perhaps most importantly, an uncertainty analysis of the dose-response model parameters using a bootstrap resampling (Haas 1999) of the data in Table J–4a, reveals that extrapolated estimates are extremely sensitive to perturbations of the data, such that the uncertainty ranges for low-dose estimates would traverse several orders of magnitude. Given these difficulties, it was determined that the data in the literature do not support quantitative dose-response estimates for 1918 H1N1V that would provide useful insight for this RA.

J.3.4.5 Dose-Response Estimates Derived from Expert Panel

In the procedure described previously, dose-response curves were fit to the ID₁₀, ID₅₀, and ID₉₀ estimates provided by each expert on the Delphi panel. The results of this model fitting procedure for 1918 H1N1V are displayed in Table J–4d, including which models were retained from each expert according to the BIC. Twelve curves were retained for application in this RA, and plots of those curves are shown in Figure J–4. ID estimates provided by the retained curves are shown in Table J–4e.

Table J-4d: Dose response model fitting for 1918 H1N1 influenza virus

Expert	ID ₁₀ ID ₅₀ ID ₉₀	Exp. model	Log-probit model		Beta Poisson model		$\Delta\text{BIC}^{\text{Exp}}$	$\Delta\text{BIC}^{\text{Lp}}$	$\Delta\text{BIC}^{\text{BP}}$

Fitted parameters for three dose response models to each set of three data points from each expert panelist. Optimal parameter values were rounded to two significant figures. ΔBIC is the Bayesian Information Criterion value relative to the lowest value in that row, where a lower value indicates that the model better represents the available information. Bolded values in the BIC columns indicate that the model for that column was kept in consideration for representing the data provided by the expert panelist in that row, and grey values indicate that the model was eliminated from consideration, generally because its value was more than six greater than the lowest BIC value in that row. ^a indicates that the Beta Poisson model fit produced a curve virtually identical to the exponential model, so it was redundant to keep it in consideration. *Exact* entries indicate that the Log-probit model fit the expert panelist values in that row exactly (which results in a BIC value of negative infinity), so the other two models in that row are not applied (N/A). Abbreviations: Exp = Exponential model; Lp = Log-probit model; BP = Beta Poisson model.

Figure J-4

Plot of all retained dose response curves used to estimate probability of infection for each dose. Solid curves were weighted with 1/8 probability; dashed curves were weighted with 1/16 probability; dotted curves were weighted with 1/24 probability.

Table J–4e. Results for retained expert-derived 1918 H1N1V dose-response models

Expert	Model	ID ₅₀	ID ₁₀	ID ₁	ID _{0.1}	ID _{0.01}
1	Exp	290000	44000	4200	420	42
	LP	230000	52000	15000	6300	3000

	BP	260	19	1.6	0.16	0.016
Median (Min–Max)		700 org. (110–290000)	42 (8.6–52000)	3.3 (0.64–15000)	0.52 (0.063–6300)	0.11 (0.0063–3000)

Results are listed for the models that were retained after applying the Bayesian information criterion for model comparison. Each ID_x result refers to the expected inhaled dose estimated to result in infection of x% of exposed individuals. For example, ID_{0.01} refers to the dose estimated to result in infection of 0.01%, or one in ten thousand individuals. The medians were calculated after weighing each of the eight experts equally and weighing each model equally within each expert if more than one was retained. Abbreviations: org. = organisms, Exp = exponential, LP = log-probit and BP = beta Poisson.

J.3.4.6 Other Considerations

The units of exposure for events analyzed in this RA for 1918 H1N1V are in terms of PFU (plaque forming units), which is assumed to measure the expected number of infectious units with potential to reproduce when inhaled. PFU is not a measure of the absolute number of virions in a sample, because individual virions may aggregate or clump to form one plaque and because the plaque assay may not be entirely sensitive to detecting all virions that would have the ability to infect cells in a different medium or host.

The expert panelists were asked to provide their ID estimates in terms of number of organisms. It is assumed that the expert values represent numbers of potentially infectious units, as estimated by PFU, and that it is appropriate to apply the curves derived from their estimates to the exposure estimates. It is possible that this assumption is non-conservative if the plaque assay used to derive the estimated inventories did not count all the organisms with potential to infect a human as envisioned by the experts. The potential magnitude of non-conservatism in assuming that *organisms* (as envisioned by the experts) are adequately measured by PFU is unknown.

J.3.4.7 Summary of Approach

The following summarizes the dose-response estimates for 1918 H1N1V to be applied to exposure data for this RA.

- Range of dose-response models derived from the expert-provided values: the distribution of estimates shown in Table J-4e, with the model or set of models derived from each expert weighted equally.

While it was determined that the available published experimental data did not support a literature-based dose-response model, it can be assessed whether the information that does exist in the literature is adequately represented within the range of expert-derived models. First, the H1N1 human volunteer data in Table J-4a suggests that doses ranging from ten thousand to one million CCID₅₀ result in approximately 80 to 95 percent infection probability. The expert estimates of the ID₉₀ range from three thousand to one million organisms (assumed to be equivalent to PFU). Titers of virus in units of CCID₅₀ are generally higher than in units of PFU. Assuming the difference in virus quantities as measured by PFU and CCID₅₀ is not more than about a factor of ten, the ranges of ID₉₀ estimates from the expert-derived models are not inconsistent with what was seen in the data. Second, the low-dose inhalational data shown in Table J-4b reveal that roughly 50 percent of unprotected humans were infected after inhaling doses of 1–5 CCID₅₀. The lowest ID₅₀ estimated by the experts was 100 organisms (PFU), which appears to suggest that the Table J-4b data might support higher infectivity than is represented by the expert range of estimates, especially considering that the infective doses in the volunteer experiment were likely even lower in units of PFU. However, the data in Table J-4b were restricted to cases where the human volunteers showed no or very little previous protection from the virus strain. As discussed in Section J.3.4.2, it is likely that some percentage of laboratory workers and the general public would be protected from infection with 1918 H1N1V. Therefore, it is reasonable that the expert estimates suggest a lower overall probability of infection than do data that were restricted to unprotected humans.

J.3.5 SARS-Associated Coronavirus

SARS-associated coronavirus (SARS-CoV) causes severe acute respiratory syndrome (SARS), a highly infectious zoonotic disease of humans, as described in Chapter 3 and Appendix C. This section synthesizes the available dose-response information and derives a range of dose-response estimates to be applied to the exposure results from each of the event sequence analyses.

J.3.5.1 Routes of Exposure

The primary natural routes of exposure and infection for humans are assumed to be inhalation of aerosolized droplets and intranasal exposure after touching contaminated fomites or hands of a primary case. Infections resulting from laboratory activities are assumed to be possible via inhalation, ingestion, direct contact, puncture, and animal-related (NHP and rodent) routes. The inhalational and direct contact (intranasal) routes are the primary focus of the dose-response assessment in this section, and it is assumed that the dose-response relationship is similar for both routes. The ingestion route is assumed to require an equal or higher dose to achieve the same probability of infection as compared to the inhalational route. The puncture and animal-related routes are discussed separately in conjunction with the event sequences for which those routes are relevant.

J.3.5.2 Vaccine and Prophylaxis

There are currently no vaccines and no approved or validated post-exposure prophylactic regimens available for SARS-CoV.

J.3.5.3 Dose-Response Information from the Literature

There are no direct human dose-response data for SARS-CoV. The virus is highly transmissible person-to-person, and there were documented cases of airborne transmission across floors of buildings in hospitals and in an apartment complex as well as on airplanes (see Chapter 3 and Appendix C for details and references). This evidence of transmissibility might suggest that the IDs for humans are relatively low. Alternatively, the frequent occurrence of transmissions could have occurred because primary cases shed a large number of pathogens resulting in very high doses received by secondary cases. There is no information on the likely doses received in the known cases of LAI.

There was one dose-response modeling study of SARS-CoV found in the literature (Watanabe 2010), which consisted of an analysis of multiple data sets generated by others from experiments on mice. One data set (De Albuquerque 2006) was generated from intranasal inoculation of A/J mice with murine hepatitis virus (MHV-1), a virus that may be in the same genome-sequence-based grouping of coronaviruses as SARS-CoV (Watanabe 2010) and that produced pulmonary pathological features of SARS in the infected mice (De Albuquerque 2006). Mice were exposed to a wide range of doses, including one group exposed to a low dose of 5 PFU. Another data set (DeDiego 2008) was generated from intranasal inoculation with recombinant SARS-CoV of transgenic mice developed to express the human receptor for SARS-CoV (McCray 2007). The mice were exposed to a range of doses as low as 240 PFU. In both data sets, the response recorded in the exposed mice was death.

1
2 The exponential model and the beta Poisson model were the candidate dose-response models employed in
3 Watanabe et al. (2010). The exponential model provided statistically significant fits to both data sets, and
4 the beta Poisson model either could not be applied or did not provide a statistically significant
5 improvement over the exponential model. Despite the fact that the two data sets were derived for different
6 viruses on different strains of mice, the fitted exponential parameter was similar across the two data sets,
7 and the authors demonstrated through a statistical procedure that the two data sets could be pooled for
8 purposes of fitting a single exponential model to the combined data. They recommended the exponential
9 fit to this pooled data set ($k = 4.1 \times 10^2$, where k is the reciprocal of the parameter r described in section
10 J.2.5.1) as a dose-response model for SARS-CoV with potential relevance for the endpoint of human
11 infection. This model results in an estimated ID₅₀ of 280 PFU (95 percent confidence interval 130 to 530
12 PFU), ID₁₀ of 43 PFU (95 percent confidence interval 20 to 81 PFU), and ID₁ of 4 PFU (95 percent
13 confidence interval not reported, but estimated 2 to 8 PFU).

14
15 Watanabe et al. (2010) also summarized and fit models when possible to thirteen other data sets from six
16 other papers in the literature involving viruses related to SARS-CoV. One of those papers (Bradburne,
17 1967), studied the effects of exposing human volunteers via intranasal inoculation to human coronavirus
18 229E (HCoV-229E), which causes common cold symptoms in humans. In this study, the doses of
19 exposure were recorded in units of TCD₅₀ (median tissue culture dose)⁴, and the response to exposure
20 recorded was the presence or absence of cold symptoms, which is assumed to indicate the presence or
21 absence of infection. The exponential model was shown to provide a statistically significant fit to this
22 data, and the beta Poisson model did not provide a statistically significant improvement over the
23 exponential model. The fitted exponential parameter results in estimates of the ID₅₀ at 13 TCD₅₀ and ID₁₀
24 at 2.0 TCD₅₀. To compare these results to those obtained from the pooled data set derived from the De
25 Albuquerque and DeDiego mouse experiments, Watanabe et al. make note of a report (Schmidt, 1979)
26 that the 50 percent endpoint assay used to calculate TCD₅₀ is 10 to 30 times less sensitive than the plaque
27 assay used to calculate PFU for HCoV-229E. If one assumes a conversion factor of 10 to 30 in converting
28 the ID₅₀ and ID₁₀ results from units of TCD₅₀ to PFU, the model estimates based on the Bradburne human
29 data fall into the 95 percent confidence interval ranges for the estimates based on the pooled mouse data,
30 suggesting that the results are consistent.

31

⁴ In the terminology used in this RA, TCD₅₀ is termed CCID₅₀ (median cell culture infectious dose), which is used elsewhere in this RA. Here, the units as reported by the cited authors are retained.

Ten other animal data sets for SARS-CoV-related coronaviruses examined by Watanabe et al. were amenable to dose-response model fitting, and the exponential model provided a statistically significant fit to all but two: 8 week old rats exposed to porcine hemagglutinating encephalomyelitis virus 67-N (HEV-67N), (Hirano 2001), and chicks exposed to avian infectious bronchitis virus (Uenaka 1998). The beta Poisson model provided a statistically significant improvement in fit over the exponential model for these two data sets only. Two of the ten data sets resulted in a best fit model that estimates IDs lower than those derived from the De Albuquerque / DeDiego pooled data. Both of those two data sets (Hirano 2001, Hirano 2004) were for young (1 week old) rodents exposed to HEV-67N, and in both studies older rodents were shown to have susceptibility more in line with the other data sets or lower. This age-dependent pattern of susceptibility is not consistent with the observed pattern of SARS-CoV cases in humans, which suggested a lower susceptibility in younger individuals and higher mortality rate in older individuals (see Chapter 3 and Appendix C).

Table J–5a. Estimates of LD for mice and ID for humans (with 95% confidence intervals) from coronavirus dose-response models from the literature

Data Set	Model	L/ID ₅₀	L/ID ₁₀	L/ID ₁	L/ID _{0.1}
A: tgMice/rSARS-CoV (De Albuquerque 2006, Watanabe 2010)	Exp	230 PFU (0–630)	35 (0–96)	3.4 (0–9.2)	0.34 (0–0.92)
B: Mice / MHV-1 (DeDiego 2008, Watanabe 2010)	Exp	320 PFU (110–1100)	50 (16–160)	4.7 (1.5–15)	0.47 (0.15–1.5)
C: Pooled A and B (Watanabe 2010)	Exp	280 PFU (110–580)	43 (17–89)	4.1 (1.6–8.5)	0.41 (0.16–0.85)
D: Humans / HCoV-229E (Bradburne 1967, Watanabe 2010)	Exp	13 TCD₅₀ (5.7–28)	1.9 (0.87–4.3)	0.19 (0.083–0.41)	0.018 (0.0083–0.041)

Each L/ID_x result refers to the expected inhaled dose estimated to result in death/infection of x% of exposed individuals. 95% confidence intervals based on model fits to bootstrap replicates from each data set; lower limit of zero for data set A means that more than 2.5% of replicates included no negative cases. Abbreviations: tgMice = transgenic mice; rSARS-CoV = recombinant SARS-CoV; MHV-1 = murine hepatitis virus; HCoV = human coronavirus; Exp = exponential; PFU = plaque forming unit; TCD₅₀ = median tissue culture infective dose. As described in the text, for data set D, a conversion factor of 10–30 may be appropriate for converting the given TCD₅₀ values into units of PFU. The model fit to data set C was chosen as the literature-based model for this RA, as described in Section J.3.5.4.

J.3.5.4 Literature-Based Dose-Response Estimate

This section consists of a discussion of the dose-response data, evidence, and published models for SARS-CoV outlined in the previous section and provides the literature-based dose-response estimate to be used for this RA.

1
2 The Watanabe et al. (2010) study is quite recent and seems to have exhaustively covered the animal
3 models that are the most relevant to human infection with SARS-CoV and for which published data
4 amenable to quantitative dose-response assessment exist. The data examined were from experiments
5 using related viruses and not SARS-CoV specifically; efforts to expose rodents and NHPs to SARS-CoV
6 itself have revealed that those species do not succumb to disease as humans do even at very high doses, so
7 those experiments have not shed light on human dose-response. The viruses used in the experiments
8 examined by Watanabe et al. produced responses in the animals similar to the human response to SARS-
9 CoV and, therefore, may be more relevant.

10
11 The pooled mouse data set identified in the Watanabe et al. study appears to be the most relevant animal
12 model for human infection, and the best fit exponential model for these data is applied to the exposure
13 data for this RA. There are potential objections to applying a model derived from mouse data to humans.
14 However, the fact that data from human exposure to a related coronavirus are consistent with the mouse
15 data is evidence that the species differences in susceptibility to the respective viruses may not be large.
16 Nevertheless, given that SARS-CoV appears to be unique in its virulence and pathogenicity to humans,
17 the assumption that human dose-response is adequately assessed by this model must be applied
18 cautiously.

20 **J.3.5.5 Dose-Response Estimates Derived from Expert Panel**

21 In the procedure described previously, dose-response curves were fit to the ID₁₀, ID₅₀, and ID₉₀ estimates
22 provided by each expert on the Delphi panel. The results of this model fitting procedure for SARS-CoV
23 are displayed in Table J–5b, including which models were retained from each expert according to the
24 BIC. Fourteen curves were retained for application in this RA, and plots of those curves are shown in
25 Figure J–5. ID estimates provided by the retained curves are shown in Table J–5c.

Table J–5b: Dose-response model fitting for SARS-associated coronavirus

Expert	ID ₁₀ ID ₅₀ ID ₉₀	Exp. model	Log-probit model		Beta Poisson model		$\Delta\text{BIC}^{\text{Exp}}$	$\Delta\text{BIC}^{\text{Lp}}$	$\Delta\text{BIC}^{\text{BP}}$
		r	m	ID ₅₀	α	β			
1	100 1,000 10,000	5.5×10^{-4}	0.56	1,000	8.9×10^{-1}	8.2×10^2	N/A	Exact	N/A
2	43 283 950	2.4×10^{-3}	0.83	230	1.0×10^2	4.1×10^4	0	21.8	0.5 ^a
3	100 5,000 40,000	2.0×10^{-4}	0.43	2,700	5.9×10^{-1}	9.8×10^2	5.1	0	2.1
4	100 1,000 10,000	5.5×10^{-4}	0.56	1,000	8.9×10^{-1}	8.2×10^2	N/A	Exact	N/A
5	100 8,000 40,000	1.7×10^{-4}	0.43	3,200	6.3×10^{-1}	1.3×10^3	3	0	1.4
6	400 4,000 40,000	1.4×10^{-4}	0.56	4,000	8.9×10^{-1}	3.3×10^3	N/A	Exact	N/A
7	1,000 3,000 300,000	5.7×10^{-5}	0.45	9,700	4.8×10^{-1}	2.1×10^3	4.1	1.8	0
8	200 4,000 80,000	1.4×10^{-4}	0.43	4,000	5.3×10^{-1}	1.1×10^3	N/A	Exact	N/A

Fitted parameters for three dose-response models to each set of three data points from each expert panelist. Optimal parameter values were rounded to two significant figures. ΔBIC is the Bayesian Information Criterion value relative to the lowest value in that row, where a lower value indicates that the model better represents the available information. Bolded values in the BIC columns indicate that the model for that column was kept in consideration for representing the data provided by the expert panelist in that row, and grey values indicate that the model was eliminated from consideration, generally because its value was more than six greater than the lowest BIC value in that row. ^a indicates that the beta Poisson model fit produced a curve virtually identical to the exponential model, so it was redundant to keep it in consideration. *Exact* entries indicate that the Log-probit model fit the expert panelist values in that row exactly (which results in a BIC value of negative infinity), so the other two models in that row are not applied (N/A). Abbreviations: Exp = Exponential model; Lp = Log-probit model; BP = Beta Poisson model.

Figure J-5

Plot of all dose-response curves retained from fitting models to the information provided by the experts as part of the Delphi process, used to estimate probability of infection for each dose. Solid curves are weighted with 1/8 probability; dashed curves are weighted with 1/16 probability; dotted curves are weighted with 1/24 probability.

Table J-5c. Results for retained expert-derived SARS-CoV dose-response models

Expert	Model	ID ₅₀	ID ₁₀	ID ₁	ID _{0.1}	ID _{0.01}
1	LP	1000	100	15	3.9	1.3
2	Exp	280	43	4.1	0.41	0.041
3	Exp	3400	520	49	4.9	0.49
	LP	2700	140	12	2.0	0.46
	BP	2200	190	17	1.7	0.17
4	LP	1000	100	15	3.9	1.3
5	Exp	4000	600	58	5.8	0.58
	LP	3200	160	14	2.3	0.53
	BP	2600	240	21	2.1	0.21
6	LP	4000	400	61	16	5.0
7	Exp	12000	1800	180	18	1.7
	LP	9700	560	55	10	2.5
	BP	6900	520	45	4.4	0.44
8	LP	4000	200	17	2.9	0.67
Median (Min–Max)		2900 org. (280–12000)	200 (43–1800)	17 (4.1–180)	3.9 (0.41–18)	0.67 (0.041–5.0)

Results are listed for the models that were retained after applying the Bayesian information criterion for model comparison. Each ID_x result refers to the expected inhaled dose estimated to result in infection of x% of exposed individuals. For example, ID_{0.01} refers to the dose estimated to result in infection of 0.01%, or one in ten thousand individuals. The medians were calculated after weighing each of the eight experts equally and weighing each model equally within each expert if more than one was retained. Abbreviations: org. = organisms, Exp = exponential, LP = log-probit and BP = beta Poisson.

It is noted that the estimates derived from Expert 2 are the same as the estimates derived from the chosen dose-response model from the literature. This can be explained by the fact that this expert was an author of the study in which the literature-based model was found and clearly was of the opinion that this model is applicable to humans.

J.3.5.6 Other Considerations

The units of exposure for events analyzed in this RA for SARS-CoV are in terms of PFU (plaque forming units), which is assumed to measure the expected number of infectious units with potential to reproduce when inhaled. PFU is not a measure of the absolute number of virions in a sample, because individual virions may aggregate or clump to form one plaque and because the plaque assay may not be entirely sensitive to detecting all virions that would have the ability to infect cells in a different medium or host. The exposures in the mouse experiments that form the basis for the literature-based dose-response estimates are in terms of PFU, so it is appropriate to apply the curves derived from these data.

The expert panelists were asked to provide their ID estimates in terms of number of organisms. It is assumed that the expert values represent numbers of potentially infectious units, as estimated by PFU, and that it is appropriate to apply the curves derived from their estimates to the exposure estimates. It is possible that this assumption is non-conservative if the plaque assay used to derive the estimated inventories did not count all the organisms with potential to infect a human as envisioned by the experts. Some authors have reported counts of viral genomes in samples of SARS-CoV virus that were also assayed for plaques, resulting in estimates of about 300 genome equivalents per PFU (Sampath 2005), 360 viral genomes per PFU (Vicenzi 2004), and 1200-1600 genomic equivalents per PFU (Houng 2004). These data are of limited use, however, as it is likely that many or perhaps most viral genomes did not become packaged into fully formed, viable virions that could possibly infect cells in a potential host. Therefore, the potential magnitude of non-conservatism in assuming that *organisms* (as envisioned by any particular expert) are adequately measured by PFU is unknown.

J.3.5.7 Summary of Approach

The following summarizes the two sets of dose-response estimates for SARS-CoV to be applied to exposure data for this RA. ID estimates derived from these models are compared in Table J–5d.

- Literature-based dose-response model: The exponential model with $r = 2.5 \times 10^{-3}$, derived from the pooled data set C described in Table J–5a. Use a distribution of r values derived from bootstrap replicates of the data set, which results in a 95 percent range of $(1.2 \times 10^{-3}$ to $6.8 \times 10^{-3})$, for uncertainty and sensitivity analyses.
- Range of dose-response models derived from the expert-provided values: the distribution of estimates shown in Table J–5c, with the model or set of models derived from each expert weighted equally.

Table J–5d. ID estimates and associated ranges for SARS-CoV.

Model	ID ₅₀	ID ₁₀	ID ₁	ID _{0.1}	ID _{0.01}
Literature-based	280 PFU (120–580)	43 (18–88)	4.1 (1.7–8.4)	0.41 (0.17–0.84)	0.041 (0.017–0.084)
Expert-based	2900 org. (280–12000)	200 (43–1800)	17 (4.1–180)	3.9 (0.41–18)	0.67 (0.041–5.0)

Each ID_x result refers to the expected inhaled dose estimated to result in infection of x% of exposed humans. The literature-based ranges are the 95% intervals derived from the bootstrap parameter distribution; the actual range of values applied to the RA may be wider. The expert-based ranges are the minimum and maximum values from Table J–5c. Abbreviations: PFU = plaque forming unit; org. = organisms.

For each ID point displayed in Table J–5d, the literature-based range extends lower (higher risk) than the expert-based range. It is assumed that dose units of PFU and organisms (as conceived by the experts) are equivalent, although this assumption may be non-conservative for the expert-based numbers as described in Section J.3.5.6. The literature-based results, being more conservative than the expert-based results by roughly a factor of ten, can in part serve to assess the implications of the possibility that the expert-based results are non-conservative by a similar factor. Both sets of estimates shown in Table J–5d are applied to the exposure estimates in the initial infection portions of this RA to determine the implications of each estimate for the overall risk posed by SARS-CoV.

J.3.6 Rift Valley Fever Virus

Rift Valley fever virus (RVFV) causes Rift Valley fever, a highly infectious zoonotic disease of animals and humans, as described in Chapter 3 and Appendix C. This section synthesizes the available dose-response information and derives a range of dose-response estimates to be applied to the exposure results from each of the event sequence analyses.

J.3.6.1 Routes of Exposure

The primary natural routes of exposure and infection for humans are assumed to be animal-related, through bites from infected mosquitoes, direct contact from infected livestock or contaminated fomites, or inhalation of aerosols from contaminated blood and bodily fluids from infected animals. Infections resulting from laboratory activities are assumed to be possible via inhalation, ingestion, direct contact, puncture, and animal-related (insect, NHP, and rodent) routes. The inhalational route is the primary focus of the dose-response assessment in this section, in support of the events analyzed in this RA that lead to aerosol releases in the laboratory or outside the NEIDL. The direct contact and ingestion routes are

assumed to require an equal or higher dose to achieve the same probability of infection as compared to the inhalational route. The puncture and animal-related routes are discussed separately in conjunction with the event sequences for which those routes are relevant.

J.3.6.2 Vaccine and Prophylaxis

An attenuated vaccine for RVFV currently is available under an FDA IND authority for use in at-risk military and laboratory personnel from the Special Immunizations Program at the US Army Medical Research Institute of Infectious Diseases, Department of Defense, Fort Detrick, MD (NRC 2011). Research continues on an inactivated formalinized cell culture origin human vaccine (Meegan 1989) and a reverse genetics-generated recombinant RVFV vaccine candidate containing precise deletions of complete virus genes with known roles in virulence; both show promise for humans (Bird 2008). Attenuated and formalin-inactivated vaccines have been used for ruminant livestock, although the attenuated vaccine is abortigenic in pregnant ewes (Meegan 1989).

For this RA, it is assumed that most NEIDL laboratory workers assigned to work with RVFV in BSL-3 labs would have received RVFV vaccine available from the Special Immunizations Program, described above, before a potential exposure event. This assumption has no impact on the estimated risk posed by laboratory workers to the public, as RVFV is not transmissible person-to-person. It is assumed that no member of the public would be vaccinated against RVFV in the case of direct exposure from a NEIDL-related release event.

There is no established course of prophylaxis or specific treatment for individuals exposed to or infected with RVFV (Sidwell 2003, Bird 2009). Treatment of exposed humans with immune plasma and ribavirin has been recommended (Swanepoel 2009).

J.3.6.3 Dose-Response Information from the Literature

There are no human dose-response data available for RVFV. Epidemiological evidence suggests that humans have become infected through inhaling aerosolized particles containing RVFV, but the amount of virus inhaled by humans who became infected is not known. In the absence of human data, studies on RVFV infectivity in animals provide the best-available information through which dose-response information potentially relevant for humans might be obtained.

A dose-response data set was reported in a study in which ICR mice were exposed to various doses of RVFV via the inhalational route and observed for mortality response (Brown 1981). Groups of mice were

exposed to doses as low as 3.2 PFU of four different strains of RVFV. The data are reproduced in Table J-6a.

Table J-6a. Mice dose-response data (Brown 1981) for RVFV

Strain	Challenge Dose (PFU)	Number exposed	Number of deaths
ZH-501	4.0	40	3
	50	43	13
	500	40	26
	6300	40	39
	50,000	37	37
Entebbe	7.9	20	0
	79	20	12
	790	20	19
	6300	20	20
	63,000	20	20
SA-51	3.2	20	0
	40	18	2
	500	20	10
	6300	20	20
	63,000	20	20
SA-75	3.2	20	0
	32	20	4
	160	20	16
	1300	20	20
	20,000	20	20

Data from Brown et al. (1981). The challenge dose was the number of inhaled PFU in each group.

Brown et al. fit the log-probit model to the data in Table J-6a from each strain separately, from which LD₅₀ estimates ranging from about 80 PFU to about 400 PFU were generated. They concluded that there were statistical differences in infectivity between strains but that the differences were not practically significant. It is noted that the lowest dose that caused death was 4.0 PFU (4 dead out of 40 exposed to the ZH-501 strain).

Keefer et al. (1972) exposed young dogs and cats to a wide range of inhalational doses of RVFV, measured in units of median mouse intracerebral lethal dose (MICLD₅₀), and observed infections at all doses. Infection was indicated by the presence of neutralizing antibodies after exposure. The data from this study are presented in Table J-6b.

Table J–6b. Young dog and cat dose-response data (Keefer 1972) for RVFV (Van Wyk strain)

Animal	Challenge Dose (MICLD ₅₀)	Number exposed	Number infected
Young Dog	17–36	8	6
	945–1550	4	4
	36000–51400	4	4
Young Cat	5–7	4	2
	27–36	4	4
	1065–1725	4	4

Data from Keefer et al. (1972). The challenge dose was the number of inhaled MICLD₅₀ in each group. Infection was indicated by the presence of neutralizing antibodies.

Keefer et al. used the data in Table J–6b to estimate an ID₅₀ for young dogs of approximately 25 MICLD₅₀ and an ID₅₀ for young cats of about 5–7 MICLD₅₀.

Miller et al. (1963) exposed hamsters and rhesus monkeys (*Macaca mulatta*) to inhalational doses of RVFV, measured in units of median mouse intraperitoneal lethal dose (MIPLD₅₀). The authors assumed that infection was indicated by mortality in hamsters, and they observed deaths at all doses, including 6 deaths out of 24 exposed to the lowest dose of 0.2 MIPLD₅₀. Infection in rhesus monkeys was observed in all sixteen monkeys exposed to doses ranging from 76 to 2820 MIPLD₅₀, as indicated by post-exposure detection of viremia and neutralizing antibodies. The data from this study are presented in Table J–6c.

Table J–6c. Hamster and rhesus monkey inhalational dose-response data (Miller 1963) for RVFV (pantropic strain)

Animal	Challenge Dose (MIPLD ₅₀)	Number exposed	Number infected
Hamster	0.2	24	6
	0.7	24	14
	2	24	20
	14	24	23
Rhesus Monkey	76	4	4
	145	4	4
	275	4	4
	2820	4	4

Data from Miller et al. (1963). The challenge dose was the number of inhaled MIPLD₅₀ in each group. The endpoints to indicate infection were death for hamsters and viremia and measured levels of neutralizing antibodies for monkeys.

Miller et al. fit the log-probit model to the hamster data in Table J–6c, from which they reported an estimated an LD₅₀ for hamsters of 0.525 MIPLD₅₀ (95 percent confidence interval 0.334–0.824).

Two studies (Easterday 1962, Easterday 1963) reported dose-response data on lambs, mice, and hamsters exposed to aerosols of the van Wyk strain of RVFV. The data are shown in Table J–6d.

Table J–6d. Animal inhalational dose-response data for RVFV (van Wyk strain)

Animal	Challenge Dose (MIPLD ₅₀)	Number exposed	Number infected
Lamb (Easterday 1962)	0.9	1	0
	1.0	1	1
	9.0	2	2
	67.0	1	1
	78.0	1	1
Mouse (Easterday 1963)	0.2	20	0
	0.6	20	0
	1.9	20	0
	2.4	20	0
	3.7	19	2
	12.0	20	6
	24.0	20	8
	188.0	20	16
Hamster (Easterday 1963)	937.0	20	16
	0.14	9	0
	0.7	6	0
	2.7	9	1
	8.6	10	2
	17.25	10	6
	55.0	9	7
	860.0	10	10
	4300.0	9	8

The challenge dose was the number of inhaled MIPLD₅₀ (median mouse intraperitoneal lethal dose) in each group. The endpoints to indicate infection were death for hamsters and mice and detection of viremia for lambs.

A review paper (Easterday 1965) reports that the author also infected two species of NHPs (*Macaca mulatta* and *Macaca fascicularis*) with aerosols of RVFV, although the data appear not to have been published in a peer-reviewed journal. The author states, “the amount of virus necessary to infect by the respiratory route (aerosol) was calculated to be less than 1.0 MIPLD₅₀.”

J.3.6.4 Literature-Based Dose-Response Estimate

This section consists of a discussion of the dose-response data, evidence, and published models for RVFV outlined in the previous section and provides the literature-based dose-response estimate to be used for this RA.

Section J.3.6.3 contains several animal dose-response data sets from which dose-response models can be derived and compared. Brown et al. fit the log-probit model to their mouse data (Table J–6a), but they did not statistically assess the adequacy of the model fit nor did they attempt fitting of alternate models. For this RA, the exponential, log-probit, and beta Poisson models were fit to the data in Table J–6a to compare the fits and assess the implications of different model assumptions on low-dose estimates derived from the models. The results of this procedure are shown in Table J–6e.

Table J–6e. Model fitting for inhalational RVFV mice dose-response data sets (Brown 1981)

Strain	Model	Optimal param. values	Optimal deviance	$\chi^2_{0.95, df}$	Acceptable fit?	LD ₅₀ (PFU)	LD ₁₀	LD ₁	LD _{0.1}	LD _{0.01}
ZH-501	Exp	$r = 0.0020$	39	9.5	NO	-	-	-	-	-
	LP	$m = 0.45$ LD ₅₀ = 150	1.8	7.8	YES	150	8.4	0.81	0.15	0.036
	BP	$\alpha = 0.69$ $\beta = 78$	5.0	7.8	YES	140	13	1.1	0.11	0.011
Entebbe	Exp	$r = 0.0063$	7.8	9.5	YES	110	17	1.6	0.16	0.016
	LP	$m = 0.85$ LD ₅₀ = 75	2.2	7.8	YES	75	17	4.9	2.0	0.95
	BP	$\alpha = 1.9$ $\beta = 180$	4.1	7.8	YES	76	9.9	0.92	0.092	0.0091
SA-51	Exp	$r = 0.0015$	1.0	9.5	YES	460	70	6.6	0.66	0.066
	LP	$m = 0.67$ LD ₅₀ = 360	2.2	7.8	YES	360	53	11	3.5	1.4
	BP	$\alpha = 12$ $\beta = 7400$	0.98	7.8	YES	450	67	6.4	0.64	0.064
SA-75	Exp	$r = 0.0089$	1.6	9.5	YES	78	12	1.1	0.11	0.011
	LP	$m = 1.1$ LD ₅₀ = 71	0.067	7.8	YES	71	21	8.0	3.9	2.2
	BP	$\alpha = 7.8M$ $\beta = 880M$	1.6	7.8	YES	78	12	1.1	0.11	0.011

Dose-response model fitting to the inhalational mouse data (Brown 1981) from Table J–6a. Exp = exponential, LP = log-probit, BP = beta Poisson. Model parameters are defined in Section J.2.5.1. Fit acceptability was confirmed if the deviance at the optimal parameter values was less than the corresponding 95th percentile chi-squared statistic with degrees of freedom (df) equal to 4 for the exponential model and 3 for the log-probit and beta Poisson models. Each ID_x result refers to the expected inhaled dose estimated to result in death/infection of x% of exposed individuals under each model. All ID estimates in units of PFU (plaque forming units).

1 All three models provide acceptable fits to the data from each of the four strains, except for the
2 exponential model to the ZH-501 strain. The log-probit model produces the lowest deviance for the ZH-
3 501 and Entebbe strains, although the beta Poisson models also provide acceptable fits to these strains,
4 and the difference in optimal deviance is not enough to warrant a definitive choice of the log-probit model
5 as the preferred model. The exponential model would be the preferred choice for the SA-51 and SA-75
6 strains, as the other models do not lower the optimal deviance enough to warrant the additional parameter
7 used by the log-probit or beta Poisson models (Haas 1999).

8
9 The right-most columns of Table J–6e illustrate the effects of assuming different models on the estimates
10 for low-dose infectivity of RVFV. The beta Poisson model or the exponential model (when it is
11 acceptable) are more conservative (estimate higher infectivity) at low doses than the log-probit model.
12 Given that the log-probit model is not definitively preferred over the other models for any strain
13 according to the given statistical assessments, the higher-risk implications of the other models cannot be
14 ignored and, therefore, the log-probit model is not chosen as the literature-based model to represent this
15 data for this RA.

16
17 The beta Poisson model provides an acceptable fit for all four strains and provides relatively conservative
18 infectivity estimates at low doses. Therefore, the beta Poisson model is carried forward for consideration
19 as the literature-based model for this RA. Table J–6f displays the estimates derived from each of the four
20 beta Poisson models along with 95 percent confidence intervals calculated from bootstrap resampling of
21 each data set (Haas 1999). While the estimates appear similar across the different strains, the data sets
22 cannot be pooled to form a single data set according to the statistical test described in Section J.3.2.4. It is
23 not known which strains of RVFV would be more or less likely to be studied at NEIDL. Therefore, the
24 four different models are retained separately and given equal weight in forming an overall model for
25 further consideration. The *combined* row in Table J–6f represents an equal weighting of the four
26 individual strain models, with the 95 percent confidence interval derived from random sampling from the
27 bootstrapped estimates from all four sets.

Table J–6f. Model fitting for inhalational RVFV mice dose-response data sets (Brown 1981)

Strain	Model	LD ₅₀	LD ₁₀	LD ₁	LD _{0.1}	LD _{0.01}
ZH-501	BP	140 PFU (60–250)	13 (5.0–30)	1.1 (0.43–2.8)	0.11 (0.042–0.28)	0.011 (0.0042–0.028)
Entebbe	BP	76 PFU (37–180)	9.9 (4.5–27)	0.92 (0.41–2.5)	0.092 (0.040–0.25)	0.0091 (0.0040–0.025)
SA-51	BP	450 PFU (220–840)	67 (30–130)	6.4 (2.8–12)	0.64 (0.28–1.2)	0.064 (0.028–0.12)
SA-75	BP	78 PFU (48–130)	12 (6.6–20)	1.1 (0.61–2.0)	0.11 (0.061–0.19)	0.011 (0.0061–0.019)
Combined	BP	186 PFU (47–650)	25 (5.4–99)	2.4 (0.48–9.4)	0.24 (0.047–0.94)	0.024 (0.0047–0.094)

Each LD_x result refers to the expected inhaled dose, in plaque-forming units (PFU), estimated to result in death of x% of exposed individuals. 95% confidence intervals based on model fits to bootstrap replicates from each data set. Abbreviations: BP = Beta Poisson. Units of dose are PFU.

Keefer et al. (1972) provided ID₅₀ estimates based on their young dog and cat data (Table J–6b), but did not specify what quantitative procedure or assumed dose-response model, if any, was used to derive their estimates. For this RA, the exponential model was fit to the data in Table J–6b, using the midpoint of the given dose range for each dose group. The beta-Poisson and log-probit models are not appropriate models to fit to these data because they are two-parameter models and, for each animal, there was only one dose level at which an infection rate less than 100 percent was observed. Regardless, the exponential model fit results in a very low optimal deviance, which could not be improved enough to justify the use of a model with additional parameters. In addition, it was tested whether the results from the two data sets were consistent enough to be pooled, under the same statistical test described in Section J.3.2.4. As shown in Table J–6g, it was determined that pooling the two data sets was acceptable, and the model fit to this pooled data set is carried forward as a candidate model for this RA.

Table J–6g. Model fitting for inhalational RVFV dose-response data sets (Keefer 1972)

Data Set	Model	Optimal param. values	Optimal deviance	$\chi^2_{0.95, df}$	Acceptable fit?	Pooling acceptability test
A: Young Dog	Exp	$r = 0.052$	$Y_A = 0$	6.0	YES	$Y_C - (Y_A + Y_B) = 1.6$ $\chi^2_{0.95, 1} = 3.8$ Acceptable to pool
B: Young Cat	Exp	$r = 0.13$	$Y_B = 0.16$	6.0	YES	
C: Pooled A and B	Exp	$r = 0.072$	$Y_C = 1.8$	7.8	YES	

Dose-response model fitting to the inhalational animal data (Keefer 1972) from Table J–6b. Exp = exponential. Model parameter r is defined in Section J.2.5.1. Fit acceptability was confirmed if the deviance at the optimal parameter values was less than the corresponding 95th percentile chi-squared statistic with degrees of freedom (df) equal to (2, 2, 3) for data sets (A, B, C), respectively. Optimal deviance for the exponential fit to the young dog data is not exactly zero but is less than the degree of computer precision used.

Miller et al. (1963) generated dose-response data sets for inhalational exposure of hamsters and rhesus monkeys (Table J–6c), and they fit the log-probit model to the hamster data set. It is not possible to find an optimal dose-response model for the monkey data set, because every monkey became infected at every dose level. However, the data do provide some insight into probable upper bounds for ID levels for rhesus monkeys. For example, the exponential dose-response model can be evaluated in terms of how low the model parameter r can be while still producing a deviance low enough to be acceptable under statistical criteria in light of the data. The results of the exercise are shown in Table J–6h. For the hamster data set, Miller et al. did not test alternate dose response models, so the exponential, log-probit, and beta Poisson models were fit to the data as alternate candidate models for this RA. The results in Table J–6h show that log-probit and beta Poisson models provide acceptable fits to the data set, with the beta Poisson model producing a slightly lower optimal deviance and more conservative infectivity estimates at very low doses. Therefore, the beta Poisson model fit is carried forward for further consideration.

Table J–6h. Model fitting for inhalational RVFV animal dose-response data set (Miller 1963)

Animal	Model	Optimal or bound param. values	Deviance	$\chi^2_{0.95, df}$	Acceptable fit?	ID ₅₀	ID ₁₀	ID ₁	ID _{0.1}
Monkey	Exp	$r > 0.01$	< 7.8	7.8	-	< 70	< 10	< 1	< 0.1
Hamster	Exp	$r = 0.75$	18	7.8	NO	-	-	-	-
	LP	$m = 0.69$ $LD_{50} = 0.52$	0.69	6.0	YES	0.52	0.064	0.011	0.0033
	BP	$\alpha = 1.1$ $\beta = 0.57$	0.33	6.0	YES	0.52	0.059	0.0054	0.00053

Dose-response modeling for the inhalational animal data (Miller 1963) from Table J–6c. Exp = exponential, LP = log-probit, BP = beta Poisson. Model parameters are defined in Section J.2.5.1. For the monkey data, the lower bound r value produces deviance equal to 95th percentile of the chi-squared distribution with df (degrees of freedom) equal to 3, the number of distinct doses in the data set (4) minus the number of model parameters (1). For the hamster data, fit acceptability was confirmed if the deviance at the optimal parameter values was less than the corresponding 95th percentile chi-squared statistic with degrees of freedom (df) equal to 3 for the exponential model and 2 for the log-probit and beta Poisson models. Each ID_x result refers to the expected inhaled dose estimated to result in infection of x% of exposed individuals under each model. Units of dose are MIPLD₅₀.

Easterday et al. (1962) and Easterday and Murphy (1963), generated dose response data sets for inhalational exposure of lambs, mice, and hamsters (Table J–6d), but it appears they did not attempt dose-response model fitting to the data. The data for lambs are not extensive enough to justify dose-response model fitting, as they do not reveal a statistically significant trend for increasing infection rate for increasing dose. However, the data do provide some insight into probable upper bounds for ID levels for lambs. For example, the exponential dose-response model can be evaluated in terms of how low the model parameter r can be while still producing a deviance low enough to be acceptable under statistical criteria in light of the data. The results of the exercise are shown in Table J–6i. The data for mice and hamsters were appropriate for fitting to the exponential, log-probit, and beta Poisson models, with results also shown in Table J–6i.

Table J–6i. Model fitting for inhalational RVFV animal dose-response data sets (Easterday 1962, Easterday 1963)

Animal	Model	Optimal or bounded param. values	Deviance	$\chi^2_{0.95, df}$	Acceptable fit?	ID ₅₀	ID ₁₀	ID ₁	ID _{0.1}
Lamb	Exp	$r > 0.6$	< 9.5	9.5	-	< 10	< 2	< 0.2	< 0.02
Mouse	Exp	$r = 0.005$	48	14	NO	-	-	-	-
	LP	$m = 0.47$ ID ₅₀ = 58	6.7	13	YES	58	3.7	0.39	0.076
	BP	$\alpha = 0.48$ $\beta = 15$	5.1	13	YES	47	3.6	0.31	0.031
Hamster	Exp	$r = 0.034$	65	14	NO	-	-	-	-
	LP	$m = 0.44$ ID ₅₀ = 25	7.8	13	YES	25	1.4	0.14	0.025
	BP	$\alpha = 0.61$ $\beta = 9.6$	5.5	13	YES	20	1.8	0.16	0.016

Dose-response model fitting to inhalational animal data (Easterday 1962, Easterday 1963) from Table J–6d. Exp = exponential, LP = log-probit, BP = beta Poisson. Model parameters are defined in Section J.2.5.1. For lambs, the lower bound r value produces deviance equal to 95th percentile of the chi-squared distribution with df (degrees of freedom) equal to 4, the number of distinct doses in the data set (5) minus the number of model parameters (1). For mice and hamsters, fit acceptability was confirmed if the deviance at the optimal parameter values was less than the corresponding 95th percentile chi-squared statistic with degrees of freedom (df) equal to the number of distinct doses in the data set minus the number of parameters for the fitted model. Each ID_x result refers to the expected inhaled dose estimated to result in death/infection of $x\%$ of exposed individuals under each model. Units of dose are MIPLD₅₀.

The lamb-based results in Table J–6i are intended to be guidelines for upper bounds of ID estimates. For example, if the true ID₅₀ for lambs is greater than about 10 MIPLD₅₀ and if the exponential model is appropriate, then it would be unlikely (less than about 5 percent chance) that the data in Table J–6d would be observed. These results give no information on lower bounds for IDs for lambs. For the mouse and hamster data, the exponential model does not provide an acceptable fit under the given statistical criteria. The log-probit and beta Poisson models provide acceptable fits and lead to similar ID estimates at the levels shown in the table. Because the beta Poisson model produces a slight lower deviance and slightly more conservative estimates at the ID_{0.1} level and lower, the beta Poisson model fits to the mouse and hamster data are carried forward for further consideration.

The candidate literature-based models, as well as information from some animal data that could not be fit to models, are compared in Table J–6j.

Table J–6j. Candidate models and information derived from inhalational RVFV animal dose-response data sets

Animal (Ref)	Model	I/LD ₅₀	I/LD ₁₀	I/LD ₁	I/LD _{0.1}
Mouse (Brown 1981)	BP	186 PFU (47–650)	25 (5.4–99)	2.4 (0.48–9.4)	0.24 (0.047–0.94)
Mouse (Easterday 1963)	BP	47 MIPLD₅₀ (28–120)	3.5 (1.8–9.9)	0.31 (0.15–0.88)	0.030 (0.014–0.087)
Young Dog & Cat (Keefer 1972)	Exp	9.7 MICLD₅₀ (2.9–18)	1.5 (0.44–2.8)	0.14 (0.042–0.27)	0.014 (0.0042–0.026)
Hamster (Miller 1963)	BP	0.52 MIPLD₅₀ (0.29–0.91)	0.059 (0.026–0.13)	0.0054 (0.0023–0.012)	0.00053 (0.00023–0.0012)
Hamster (Easterday 1963)	BP	20 MIPLD₅₀ (8.8–75)	1.8 (0.56–7.0)	0.16 (0.044–0.66)	0.016 (0.0043–0.065)
Lamb (Easterday 1962)	Exp	< 10 MIPLD₅₀	< 2	< 0.2	< 0.02
Rhesus Monkey (Miller 1963)	Exp	< 70 MIPLD₅₀	< 10	< 1	< 0.1
Rhesus Monkey (Easterday 1965)	None	< 1.0 MIPLD₅₀	-	-	-
Cynomolgus Monkey (Easterday 1965)	None	< 1.0 MIPLD₅₀	-	-	-

Each I/LD_x result refers to the expected inhaled dose estimated to result in infection/death of x% of exposed individuals. 95% confidence intervals based on model fits to bootstrap replicates from each data set. Abbreviations: BP = beta Poisson, Exp = exponential, PFU = plaque-forming units, MICLD₅₀ = median mouse intracerebral lethal dose, MIPLD₅₀ = median mouse intraperitoneal lethal dose.

Mouse-based models: It appears from the results in Table J–6j that mice can be considered less susceptible to infection with RVFV via aerosols than other animals, with the possible exception of hamsters, for which results were similar in the same study (Easterday 1963). To attempt to reconcile the different units of dose (PFU) used by Brown et al., it is noted that titers of RVFV stock found in the literature were generally smaller in units of PFU than they were in units of median mouse lethal dose (e.g., Klein 1970, Klein 1971). This relationship would imply that the ID values in units of PFU would be even higher in units of MIPLD₅₀ or MICLD₅₀ which strengthens support for the notion that mice are less susceptible to infection from aerosols than other animals. Given that it appears that mice are significantly less susceptible to aerosols of RVFV than are larger mammals with physiologies more similar to humans,

1 it was determined that applying a mouse-based dose-response model would not be appropriate for this
2 RA.

3
4 **Hamster-based models:** The two hamster-based models shown in Table J–6j give significantly different
5 ID estimates from each other. It is not clear what caused the difference, as the two papers describe the use
6 of similar RVFV strain preparations and similar animals used in the studies. The different estimates could
7 have resulted from different procedures used to estimate the amount of virus inhaled by the hamsters;
8 both sets of authors acknowledged the difficulty of measuring the low doses applied. Given the
9 inconsistency in these results, it was determined that a hamster-based dose-response model would not be
10 appropriate to apply for this RA.

11
12 **Young dog and cat-based model:** The model based on young dog and cat data (Keefer 1972) expresses
13 the dose in units of MICLD₅₀, which is similar to MIPLD₅₀ except the route of exposure is intracerebral
14 vs. intraperitoneal. One study (Boyle 1965) tested the same RVFV suspension on mice by both routes of
15 exposure and obtained titer concentrations that were roughly 3-fold less by MIPLD₅₀ than by MICLD₅₀.
16 Assuming that a similar relationship applies to the samples used by Keefer et al. and the Easterday
17 studies, the ID estimates for young dogs and cats could be reduced by a factor of three to compare to the
18 Easterday-derived estimates. That suggests that the young dog- and cat-based estimates could be
19 consistent with the evidence shown for lambs and monkeys, and, therefore might be an appropriate set of
20 estimates to apply for this RA. Furthermore, exposure estimates for this RA are given in units of
21 MICLD₅₀, so the young dog- and cat-based model can be applied directly to the exposure estimates
22 without adding another layer of uncertainty in converting to different units.

23
24 **Goat and monkey evidence:** The goat and monkey data suggest that these animals might be as, or
25 perhaps more, susceptible to infection from aerosols of RVFV as young dogs and cats. However, the data
26 for these animals are not available or not extensive enough to perform model fitting or a proper statistical
27 comparison.

28
29 In light of the points in the above discussion, it was determined that the young dog- and cat-based model
30 would be most appropriate to serve as the literature-based model for this RA. It is not known how the
31 susceptibility of humans to RVFV inhalation would compare to any of the animals from which the
32 estimates in Table J–6j were derived, so this model is applied with caution.

J.3.6.5 Dose-Response Estimates Derived from Expert Panel

In the procedure described previously, dose-response curves were fit to the ID₁₀, ID₅₀, and ID₉₀ estimates provided by each expert on the Delphi panel. The results of this model fitting procedure for RVFV are displayed in Table J–6k, including which models were retained from each expert according to the BIC. Sixteen curves were retained for application in this RA, and plots of those curves are shown in Figure J–6. ID estimates provided by the retained curves are shown in Table J–6l.

Table J–6k: Dose response model fitting for Rift Valley fever virus

Expert	ID ₁₀ ID ₅₀ ID ₉₀	Exp. model	Log-probit model		Beta Poisson model		$\Delta\text{BIC}^{\text{Exp}}$	$\Delta\text{BIC}^{\text{Lp}}$	$\Delta\text{BIC}^{\text{BP}}$
		r	m	ID ₅₀	α	β			
1	1,000 5,000 50,000	8.8×10^{-5}	0.66	6,300	1.3	9.3×10^3	5.2	0	1.7
2	15 99 329	7.0×10^{-3}	0.83	79	1.0×10^3	1.4×10^5	0	28.7	1.1 ^a
3	100 1,500 10,000	4.8×10^{-4}	0.56	1,100	9.7×10^{-1}	1.1×10^3	6	0	0.5
4	100 1,000 10,000	5.5×10^{-4}	0.56	1,000	8.9×10^{-1}	8.2×10^2	N/A	Exact	N/A
5	100 1,000 10,000	5.5×10^{-4}	0.56	1,000	8.9×10^{-1}	8.2×10^2	N/A	Exact	N/A
6	100 1,000 10,000	5.5×10^{-4}	0.56	1,000	8.9×10^{-1}	8.2×10^2	N/A	Exact	N/A
7	10 40 300	1.1×10^{-2}	0.75	49	2.4	1.7×10^2	3.8	0	3.4
8	100 1,500 10,000	4.8×10^{-4}	0.56	1,100	9.7×10^{-1}	1.1×10^3	6	0	0.5

Fitted parameters for three dose response models to each set of three data points from each expert panelist. Optimal parameter values were rounded to two significant figures. ΔBIC is the Bayesian Information Criterion value relative to the lowest value in that row, where a lower value indicates that the model better represents the available information. Bolded values in the BIC columns indicate that the model for that column was kept in consideration for representing the data provided by the expert panelist in that row, and grey values indicate that the model was eliminated from consideration, generally because its value was more than six greater than the lowest BIC value in that row. ^a indicates that the Beta Poisson model fit produced a curve virtually identical to the exponential model, so it was redundant to keep it in consideration. *Exact* entries indicate that the Log-probit model fit the expert panelist values in that row exactly (which results in a BIC value of negative infinity), so the other two models in that row are not applied (N/A). Abbreviations: Exp = Exponential model; Lp = Log-probit model; BP = Beta Poisson model.

Figure J-6

Plot of all retained dose response curves used to estimate probability of infection for each dose. Solid curves were weighted with 1/8 probability; dashed curves were weighted with 1/16 probability; dotted curves were weighted with 1/24 probability.

Table J–6I. Results for retained expert-derived RVFV dose-response models

Expert	Model	ID ₅₀	ID ₁₀	ID ₁	ID _{0.1}	ID _{0.01}
1	Exp	7900	1200	110	11	1.1
	LP	6300	890	180	56	22
	BP	6700	800	73	7.3	0.73

	LP	1100	110	18	4.4	1.4
	BP	1100	120	11	1.1	0.11
Median (Min–Max)		1000 org. (49–7900)	100 (7.6–1200)	15 (0.71–180)	3.9 (0.071–56)	1.2 (0.0071–22)

Results are listed for the models that were retained after applying the Bayesian information criterion for model comparison. Each ID_x result refers to the expected inhaled dose estimated to result in infection of x% of exposed individuals. For example, ID_{0.01} refers to the dose estimated to result in infection of 0.01%, or one in ten thousand individuals. The medians were calculated after weighing each of the eight experts equally and weighing each model equally within each expert if more than one was retained. Abbreviations: org. = organisms, Exp = exponential, LP = log-probit and BP = beta Poisson.

J.3.6.6 Other Considerations

The units of exposure for events analyzed in this RA for RVFV are in terms of CCID₅₀ (median cell culture infective dose) and MICLD₅₀ (median mouse intracerebral lethal dose). Alternate exposure estimates are also given in plaque-forming units (PFU). The exposures in the young dog and cat experiments that form the basis for the literature-based dose-response estimates are in terms of MICLD₅₀, so it is appropriate to apply the literature-based dose response estimates to the exposure estimates.

The expert panelists were asked to provide their ID estimates in terms of number of organisms. It is assumed that the expert values represent numbers of potentially infectious units, as estimated by PFU, and that it is appropriate to apply the curves derived from their estimates to the PFU exposure estimates. It is possible that this assumption is non-conservative if the plaque assay used to derive the estimated inventories did not count all the organisms with potential to infect a human as envisioned by the experts. One study reported a count of 1,000–3,000 virus subunits per PFU of RVFV (Garcia 2001), and a recent

study has reported counts of viral genomes as well as virus particles in samples of RVFV that were also assayed for FFU, resulting in estimates of about 290,000 viral genomes per FFU and about 2,500 virus particles per FFU (Weidmann 2011). It is clear from these data that the number of viral genomes in a sample of RVFV is not an appropriate estimate for the number of organisms, because there were 119 times as many genomes as there were particles available to contain genomes and form complete virions. The number of virus particles observed might be a more accurate estimate for the number of organisms, but it is also possible that many of those particles did not represent replication-competent virions with the ability to infect host cells, which is supported by the fact that roughly 2,500 particles were measured for each focus-forming unit in the cell culture. However it is possible that some portion of the particles that were not infective in the cell culture would be infective to cells in a live host. Therefore, these data suggest that the assumption that numbers of organisms as envisioned by any particular expert are adequately measured by PFU might be non-conservative.

J.3.6.7 Summary of Approach

The following summarizes the two sets of dose-response estimates for RVFV to be applied to exposure data for this RA. ID estimates derived from these models are compared in Table J–6m.

- Literature-based dose-response model: the exponential model with $r = 0.072$, derived by fitting the model to consolidated young dog and cat inhalational dose-response data (Table J–6b). Use a distribution of r values derived from bootstrap replicates of the data set for uncertainty and sensitivity analyses.
- Range of dose-response models derived from the expert-provided values: the distribution of estimates shown in Table J–6k, with the model or set of models derived from each expert weighted equally.

Table J–6m. ID estimates and associated ranges for RVFV.

Model	ID ₅₀	ID ₁₀	ID ₁	ID _{0.1}
Literature-based	9.7 MICLD₅₀ (2.9–18)	1.5 (0.44–2.8)	0.14 (0.042–0.27)	0.014 (0.0042–0.026)
Expert-based	1000 org. (49–7900)	100 (7.6–1200)	15 (0.71–180)	3.9 (0.071–56)

Each ID_x result refers to the expected inhaled dose estimated to result in infection of x% of exposed humans. The literature-based ranges are the 95% intervals derived from the bootstrap parameter distribution; the actual range of values applied to the RA may be wider. The expert-based ranges are the minimum and maximum values from Table J–6l. Abbreviations: PFU = plaque forming unit; org. = organisms.

For each ID point displayed in Table J–6m, the literature-based range extends lower (higher risk) than the expert-based range. It is assumed that dose units of PFU and organisms (as conceived by the experts) are equivalent, although this assumption may be non-conservative for the expert-based numbers as described in Section J.3.6.6. The literature-based results, being more conservative than the expert-based results, can in part serve to assess the implications of the possibility that the expert-based results are non-conservative by a similar factor. Both sets of estimates shown in Table J–6m are applied to the exposure estimates in the initial infection portions of this RA to determine the implications of each estimate for the overall risk posed by RVFV. As noted in Section J.3.6.6, alternate exposure estimates are given in units of MICLD₅₀ and also in units of PFU.

J.3.7 Andes Virus

Andes virus (ANDV) is a hantavirus that causes hantavirus pulmonary syndrome (HPS), a highly infectious, zoonotic, rodent-transmitted disease that has infected humans, as described in Chapter 3 and Appendix C. This section synthesizes the available dose-response information and derives a range of dose-response estimates to be applied to the exposure results from each of the event sequence analyses.

J.3.7.1 Routes of Exposure

For ANDV, the primary natural routes of exposure and infection for humans are assumed to be through inhalation of aerosolized excretions from infected rodents, specifically the long-tailed pygmy rice rat, or direct contact with rodent excretions or contaminated fomites. Ingestion of particles contaminated with rodent excretions or bites from infected rodents might also cause infection. Bodily fluids of infected humans may cause infection in contacts as well. Infections resulting from laboratory activities are assumed to be possible via inhalation, ingestion, direct contact, puncture, and animal-related (NHP and

rodent) routes. The inhalational route is the primary focus of the dose-response assessment in this section, in support of the events analyzed in this RA that lead to aerosol releases in the laboratory or outside the NEIDL. Non-inhalational routes of exposure and their potential consequences are considered separately and as needed in conjunction with relevant events.

J.3.7.2 Vaccine and Prophylaxis

No vaccines are available for ANDV, although experimental vaccines might be efficacious in animal models as described in Chapter 3. For this RA, it is assumed that no potentially exposed laboratory worker, facility worker, or member of the general public would be vaccinated against infection or disease with ANDV. That is a conservative assumption because it is possible that some individuals (especially laboratory workers) would be partially protected from an administered vaccine that could become FDA-approved or that could be available before official FDA-approval, such as those classified as an IND.

No prophylactic treatments have been shown to protect against ANDV infection after exposure, nor do any specific treatments or cures exist for HPS.

J.3.7.3 Dose-Response Information from the Literature

There are no human dose-response data available for ANDV. Epidemiological evidence suggests that humans have become infected through inhaling aerosolized particles containing ANDV, but the amount of virus inhaled by humans who became infected is not known. In the absence of human data, studies on ANDV infectivity in animals provide the best-available information through which dose-response information potentially relevant for humans might be obtained.

Hooper et al. (2008) exposed groups of Syrian hamsters to different amounts of ANDV through different routes of exposure, including the intranasal route, which serves as a model of exposure to respiratory mucosa that would occur upon inhalation. Syrian hamsters had previously been shown to be an animal model that closely mimics human HPS (Hooper 2001). The dose-response data from intranasal exposure of the hamsters are shown in Table J-7a. The authors reported an LD₅₀ of 95 PFU and an ID₅₀ of 48 PFU, which appear to have been calculated under the assumptions of the log-probit model.

Table J–7a. Hamster intranasal dose-response data (Hooper 2008) for ANDV.

Challenge Dose (PFU)	Number exposed	Number infected
2	8	0
20	8	2
200	8	7
2000	8	8
20000	8	8

Data from Hooper et al. (2008). Infected animals included animals that died and animals that survived for 35 days but were seropositive for antinucleocapsid antibodies at day 35.

J.3.7.4 Literature-Based Dose-Response Estimate

This section consists of a discussion of the dose-response data, evidence, and published model for ANDV outlined in the previous section and provides the literature-based dose-response estimate to be used for this RA.

The Syrian hamster data from Hooper et al. (2008) appears to be the only intranasal or inhalational dose-response animal data available in the literature. The hamster data with infection as the response is amenable to dose-response model fitting. Hooper et al. (2008) reported median lethal and ID estimates that appear to have been derived from a log-probit model, but they did not assess the goodness of fit for this model nor did they report attempts to fit alternate models. For this RA, the exponential, log-probit, and beta Poisson models were fit to the data, and the model-fitting results are presented in Table J–7b.

Table J–7b. Model fitting for intranasal ANDV hamster dose-response data set (Hooper 2008)

Model	Optimal param. values	Optimal deviance	$\chi^2_{0.95, df}$	Acceptable fit?	ID ₅₀	ID ₁₀	ID ₁	ID _{0.1}	ID _{0.01}
Exp	$r = 0.011$	0.50	9.5	YES	63 PFU	9.6	0.91	0.091	0.0091
LP	$m = 0.84$ ID ₅₀ = 48	0.097	7.8	YES	48 PFU	10	2.9	1.2	0.55
BP	$\alpha = 5.3$ $\beta = 410$	0.45	7.8	YES	57 PFU	8.3	0.78	0.078	0.0078

Dose-response modeling for the intranasal hamster data (Hooper 2008) from Table J–7a. Exp = exponential, LP = log-probit, BP = beta Poisson, PFU = plaque forming units. Model parameters are defined in Section J.2.5.1. Fit acceptability was confirmed if the deviance at the optimal parameter values was less than the corresponding 95th percentile chi-squared statistic with degrees of freedom (df) equal to 4 for the exponential model and 3 for the log-probit and beta Poisson models. Each ID_x result refers to the expected inhaled dose estimated to result in infection of x% of exposed individuals under each model.

1 All three models provide acceptable fits to the data. The exponential model is the preferred choice of the
2 three, as the log-probit model and beta Poisson models do not lower the optimal deviance enough to
3 justify the use of an extra parameter (Haas 1999). Therefore, the exponential model is used as the
4 literature-based dose-response estimate for this RA.
5

6 **J.3.7.5 Dose-Response Estimates Derived from Expert Panel**

7 In the procedure described previously, dose-response curves were fit to the ID₁₀, ID₅₀, and ID₉₀ estimates
8 provided by each expert on the Delphi panel. The results of this model fitting procedure for ANDV are
9 displayed in Table J-7c, including which models were retained from each expert according to the BIC.
10 Twelve curves were retained for application in this RA, and plots of those curves are shown in Figure J-7.
11 ID estimates provided by the retained curves are shown in Table J-7d.
12

Table J–7c: Dose response model fitting for Andes virus

Expert	ID ₁₀ ID ₅₀ ID ₉₀	Exp. model	Log–probit model		Beta Poisson model		$\Delta\text{BIC}^{\text{Exp}}$	$\Delta\text{BIC}^{\text{Lp}}$	$\Delta\text{BIC}^{\text{BP}}$
		r	m	ID ₅₀	α	β

7	BP	1100	92	8.0	0.79	0.079
8	LP	1000	100	15	3.9	1.3
Median (Min–Max)		520 org. (10–1100)	44 (1.0–160)	7.1 (0.15–15)	0.79 (0.039–6.3)	0.079 (0.013–3.0)

Results are listed for the models that were retained after applying the Bayesian information criterion for model comparison. Each ID_x result refers to the expected inhaled dose estimated to result in infection of x% of exposed individuals. For example, ID_{0.1} refers to the dose estimated to result in infection of 0.1%, or one in one thousand individuals. The medians were calculated after weighing each of the eight experts equally and weighing each model equally within each expert if more than one was retained. Abbreviations: org. = organisms, Exp = exponential, LP = log-probit and BP = beta Poisson.

J.3.7.6 Other Considerations

The units of exposure for events analyzed in this RA for ANDV are in terms of CCID₅₀ (median cell culture infective dose). The exposures in the hamster experiments that form the basis for the literature-based dose-response estimates are in terms of PFU. It is likely that the exposure estimates would be lower in terms of PFU, because the estimated inventory concentration (1×10^6 CCID₅₀ / ml), which is proportional to the exposure estimates, was chosen in those units because titers in other units, including PFU, were generally found to be lower in the literature. However, there is at least one example of up to 10^6 PFU / mL being achieved in the laboratory for ANDV (Wahl-Jensen 2007). Therefore, it is conservatively assumed that it is appropriate to apply the dose-response estimates in terms of PFU to the exposure estimates in units of CCID₅₀.

The expert panelists were asked to provide their ID estimates in terms of number of organisms. It is assumed that the expert values represent numbers of potentially infectious units, as estimated by PFU. It is possible that this assumption is non-conservative if the assays used to derive the estimated inventories did not count all the organisms with potential to infect a human as envisioned by the experts. There is

little information in the literature on the sensitivity of ANDV assays in detecting virions. Therefore, the potential magnitude of non-conservatism resulting from the assumption that numbers of organisms as envisioned by any particular expert are adequately measured by PFU is unknown.

J.3.7.7 Summary of Approach

The following summarizes the two sets of dose-response estimates for ANDV to be applied to exposure data for this RA. ID estimates derived from these models are compared in Table J–7e.

- Literature-based dose-response model: the exponential model with $r = 0.011$, derived by fitting the model to Syrian hamster intranasal dose-response data (Hooper 2008). Use a distribution of r values derived from bootstrap replicates of the data set, which results in a 95 percent range of (0.0051 to 0.029), for uncertainty and sensitivity analyses.
- Range of dose-response models derived from the expert-provided values: the distribution of estimates shown in Table J–7d, with the model or set of models derived from each expert weighted equally.

Table J–7e. ID estimates and associated ranges for ANDV.

Model	ID ₅₀	ID ₁₀	ID ₁	ID _{0.1}	ID _{0.01}
Literature-based	63 PFU (24–140)	9.6 (3.6–21)	0.91 (0.35–2.0)	0.091 (0.034–0.20)	0.0091 (0.0034–0.020)
Expert-based	520 org. (10–1100)	44 (1.0–160)	7.1 (0.15–15)	0.79 (0.039–6.3)	0.079 (0.013–3.0)

Each ID_x result refers to the expected inhaled dose estimated to result in infection of x% of exposed humans. The literature-based ranges are the 95% intervals derived from the bootstrap parameter distribution; the actual range of values applied to the RA may be wider. The expert-based ranges are the minimum and maximum values from Table J–7d. Abbreviations: PFU = plaque forming unit; org. = organisms.

Both sets of estimates shown in Table J–7e are applied to the exposure estimates in the initial infection portions of this RA to determine the implications of each estimate for the overall risk posed by ANDV.

J.3.8 Ebola Virus

Ebola virus (EBOV) causes Ebola hemorrhagic fever (EHF), a highly infectious, zoonotic disease that has infected humans in both natural and laboratory settings, as described in Chapter 3 and Appendix C. This

section synthesizes the available dose-response information and derives a range of dose-response estimates to be applied to the exposure results from each of the event sequence analyses.

J.3.8.1 Routes of Exposure

For EBOV, the primary natural routes of exposure and infection for humans are assumed to be through inhalation of aerosolized particles from contaminated bodily fluids of infected animals or humans, or through ingestion or direct contact with such fluids. Infections resulting from laboratory activities are assumed to be possible via inhalation, ingestion, direct contact, puncture, and animal-related (NHP and rodent) routes. The inhalational route is the primary focus of the dose-response assessment in this section, in support of the events analyzed in this RA that lead to aerosol releases in the laboratory or outside the NEIDL. Non-inhalational routes of exposure and their potential consequences are considered separately and as needed in conjunction with relevant events.

J.3.8.2 Vaccine and Prophylaxis

There are currently no vaccines available for EBOV, although candidate vaccines are in development that have been shown to be successful in protecting NHPs from disease after inhalational exposure (Geisbert 2008, Pratt 2010). For this RA, it is assumed that no potentially exposed laboratory worker, facility worker, or member of the general public would be vaccinated against infection or disease with EBOV. This is a conservative assumption, as it is possible that some individuals (especially laboratory workers) would be partially protected from an administered vaccine that may become FDA-approved or that may be available before official FDA-approval, such as those classified as an IND.

There are no prophylactic treatments that have been shown to protect against EBOV infection after exposure, nor are there any validated specific treatments for disease after symptoms appear.

J.3.8.3 Dose-Response Information from the Literature

There are no human dose-response data available for EBOV. Epidemiological evidence suggests that humans have become infected through inhaling aerosolized particles containing EBOV, but the amount of virus inhaled by humans who became infected is not known. In the absence of human data, studies on EBOV infectivity in animals provide the best-available information through which dose-response information potentially relevant for humans might be obtained.

Unimmunized NHPs (*Macaca mulatta* or *Macaca fascicularis*) have been infected after inhalational exposure to EBOV in a number of studies. Johnson et al. (1995) exposed two monkeys to an inhalational

dose of 400 PFU and two monkeys to a dose of 50,000 PFU and all four monkeys subsequently died of disease. Geisbert et al. (2008), in a vaccine study, exposed three unprotected control group monkeys to target inhalational doses of 1000 PFU and all three monkeys subsequently died of disease. Pratt et al. (2010), in another vaccine study, exposed eight unprotected control group monkeys to doses as low as 100 PFU to as high as 1200 PFU, and all eight subsequently died of disease. These authors also make reference to *historical controls*, apparently unpublished data to which the authors had access, consisting of an additional six unprotected monkeys that died after exposure of approximately 20 PFU to as high as 500 PFU. The available unimmunized NHP data from the above three studies are summarized in Table J-8a.

Table J-8a. NHP inhalational dose-response data for EBOV

Challenge Dose (PFU)	Number exposed	Number died	Strain	Reference
20	3	3	Sudan	Pratt 2010 (historical controls)
100–500	3	3	Sudan	Pratt 2010 (historical controls)
100–500	2	2	Sudan	Pratt 2010
400	2	2	Zaire	Johnson 1995
500	1	1	Zaire	Pratt 2010
800–1200	3	3	Zaire	Pratt 2010
900–1000	1	1	Zaire	Pratt 2010
1000	3	3	Zaire	Geisbert 2008
1100	1	1	Zaire	Pratt 2010
50,000	2	2	Zaire	Johnson 1995

Data from unprotected (unimmunized) monkeys that inhaled the given dose in plaque-forming units (PFU).

As shown in Table J-8a, these studies did not observe any unprotected NHPs surviving exposure, which suggests that doses lower than 20 PFU might also be highly infective to monkeys. Another study (P'iankov 1995) did observe dose-dependent survivorship in rhesus macaques (*Macaca mulatta*), with nine out of sixteen monkeys surviving after inhalational exposure of EBOV. The survivors occurred at the lower doses, which were quantified in units of median mouse intracerebral lethal dose (MICLD₅₀). The data from this study are shown in Table J-8b.

Table J–8b. NHP inhalational dose-response data for EBOV (P’iankov 1995)

Challenge Dose (MICLD ₅₀)	Number exposed	Number died
2.9	4	0
3.5	4	1
16.2	4	2
214	4	4
3550	4	4

Data from P’iankov et al. (1995). Dose amounts were quantified in units of median mouse intracerebral lethal dose (MICLD₅₀) using suckling mice.

Based on the data in Table J–8b, P’iankov et al. reported an estimated LD₅₀ range of 5–20 MICLD₅₀.

J.3.8.4 Literature-Based Dose-Response Estimate

This section consists of a discussion of the dose-response data and evidence for EBOV outlined in the previous section and provides the literature-based dose-response estimate to be used for this RA.

The NHP dose-response data in Table J–8a, with doses quantified in terms of PFU, are not amenable to dose-response model fitting because a 100 percent death rate was observed within every dose group. The P’iankov et al. (1995) data in Table J–8b are amenable to model fitting, but the doses are expressed in different units (MICLD₅₀). A report in the literature (Moe 1981) related units of PFU, MICLD₅₀ and CCID₅₀ by performing titration of the Zaire strain of EBOV by all three methods. They found a PFU/MICLD₅₀ ratio of 2.5/9.0. Therefore, this factor was used to convert units of MICLD₅₀ to units of PFU, and the data from Tables J–8a and J–8b were combined to form a single data set for analysis in this RA, shown in Table J–8c. Because the degree of precision for some dose levels was reported to only one significant digit, dose levels were rounded and consolidated for the data set. Also, the dose groups in Table J–8a reported as ranges were averaged over the endpoints of each range. Analysis showed that these consolidation and averaging procedures did not alter the model fitting results to one significant digit, well within the 95 percent confidence range.

Table J–8c. Consolidated NHP inhalational dose-response data for EBOV

Challenge Dose (PFU)	Number exposed	Number died	Reference
0.8	4	0	P'iankov 1995
1	4	1	P'iankov 1995
5	4	2	P'iankov 1995
20	3	3	Pratt 2010
60	4	4	P'iankov 1995
300	5	5	Pratt 2010
400	2	2	Johnson 1995
500	1	1	Pratt 2010
1000	12	12	Geisbert 2008, Pratt 2010, P'iankov 1995
50,000	2	2	Johnson 1995

Data from unprotected (unimmunized) monkeys that inhaled the given dose, rounded to one significant figure. Data from P'iankov et al. (1995) were converted from units of MICLD₅₀ to PFU assuming 2.5 PFU = 9.0 MICLD₅₀ as explained in the text.

The combined data in Table J–8c were fit to the exponential model, which produced an acceptable fit and an optimal deviance low enough that the beta Poisson model could not possibly improve the fit enough to justify the additional parameter (Haas 1999). The model fitting statistics and ID estimates derived from the model are shown in Table J–8d.

Table J–8d. Model fitting for inhalational NHP dose-response data set

Model	Optimal param. value	Optimal deviance	$\chi^2_{0.95}$, df = 9	LD ₅₀	LD ₁₀	LD ₁
Exp	$r = 0.2$	1.6	17	4 PFU (1–10)	0.7 (0.2–2)	0.06 (0.02–0.2)

Dose-response model fitting to the NHP data from Table J–8c. Exp = exponential. Model parameter is defined in Section J.2.5.1. Fit acceptability was confirmed if the deviance at the optimal parameter values was less than the corresponding 95th percentile chi-squared statistic with degrees of freedom (df) equal to 9, the number of distinct doses minus the number of parameters. Each LD_x result refers to the expected inhaled dose estimated to result in death of x% of exposed individuals under the model. Units of dose are plaque-forming units (PFU). Intervals under the LD estimates are 95% confidence intervals based on model fits to bootstrap replicates from the data set.

The exponential model described in Table J–8d serves as the literature-based dose-response model for this RA, under the assumption that a lethal dose for NHPs under laboratory conditions adequately represents an ID for humans potentially exposed to aerosols from a laboratory release. It is possible that the very low inhalational IDs observed among monkeys and estimated by the model overestimate the probability of infection for humans at low doses, especially in light of the fact that aerosol infection and airborne

transmission appears to have occurred infrequently during human outbreaks of EHF (Geisbert 2004). However, there are alternate explanations for infrequent occurrence of airborne transmission. It is possible that EBOV does not survive well in respirable particles outside laboratory scenarios or that humans infected with EBOV do not shed infectious particles that are easily inhaled (Leffel 2004). Therefore, the possibility that humans would be as susceptible to infection as NHPs after inhaling aerosolized EBOV released from a laboratory cannot be ruled out.

J.3.8.5 Dose-Response Estimates Derived from Expert Panel

In the procedure described previously, dose-response curves were fit to the ID₁₀, ID₅₀, and ID₉₀ estimates provided by each expert on the Delphi panel. The results of this model fitting procedure for EBOV are displayed in Table J–8e, including which models were retained from each expert according to the BIC. Fourteen curves were retained for application in this RA, and plots of those curves are shown in Figure J–8. ID estimates provided by the retained curves are shown in Table J–8f.

Table J–8e: Dose response model fitting for Ebola virus

Expert	ID ₁₀ ID ₅₀ ID ₉₀	Exp. model	Log–probit model		Beta Poisson model		$\Delta\text{BIC}^{\text{Exp}}$	$\Delta\text{BIC}^{\text{Lp}}$	$\Delta\text{BIC}^{\text{BP}}$
		r	m	ID ₅₀	α	β			
1	100 1,000 10,000	5.5×10^{-4}	0.56	1,000	8.9×10^{-1}	8.2×10^2	N/A	Exact	N/A
2	19 120 400	5.7×10^{-3}	0.84	97	1.0×10^6	1.8×10^8	0	13.7	1.1 ^a
3	30 200 3,000	2.1×10^{-3}	0.56	260	8.2×10^{-1}	1.9×10^2	8.1	1.2	0
4	100 1,000 10,000	5.5×10^{-4}	0.56	1,000	8.9×10^{-1}	8.2×10^2	N/A	Exact	N/A
5	40 200 3,000	1.9×10^{-3}	0.59	290	9.3×10^{-1}	2.5×10^2	4.5	0.1	0
6	30 300 3,000	1.8×10^{-3}	0.56	300	8.9×10^{-1}	2.5×10^2	N/A	Exact	N/A
7	100 500 2,000	1.2×10^{-3}	0.86	460	1.0×10^5	8.4×10^7	3.6	0	4.7 ^a
8	50 200 2,000	2.0×10^{-3}	0.69	270	1.5	5.1×10^2	3.3	0	1.8

Fitted parameters for three dose response models to each set of three data points from each expert panelist. Optimal parameter values were rounded to two significant figures. ΔBIC is the Bayesian Information Criterion value relative to the lowest value in that row, where a lower value indicates that the model better represents the available information. Bolded values in the BIC columns indicate that the model for that column was kept in consideration for representing the data provided by the expert panelist in that row, and grey values indicate that the model was eliminated from consideration, generally because its value was more than six greater than the lowest BIC value in that row. ^a indicates that the Beta Poisson model fit produced a curve virtually identical to the exponential model, so it was redundant to keep it in consideration. *Exact* entries indicate that the Log-probit model fit the expert panelist values in that row exactly (which results in a BIC value of negative infinity), so the other two models in that row are not applied (N/A). Abbreviations: Exp = Exponential model; Lp = Log-probit model; BP = Beta Poisson model.

Figure J-8

Plot of all retained dose response curves used to estimate probability of infection for each dose. Solid curves were weighted with 1/8 probability; dashed curves were weighted with 1/16 probability; dotted curves were weighted with 1/24 probability.

Table J–8f. Results for retained expert-derived EBOV dose-response models

Expert	Model	ID ₅₀	ID ₁₀	ID ₁	ID _{0.1}	ID _{0.01}
1	LP	1000	100	15	3.9	1.3
2	Exp	120	19	1.8	0.18	0.018
3	LP	260	26	4.0	1.0	0.33
	BP	250	25	2.3	0.23	0.023
4	LP	1000	100	15	3.9	1.3
5	Exp	360	55	5.3	0.52	0.052
	LP	290	33	5.7	1.6	0.55
	BP	280	31	2.8	0.27	0.027
6	LP	300	30	4.6	1.2	0.38
7	Exp	580	89	8.5	0.84	0.084
	LP	460	100	31	13	6.0
8	Exp	340	52	4.9	0.49	0.049
	LP	270	43	9.5	3.2	1.3
	BP	300	37	3.4	0.34	0.034
Median (Min–Max)		300 org. (120–1000)	40 (19–100)	5.1 (1.8–31)	1.2 (0.18–13)	0.38 (0.018–6.0)

Results are listed for the models that were retained after applying the Bayesian information criterion for model comparison. Each ID_x result refers to the expected inhaled dose estimated to result in infection of x% of exposed individuals. For example, ID_{0.1} refers to the dose estimated to result in infection of 0.1%, or one in one thousand individuals. The medians were calculated after weighing each of the eight experts equally and weighing each model equally within each expert if more than one was retained. Abbreviations: org. = organisms, Exp = exponential, LP = log-probit and BP = beta Poisson.

J.3.8.6 Other Considerations

The units of exposure for events analyzed in this RA for EBOV are in terms of CCID₅₀ (median cell culture infective dose). For the literature-based dose-response model for this RA, the dose amounts are expressed in plaque-forming units (PFU), so potential differences between amounts of exposure measured in CCID₅₀ vs. PFU must be addressed. A study in the literature (Moe 1981) compared titration amounts from the same sample of Ebola virus in both PFU and CCID₅₀, and found a PFU/CCID₅₀ ratio of 1/12. Therefore, in the initial infections analyses for release events in this RA, the exposure estimates in CCID₅₀ are scaled by a factor of 1/12 before being applied to the literature-based dose response model described in Section J.3.8.4.

The expert panelists were asked to provide their ID estimates in terms of number of organisms. It is assumed that the expert values represent numbers of potentially infectious units, as estimated by PFU. Therefore, the exposure estimates are scaled by a factor of 1/12, as described in the previous paragraph, before being applied to the expert-derived dose-response estimates as well. It is possible that this

assumption is non-conservative if the assays used to derive the estimated inventories did not count all the organisms with potential to infect a human as envisioned by the experts. For EBOV, many studies suggest that there could be multiple virions in sample containing 1 PFU, including experiments in which less than one PFU of virus have been shown to infect animals. Electron microscopy and PCR studies have identified 1000–10,000 EBOV genomes per PFU (Towner 2004, Trombley 2010), although many of those genomes are likely not incorporated into viral particles, and therefore are regarded as posing no threat to a potential host, as evidenced by a finding of 74–336 genomes per available shell in a sample of EBOV (Weidmann 2011). Furthermore, it is likely that even many virions with an incorporated genome may be otherwise defective or lack the ability to infect host cells. Therefore, the potential magnitude of non-conservatism resulting from the assumption that numbers of organisms as envisioned by any particular expert are adequately measured by PFU is unknown.

J.3.8.7 Summary of Approach

The following summarizes the two sets of dose-response estimates for EBOV to be applied to exposure data for this RA. ID estimates derived from these models are compared in Table J–8g.

- Literature-based dose-response model: the exponential model with $r = 0.2$, derived by fitting the model to consolidated NHP inhalational dose-response data (Table J–8c). Use a distribution of r values derived from bootstrap replicates of the data set, which results in a 95 percent range of (0.07 to 0.5), for uncertainty and sensitivity analyses.
- Range of dose-response models derived from the expert-provided values: the distribution of estimates shown in Table J–8f, with the model or set of models derived from each expert weighted equally.

Table J–8g. ID estimates and associated ranges for EBOV.

Model	ID ₅₀	ID ₁₀	ID ₁
Literature-based	4 PFU (1–10)	0.7 (0.2–2)	0.06 (0.02–0.2)
Expert-based	300 org. (120–1000)	40 (19–100)	5.1 (1.8–31)

Each ID_x result refers to the expected inhaled dose estimated to result in infection of x% of exposed humans. The literature-based ranges are the 95% intervals derived from the bootstrap parameter distribution; the actual range of values applied to the RA may be wider. The expert-based ranges are the minimum and maximum values from Table J–8f. Abbreviations: PFU = plaque forming unit; org. = organisms.

It is assumed that dose units of PFU and organisms (as conceived by the experts) are equivalent, although this assumption may be non-conservative for the expert-based numbers as described in Section J.3.8.6. The literature-based results, being more conservative than the expert-based results by roughly a factor of 100, can in part serve to assess the implications of the possibility that the expert-based results are non-conservative by a similar factor. Both sets of estimates shown in Table J–8g are applied to the exposure estimates in the initial infection portions of this RA to determine the implications of each estimate for the overall risk posed by EBOV. As described in Section J.3.8.6, the exposure estimates from the event sequence analyses are in units of CCID₅₀, which are first converted to units of PFU before the dose response models described here are applied.

J.3.9 Marburg Virus

Marburg virus (MARV) causes Marburg hemorrhagic fever (MHF), a highly infectious, zoonotic disease that has infected humans in both natural and laboratory settings, as described in Chapter 3 and Appendix C. This section synthesizes the available dose-response information and derives a range of dose-response estimates to be applied to the exposure results from each of the event sequence analyses.

J.3.9.1 Routes of Exposure

For MARV, the primary natural routes of exposure and infection for humans are assumed to be through inhalation of aerosolized particles from contaminated bodily fluids of infected animals or humans, or through ingestion or direction contact with such fluids. Infections resulting from laboratory activities are assumed to be possible via inhalation, ingestion, direct contact, puncture, and animal-related (NHP and rodent) routes. The inhalational route is the primary focus of the dose-response assessment in this section,

1 in support of the events analyzed in this RA that lead to aerosol releases in the laboratory or outside the
2 NEIDL. Non-inhalational routes of exposure and their potential consequences are considered separately
3 and as needed in conjunction with relevant events.
4

5 **J.3.9.2 Vaccine and Prophylaxis**

6 There are currently no vaccines available for MARV, although candidate vaccines are in development
7 that have been shown to be successful in protecting NHPs from disease after inhalational exposure
8 (Geisbert 2008). For this RA, it is assumed that no potentially exposed laboratory worker, facility worker,
9 or member of the general public would be vaccinated against infection or disease with MARV. This is a
10 conservative assumption, as it is possible that some individuals (especially laboratory workers) would be
11 partially protected from an administered vaccine that may become FDA-approved or that may be
12 available before official FDA-approval, such as those classified as an IND.
13

14 There are no prophylactic treatments that have been shown to protect against MARV infection after
15 exposure, nor are there any validated specific treatments for disease after symptoms appear.
16

17 **J.3.9.3 Dose-Response Information from the Literature**

18 There are no human dose-response data available for MARV. Epidemiological evidence suggests that
19 humans have become infected through inhaling aerosolized particles containing MARV, but the amount
20 of virus inhaled by humans who became infected is not known. In the absence of human data, studies on
21 MARV infectivity in animals provide the best-available information through which dose-response
22 information potentially relevant for humans might be obtained.
23

24 Unimmunized NHPs (*Macaca mulatta* or *Macaca fascicularis*) have been infected after inhalational
25 exposure to EBOV in a number of studies. Geisbert et al. (2008), in a vaccine study, exposed two
26 unprotected control group monkeys to target inhalational doses of 1000 PFU and both monkeys
27 subsequently died of disease. Alves et al. (2010), in another vaccine study, exposed six unprotected
28 control group monkeys to doses ranging from 2 PFU to 705 PFU, and all six subsequently died of disease.
29 The available unimmunized NHP data from the above two studies are summarized in Table J-9a.

Table J–9a. NHP inhalational dose-response data for MARV

Challenge Dose (PFU)	Number exposed	Number died	Strain	Reference
2	1	1	Angola	Alves 2010
11	1	1	Angola	Alves 2010
14	1	1	Angola	Alves 2010
99	1	1	Angola	Alves 2010
339	1	1	Angola	Alves 2010
705	1	1	Angola	Alves 2010
1000	2	2	Musoke	Geisbert 2008

Data from unprotected (unimmunized) monkeys that inhaled the given dose of MARV

As shown in Table J–9a, these studies did not observe any unprotected NHPs surviving exposure, which suggests that doses lower than 2 PFU might also be infective to monkeys. Another study (Bazjutin 1992) did observe dose-dependent survivorship in green monkeys (*Chlorocebus sabaeus*), with four out of ten monkeys surviving after inhalational exposure to very low doses of MARV. It appears that the four survivors were actually infected, based on titers of virus found in their blood, but eventually recovered. The doses were quantified in units of median guinea pig intraperitoneal lethal dose (GPIPLD₅₀). The data from this study are shown in Table J–9b.

Table J–9b. NHP inhalational dose-response data for MARV (Bazjutin 1992)

Challenge Dose (GPIPLD ₅₀)	Number exposed	Number died
0.003–0.1	10	6
5	5	5

Data from Bazjutin et al. (1992). Dose amounts were quantified in units of median guinea pig intraperitoneal lethal dose (GPIPLD₅₀).

J.3.9.4 Literature-Based Dose-Response Estimate

This section consists of a discussion of the dose-response data and evidence for MARV outlined in the previous section and provides the literature-based dose-response estimate to be used for this RA.

The NHP dose-response data in Table J–9a, with doses quantified in terms of PFU, are not amenable to dose-response model fitting because a 100 percent death rate was observed at every dose. The Bazjutin et al. (1992) data in Table J–9b observed four survivors exposed to low doses. However, there are a number of issues that make quantitative dose-response modeling difficult with these data.

- The relationship between GPIPLD₅₀ and PFU or other common measures is unclear. Hevey et al. (2002) report a PFU/guinea pig LD₅₀ ratio of about 0.5, but it's unclear if the data or methodology used to derive that relationship is consistent with what was done in Bazjutin et al.
- The most potentially important information for quantitative risk assessment at low doses lies in the lowest dose group, but the dose range for this group covers almost two orders of magnitude (0.003–0.1 GPIPLD₅₀) and it is not specified which doses within that range were inhaled by the survivors.

Based on the above difficulties, it was determined that a quantitative dose-response model based on the data in Tables J–9a and J–9b would not be appropriate. Nevertheless, it is clear that the data imply that low doses on the order of 1 PFU and potentially lower can be lethal to monkeys when inhaled.

Ebola virus (EBOV) is closely related to MARV, and a literature-based dose response curve for EBOV was described in Section J.3.8.4. The estimates derived from that model are consistent with the MARV dose-response data in Table J–9a (the deviance produced by the model applied to the data is less than the 95th percentile of the corresponding chi-squared distribution). In the absence of solid quantitative data for MARV with which to parameterize the low-dose region of a dose-response curve, and given the numerous similarities between EBOV and MARV, it was decided to apply the EBOV literature-based dose-response curve to MARV for this RA.

It is possible that the very low inhalational IDs observed among monkeys and estimated by the model overestimate the probability of infection for humans at low doses, especially in light of the fact that aerosol infection and airborne transmission appears to have occurred infrequently during human outbreaks of MHF (Geisbert 2004). However, there are alternate explanations for infrequent occurrence of airborne transmission. It is possible that MARV does not survive well in respirable particles outside laboratory scenarios or that humans infected with MARV do not shed infectious particles that are easily inhaled (Leffel 2004). Therefore, the possibility that humans would be as susceptible to infection as NHPs after inhaling aerosolized MARV released from a laboratory cannot be ruled out.

J.3.9.5 Dose-Response Estimates Derived from Expert Panel

In the procedure described previously, dose-response curves were fit to the ID₁₀, ID₅₀, and ID₉₀ estimates provided by each expert on the Delphi panel. The results of this model fitting procedure for MARV are

displayed in Table J–9c, including which models were retained from each expert according to the BIC. Twelve curves were retained for application in this RA, and plots of those curves are shown in Figure J–9. ID estimates provided by the retained curves are shown in Table J–9d.

Table J–9c: Dose-response model fitting for Marburg virus

Expert	ID ₁₀ ID ₅₀ ID ₉₀	Exp. model	Log–probit model		Beta Poisson model		$\Delta\text{BIC}^{\text{Exp}}$	$\Delta\text{BIC}^{\text{Lp}}$	$\Delta\text{BIC}^{\text{BP}}$
		r	m	ID ₅₀	α	β			
1	100 1,000 10,000	5.5×10^{-4}	0.56	1,000	8.9×10^{-1}	8.2×10^2	N/A	Exact	N/A
2	19 120 400	5.7×10^{-3}	0.84	97	1.0×10^6	1.8×10^8	0	13.7	1.1 ^a
3	20 100 2,000	3.5×10^{-3}	0.56	160	7.8×10^{-1}	1.0×10^2	5.0	0.8	0
4	100 1,000 10,000	5.5×10^{-4}	0.56	1,000	8.9×10^{-1}	8.2×10^2	N/A	Exact	N/A
5	20 200 2,000	2.8×10^{-3}	0.56	200	8.9×10^{-1}	1.6×10^2	N/A	Exact	N/A
6	10 100 1,000	5.5×10^{-3}	0.56	100	8.9×10^{-1}	8.2×10^1	N/A	Exact	N/A
7	10 500 9,000	1.6×10^{-3}	0.38	360	4.6×10^{-1}	6.8×10^1	10.0	0	4.8
8	20 150 2,000	3.0×10^{-3}	0.56	180	8.4×10^{-1}	1.3×10^2	10.3	1.7	0

Fitted parameters for three dose response models to each set of three data points from each expert panelist. Optimal parameter values were rounded to two significant figures. ΔBIC is the Bayesian Information Criterion value relative to the lowest value in that row, where a lower value indicates that the model better represents the available information. Bolded values in the BIC columns indicate that the model for that column was kept in consideration for representing the data provided by the expert panelist in that row, and grey values indicate that the model was eliminated from consideration, generally because its value was more than six greater than the lowest BIC value in that row. ^a indicates that the Beta Poisson model fit produced a curve virtually identical to the exponential model, so it was redundant to keep it in consideration. *Exact* entries indicate that the Log-probit model fit the expert panelist values in that row exactly (which results in a BIC value of negative infinity), so the other two models in that row are not applied (N/A). Abbreviations: Exp = Exponential model; Lp = Log-probit model; BP = Beta Poisson model.

Figure J–9

Plot of all retained dose response curves used to estimate probability of infection for each dose. Solid curves were weighted with 1/8 probability; dashed curves were weighted with 1/16 probability; dotted curves were weighted with 1/24 probability.

Table J–9d. Results for retained expert-derived MARV dose-response models

Expert	Model	ID ₅₀	ID ₁₀	ID ₁	ID _{0.1}	ID _{0.01}
1	LP	1000	100	15	3.9	1.3
2	Exp	120	19	1.8	0.18	0.018
3	Exp	260	26	4.0	1.0	0.33
3	LP	250	25	2.3	0.23	0.023
3	BP	1000	100	15	3.9	1.3
4	LP	360	55	5.3	0.52	0.052
5	LP	290	33	5.7	1.6	0.55
6	LP	280	31	2.8	0.27	0.027
7	LP	300	30	4.6	1.2	0.38
7	BP	580	89	8.5	0.84	0.084
8	LP	460	100	31	13	6.0
8	BP	340	52	4.9	0.49	0.049
Median (Min–Max)		200 org. (100–1000)	19 (10–100)	2.4 (0.74–15)	0.39 (0.098–3.9)	0.13 (0.013–1.3)

Results are listed for the models that were retained after applying the Bayesian information criterion for model comparison. Each ID_x result refers to the expected inhaled dose estimated to result in infection of x% of exposed individuals. For example, ID_{0.1} refers to the dose estimated to result in infection of 0.1%, or one in one thousand individuals. The medians were calculated after weighing each of the eight experts equally and weighing each model equally within each expert if more than one was retained. Abbreviations: org. = organisms, Exp = exponential, LP = log-probit and BP = beta Poisson.

J.3.9.6 Other Considerations

The units of exposure for events analyzed in this RA for MARV are in terms of CCID₅₀ (median cell culture infective dose). For the literature-based dose-response model for this RA, the dose amounts are expressed in plaque-forming units (PFU), so potential differences between amounts of exposure measured in CCID₅₀ vs. PFU must be addressed. No study was found in the literature comparing titration amount from the same MARV sample using both types of assays. In the absence of this information, it was assumed that same relationship found for EBOV (PFU/CCID₅₀ ratio of 1/12, described in Section J.3.8.6) also applies for MARV. In the initial infections analyses for release events in this RA, the exposure estimates in CCID₅₀ are scaled by a factor of 1/12 before being applied to the literature-based dose response model described in Section J.3.9.4.

The expert panelists were asked to provide their ID estimates in terms of number of organisms. It is assumed that the expert values represent numbers of potentially infectious units, as estimated by PFU. Therefore, the exposure estimates are scaled by a factor of 1/12, as described in the previous paragraph, before being applied to the expert-derived dose-response estimates as well. It is possible that this

assumption is non-conservative if the assays used to derive the estimated inventories did not count all the organisms with potential to infect a human as envisioned by the experts. For MARV, a PCR study found as low as 0.1 PFU/PCR (Trombley 2010). Another study found that samples of MARV contained approximately 3–5 times more particle shells than genomes, suggesting that genomes identified via PCR could all potentially be packaged into a viral particle. However, it is likely that many virions, even with an incorporated genome, may be otherwise defective or lack the ability to infect host cells. Therefore, the potential magnitude of non-conservatism resulting from the assumption that numbers of organisms as envisioned by any particular expert are adequately measured by PFU is unknown but likely less than a factor of 10.

J.3.9.7 Summary of Approach

The following summarizes the two sets of dose-response estimates for MARV to be applied to exposure data for this RA. ID estimates derived from these models are compared in Table J–9e.

- Literature-based dose-response model: the exponential model with $r = 0.2$, derived for the closely related Ebola virus based on NHP inhalational dose-response data (Table J–8c). Use a distribution of r values derived from bootstrap replicates of the data set, which results in a 95 percent range of (0.07 to 0.5), for uncertainty and sensitivity analyses.
- Range of dose-response models derived from the expert-provided values: the distribution of estimates shown in Table J–9d, with the model or set of models derived from each expert weighted equally.

Table J–9e. ID estimates and associated ranges for MARV.

Model	ID ₅₀	ID ₁₀	ID ₁
Literature-based	4 PFU (1–10)	0.7 (0.2–2)	0.06 (0.02–0.2)
Expert-based	200 org. (100–1000)	19 (10–100)	2.4 (0.74–15)

Each ID_x result refers to the expected inhaled dose estimated to result in infection of x% of exposed humans. The literature-based ranges are the 95% intervals derived from the bootstrap parameter distribution; the actual range of values applied to the RA may be wider. The expert-based ranges are the minimum and maximum values from Table J–9d. Abbreviations: PFU = plaque forming unit; org. = organisms.

It is assumed that dose units of PFU and organisms (as conceived by the experts) are equivalent, although this assumption may be non-conservative for the expert-based numbers as described in Section J.3.8.6. The literature-based results, being more conservative than the expert-based results by roughly a factor of 50, can in part serve to assess the implications of the possibility that the expert-based results are non-conservative by a similar factor. Both sets of estimates shown in Table J–9e are applied to the exposure estimates in the initial infection portions of this RA to determine the implications of each estimate for the overall risk posed by MARV. As described in Section J.3.9.6, the exposure estimates from the event sequence analyses are in units of CCID₅₀, which are first converted to units of PFU before the dose response models described here are applied.

J.3.10 Lassa Virus

Lassa virus (LASV) causes Lassa fever, a highly infectious, zoonotic, rodent-transmitted disease that has infected humans in both natural and laboratory settings, as described in Chapter 3 and Appendix C. This section synthesizes the available dose-response information and derives a range of dose-response estimates to be applied to the exposure results from each of the event sequence analyses.

J.3.10.1 Routes of Exposure

For LASV, the primary natural routes of exposure and infection for humans are assumed to be through direct contact with or ingestion of excretions from infected rodents. Inhalation of particles contaminated with rodent excretions might also cause infection. Bodily fluids of infected humans may cause infection in contacts as well. Infections resulting from laboratory activities are assumed to be possible via inhalation, ingestion, direct contact, puncture, and animal-related (NHP and rodent) routes. The inhalational route is the primary focus of the dose-response assessment in this section, in support of the events analyzed in this RA that lead to aerosol releases in the laboratory or outside the NEIDL. Non-inhalational routes of exposure and their potential consequences are considered separately and as needed in conjunction with relevant events.

J.3.10.2 Vaccine and Prophylaxis

There are currently no vaccines available for LASV, although at least one vaccine is in development that has been shown to be successful in protecting NHPs from disease (Geisbert 2005). For this RA, it is assumed that no potentially exposed laboratory worker, facility worker, or member of the general public would be vaccinated against infection or disease with LASV. This is a conservative assumption, as it is possible that some individuals (especially laboratory workers) would be partially protected from an

administered vaccine that may become FDA-approved or that may be available before official FDA-approval, such as those classified as an IND.

There are no prophylactic treatments that have been shown to protect against LASV infection after exposure. The antiviral drug ribavirin has been shown to be an effective treatment for Lassa fever if administered soon after symptoms appear (see Chapter 3 and Appendix C for references).

J.3.10.3 Dose-Response Information from the Literature

There are no human dose-response data available for LASV. Epidemiological evidence suggests that humans have become infected through inhaling aerosolized particles containing LASV, but the amount of virus inhaled by humans who became infected is not known. In the absence of human data, studies on LASV infectivity in animals provide the best-available information through which dose-response information potentially relevant for humans might be obtained.

There are data demonstrating that moderate to high doses of LASV are highly infectious in NHPs via the inhalational route of exposure. Stephenson et al. (1984) exposed nine cynomolgus monkeys (*Macaca fascicularis*) to inhaled doses ranging from 468 to 24500 PFU and all nine died from subsequent disease. Given the absence of negative cases (i.e., survivors) in this data set, it is not possible to derive a dose-response model from these data that would facilitate estimates of the probability of infection at lower doses, although the data suggest that the LD₅₀ for cynomolgus monkeys would be below the given range of doses.

Stephenson et al. (1984) also exposed outbred guinea pigs to aerosols of LASV at lower doses (see Table J-10a). These data were fit to dose-response models by Tamrakar and Haas (2008), who tested the exponential, beta Poisson, and log-probit models and accepted the exponential model as the best fit. Their best-fit model estimates an ID₅₀ of 18 PFU (95 percent confidence interval 6.7–40), an ID₁₀ of 2.7 PFU (1.0–6.0), and an ID₁ of 0.26 PFU (0.098–0.58).

Table J–10a. Guinea pig inhalational dose-response data (Stephenson 1984) for LASV.

Challenge Dose (PFU)	Number exposed	Number infected
5	8	1
48	8	7
724	8	8
5370	8	8

Data from Stephenson et al. (1984) and analyzed in Tamrakar and Haas (2008). Infected animals included animals that died and animals that survived but were seropositive for humoral antibodies.

J.3.10.4 Literature-Based Dose-Response Estimate

This section consists of a discussion of the dose-response data, evidence, and published model for LASV outlined in the previous section and provides the literature-based dose-response estimate to be used for this RA.

Tamrakar and Haas (2008) found the monkey and guinea pig data from Stephenson et al. (1984) to be the only inhalational dose-response animal data available in the literature. The guinea pig data with infection as the response was amenable to dose-response model fitting, and the best fit (exponential) model to this data is the literature-based dose response model to be used for this RA. IDs estimated by the model at varying probabilities are shown in Table J–10b.

Table J–10b. ID estimates (with 95% confidence intervals) for animals from LASV inhalational dose-response models from the literature

Set	Animal	Model	ID ₅₀	ID ₁₀	ID ₁
A	Guinea pig (Stephenson 1984, Tamrakar 2008)	Exp	18 PFU (6.7–40)	2.7 PFU (1.0–6.0)	0.26 PFU (0.098–0.58)
B	<i>Macaca fascicularis</i> (Stephenson 1984)	none	< ≈468 PFU		

Each ID_x result refers to the expected inhaled dose estimated to result in infection of x% of exposed animals. For example, ID₁ refers to the dose estimated to result in death of 1%, or one in one hundred animals. For the models, Exp = exponential. For data set A, the 95% confidence intervals are based on model fits to bootstrap replicates from the data set. For data set B, the data were not fit to a model and the ID₅₀ upper bound estimate is based on the result that 9 of 9 monkeys died from exposure to 468–24500 PFU. The model fit to data set A was chosen as the literature-based model for this RA.

1 This model is not inconsistent with the monkey data, as the model estimates less than 10^{-8} probability of
2 avoiding infection at the dose range to which all nine monkeys succumbed. However, it is unknown
3 whether monkeys or humans would exhibit similar responses to the guinea pigs at low doses. Therefore,
4 the estimates derived from this model are to be applied cautiously.

6 **J.3.10.5 Dose-response Estimates Derived from Expert Panel**

7 In the procedure described previously, dose-response curves were fit to the ID₁₀, ID₅₀, and ID₉₀ estimates
8 provided by each expert on the Delphi panel. The results of this model fitting procedure for LASV are
9 displayed in Table J–10c, including which models were retained from each expert according to the BIC.
10 Fourteen curves were retained for application in this RA, and plots of those curves are shown in Figure J–
11 10. ID estimates provided by the retained curves are shown in Table J–10d.

Table J–10c: Dose response model fitting for Lassa virus

Expert	ID ₁₀ ID ₅₀ ID ₉₀	Exp. model	Log-probit model		Beta Poisson model		ΔBIC ^{Exp}	ΔBIC ^{Lp}	ΔBIC ^{BP}
		<i>r</i>	<i>m</i>	ID ₅₀	<i>α</i>	<i>β</i>			
1	50 300 1,000	2.2×10^{-3}	0.86	250	1.0×10^6	4.5×10^8	0	8.2	1.1 ^a
2	3 18 59	3.8×10^{-2}	0.86	15	1.0×10^6	2.7×10^7	0	7.8	1.1 ^a
3	10 50 1,000	7.0×10^{-3}	0.56	79	7.8×10^{-1}	5.2×10^1	5.0	0.8	0
4	10 100 1,000	5.5×10^{-3}	0.56	100	8.9×10^{-1}	8.2×10^1	N/A	Exact	N/A
5	20 80 1,000	4.7×10^{-3}	0.66	120	1.2	1.6×10^2	3.2	0	1
6	4 40 400	1.4×10^{-2}	0.56	40	8.9×10^{-1}	3.3×10^1	N/A	Exact	N/A
7	300 30,000 3,000,000	1.8×10^{-5}	0.28	30,000	2.9×10^{-1}	1.3×10^3	N/A	Exact	N/A
8	20 40 1,500	5.2×10^{-3}	0.59	110	7.8×10^{-1}	6.9×10^1	1.3	0.2	0

Fitted parameters for three dose response models to each set of three data points from each expert panelist. Optimal parameter values were rounded to two significant figures. ΔBIC is the Bayesian Information Criterion value relative to the lowest value in that row, where a lower value indicates that the model better represents the available information. Bolded values in the BIC columns indicate that the model for that column was kept in consideration for representing the data provided by the expert panelist in that row, and grey values indicate that the model was eliminated from consideration, generally because its value was more than six greater than the lowest BIC value in that row. ^a indicates that the Beta Poisson model fit produced a curve virtually identical to the exponential model, so it was redundant to keep it in consideration. *Exact* entries indicate that the Log-probit model fit the expert panelist values in that row exactly (which results in a BIC value of negative infinity), so the other two models in that row are not applied (N/A). Abbreviations: Exp = Exponential model; Lp = Log-probit model; BP = Beta Poisson model.

Figure J-10

Plot of all retained dose response curves used to estimate probability of infection for each dose. Solid curves were weighted with 1/8 probability; dashed curves were weighted with 1/16 probability; dotted curves were weighted with 1/24 probability.

Table J–10d. Results for retained expert-derived LASV dose-response models

Expert	Model	ID ₅₀	ID ₁₀	ID ₁	ID _{0.1}
1	LP	310	47	4.5	0.45
2	Exp	18	2.8	0.27	0.027
3	Exp	100	15	1.4	0.14
	LP	79	7.9	1.2	0.31
	BP	73	7.4	0.66	0.066
4	LP	100	10	1.5	0.39
5	Exp	150	22	2.1	0.21
	LP	120	17	3.4	1.0
	BP	120	14	1.3	0.13
6	LP	40	4.0	0.61	0.16
7	LP	30000	300	7.0	0.45
8	Exp	130	20	1.9	0.19
	LP	110	12	2.1	0.58
	BP	98	9.9	0.89	0.088
Median (Min–Max)		100 org. (18–30000)	11 (2.8–300)	1.5 (0.27–7.0)	0.26 (0.027–1.0)

Results are listed for the models that were retained after applying the Bayesian information criterion for model comparison. Each ID_x result refers to the expected inhaled dose estimated to result in infection of x% of exposed individuals. For example, ID_{0.1} refers to the dose estimated to result in infection of 0.1%, or one in one thousand individuals. The medians were calculated after weighing each of the eight experts equally and weighing each model equally within each expert if more than one was retained. Abbreviations: org. = organisms, Exp = exponential, LP = log-probit and BP = beta Poisson.

It is noted that the estimates derived from Expert 2 are very close to the estimates derived from the chosen dose-response model from the literature. This can be explained by the fact that this expert was an author of the study in which the literature-based model was found and clearly was of the opinion that this model is applicable to humans.

J.3.10.6 Other Considerations

The units of exposure for events analyzed in this RA for LASV are in terms of CCID₅₀ (median cell culture infective dose), FFU (fluorescent focus units), and PFU (plaque forming units). It is assumed that the estimated inventory concentration of LASV that would be used at the NEIDL is an appropriate estimate under all three units of measure. These units do not measure the absolute number of virions in a sample, because individual virions may aggregate or clump to infect a cell or to form one plaque or focus unit and because a given assay may not be entirely sensitive to detecting all virions that would have the ability to infect cells in a different medium or host. The exposures in the guinea pig experiments that form

the basis for the literature-based dose-response estimates are in terms of PFU, so it is appropriate to apply the curves derived from these data to the exposure estimates.

The expert panelists were asked to provide their ID estimates in terms of number of organisms. It is assumed that the expert values represent numbers of potentially infectious units, as estimated by PFU or FFU, and that it is appropriate to apply the curves derived from their estimates to the exposure estimates. It is possible that this assumption is non-conservative if the assays used to derive the estimated inventories did not count all the organisms with potential to infect a human as envisioned by the experts. A recent study has reported counts of viral genomes as well as virus particles in samples of LASV that were also assayed for FFU, resulting in estimates of about 2200 viral genomes per FFU and about 100 virus particles per FFU (Weidmann 2011). It is clear from these data that the number of viral genomes in a sample of LASV is not an appropriate estimate for the number of organisms, because there were 22 times as many genomes as there were particles available to contain genomes and form complete virions. The number of virus particles observed might be a more accurate estimate for the number of organisms, but it is also possible that many of those particles did not represent replication competent virions with the ability to infect host cells, which is supported by the fact that roughly 99 percent of those particles did not form FFU in the cell culture. However, it is possible that some portion of the particles that were not infective in the cell culture would be infective to cells in a live host. Therefore, these data suggest that the assumption that numbers of organisms as envisioned by the experts are adequately measured by FFU might be non-conservative by up to a factor of 100.

J.3.10.7 Summary of Approach

The following summarizes the two sets of dose-response estimates for LASV to be applied to exposure data for this RA. ID estimates derived from these models are compared in Table J–10e.

- Literature-based dose-response model: the exponential model with $r = 0.039$, derived by Tamrakar and Haas (2008) for guinea pig inhalational dose-response data (Stephenson 1984). Use a distribution of r values derived from bootstrap replicates of the data set, which results in a 95 percent range of (0.017 to 0.10), for uncertainty and sensitivity analyses.
- Range of dose-response models derived from the expert-provided values: the distribution of estimates shown in Table J–10d, with the model or set of models derived from each expert weighted equally.

Table J–10e. ID estimates and associated ranges for LASV.

Model	ID ₅₀	ID ₁₀	ID ₁
Literature-based	18 PFU (6.7–40)	2.7 (1.0–6.1)	0.26 (0.098–0.58)
Expert-based	100 org. (18–30000)	11 (2.8–300)	1.5 (0.27–7.0)

Each ID_x result refers to the expected inhaled dose estimated to result in infection of x% of exposed humans. The literature-based ranges are the 95% intervals derived from the bootstrap parameter distribution; the actual range of values applied to the RA may be wider. The expert-based ranges are the minimum and maximum values from Table J–10d. Abbreviations: PFU = plaque forming unit; org. = organisms.

For each ID point displayed in Table J–10e, the literature-based range extends lower (higher risk) than the expert-based range. It is assumed that dose units of PFU and organisms (as conceived by the experts) are equivalent, although this assumption may be non-conservative for the expert-based numbers as described in Section J.3.10.6. The literature-based results, being more conservative than the expert-based results, can in part serve to assess the implications of the possibility that the expert-based results are non-conservative by a similar factor. Both sets of estimates shown in Table J–10e are applied to the exposure estimates in the initial infection portions of this RA to determine the implications of each estimate for the overall risk posed by LASV.

J.3.11 Junin Virus

Junin virus (JUNV) causes Argentine hemorrhagic fever (AHF), a highly infectious, zoonotic disease that has infected humans in both natural and laboratory settings, as described in Chapter 3 and Appendix C. This section synthesizes the available dose-response information and derives a range of dose-response estimates to be applied to the exposure results from each of the event sequence analyses.

J.3.11.1 Routes of Exposure

For JUNV, the primary natural route of exposure and infection for humans is assumed to be through inhalation of aerosolized virus from excretions from infected rodents. Direct contact with or ingestion of contaminated fluids or fomites or bites from infected rodents may also cause infection. Bodily fluids of infected humans may cause infection in contacts as well. Infections resulting from laboratory activities are assumed to be possible via inhalation, ingestion, direct contact, puncture, and animal-related (NHP and rodent) routes. The inhalational route is the primary focus of the dose-response assessment in this section, in support of the events analyzed in this RA that lead to aerosol releases in the laboratory or

outside the NEIDL. Non-inhalational routes of exposure and their potential consequences are considered separately and as needed in conjunction with relevant events.

J.3.11.2 Vaccine and Prophylaxis

A live attenuated vaccine, Candid-1, has been effective in decreasing incidence of AHF in Argentina (see Chapter 3 for references). However, this vaccine is not FDA-approved for use in the United States. For this RA, it is assumed that no potentially exposed laboratory worker, facility worker, or member of the general public would be vaccinated against infection or disease with JUNV. This is a conservative assumption, as it is possible that some individuals (especially laboratory workers) would be partially protected from an administered vaccine that may become FDA-approved or that may be available before official FDA-approval, such as those classified as an IND.

The Candid-1 vaccine is used for prophylaxis in Argentina but is unavailable in the United States. Specific treatment measures such as immune plasma and ribavirin have been effective in reducing the risk of mortality for AHF patients (See Chapter 3 for references).

J.3.11.3 Dose-Response Information from the Literature

There are no human dose-response data available for JUNV. Epidemiological evidence suggests that humans may become infected through inhaling aerosolized particles containing JUNV, but the amount of virus inhaled by humans who became infected is not known. In the absence of human data, studies on NIPV infectivity in animals provide the best-available information through which dose-response information potentially relevant for humans might be obtained.

A NHP, the rhesus macaque (*Macaca mulatta*), was shown to be susceptible to infection with JUNV after inhalational exposure and developed disease symptoms similar to those observed in humans (Kenyon 1992). Six monkeys were exposed to inhalational doses ranging from 32 PFU (plaque forming units) to 20,000 PFU. One monkey exposed to a high dose died before disease symptoms developed from a probable complication due to anesthesia. All the remaining five monkeys experienced disease symptoms and subsequently died. The doses inhaled by these five monkeys are shown in Table J-11a.

Table J–11a. *Macaca mulatta* inhalational dose-response data (Kenyon 1992) for JUNV.

Challenge Dose (PFU)	Number exposed	Number infected and died
32	1	1
50	1	1
79	1	1
20,000	2	2

Data from Kenyon et al. (1992). PFU = plaque forming units.

Guinea pigs have also been used extensively as an animal model for human AHF, but no studies were found in which guinea pigs were exposed to low doses (comparable to Table J–11a) via the inhalational route. One study (Parodi 1958), found a 100 percent infection rate among guinea pigs exposed intranasally to doses of a virulent strain of JUNV of 3200 CCID₅₀ and 32,000 CCID₅₀.

J.3.11.4 Literature-Based Dose-Response Estimate

This section consists of a discussion of the dose-response data and evidence for JUNV outlined in the previous section and provides the literature-based dose-response estimate to be used for this RA.

The NHP (*Macaca mulatta*) inhalational dose response data (Kenyon 1992) shown in Table J–11a provide the most potentially relevant information for infectivity of JUNV via the inhalational route at low doses. The data are not amenable to dose-response model fitting, as the infection rate was 100 percent across all doses. However, the data do provide some insight into probable upper bounds for ID levels for *Macaca mulatta*. For example, the exponential dose-response model can be evaluated in terms of how low the model parameter r can be while still producing a deviance low enough to be acceptable under statistical criteria in light of the data. Table J–11b shows the result of this exercise.

Table J–11b. Exponential dose-response model evaluation and upper bound ID estimates in light of NHP inhalational dose-response data (Kenyon 1992).

Animal	Model	Parameter value lower bound	Deviance	ID ₅₀ upper bound	ID ₁₀ upper bound	ID ₁ upper bound
<i>Macaca mulatta</i> (Kenyon 1992)	Exp	$r > 0.0064$	$< \chi^2_{0.95, 3} = 7.8$	< 110 PFU	< 16 PFU	< 1.6 PFU

Exponential model evaluation in light NHP exposure data (Kenyon 1992) shown in Table J–11a. Lower bound r value produces deviance equal to 95th percentile of the chi-squared distribution with 3 degrees of freedom, the number of distinct doses in the data set (4) minus the number of model parameters (1). Each ID_x result refers to the expected inhaled dose estimated to result in infection of $x\%$ of exposed animals. For example, ID₁ refers to the dose estimated to result in death of 1%, or one in one hundred animals. PFU = plaque forming units.

The results in Table J–11b are intended to be guidelines for upper bounds of ID estimates. For example, if the true ID₅₀ for *Macaca mulatta* were greater than 110 PFU and if the exponential model is appropriate, then it would be unlikely (less than about 5 percent chance) that the data in Table J–11a would be observed. These results give no information on lower bounds for IDs. In the absence of further data, it is not possible to estimate how low the ID₅₀ or other ID levels might be. Therefore, it was determined that a literature-based dose-response estimate would not be applied for this RA. However, the results in Table J–11b are used to assess the expert-derived estimates in Section J.3.11.7.

J.3.11.5 Dose-Response Estimates Derived from Expert Panel

In the procedure described previously, dose-response curves were fit to the ID₁₀, ID₅₀, and ID₉₀ estimates provided by each expert on the Delphi panel. The results of this model fitting procedure for JUNV are displayed in Table J–11c, including which models were retained from each expert according to the BIC. Seventeen curves were retained for application in this RA, and plots of those curves are shown in Figure J–11. ID estimates provided by the retained curves are shown in Table J–11d.

Table J-11c: Dose response model fitting for Junin virus

Expert	ID ₁₀ ID ₅₀ ID ₉₀	Exp. model	Log-probit model		Beta Poisson model		$\Delta\text{BIC}^{\text{Exp}}$	$\Delta\text{BIC}^{\text{Lp}}$	$\Delta\text{BIC}^{\text{BP}}$
		r	m	ID ₅₀	α	β			
1	50 400 1,000	2.0×10^{-3}	0.86	270	1.0×10^6	4.9×10^8	0	6.1	1.1 ^a

Fitted parameters for three dose response models to each set of three data points from each expert panelist. Optimal parameter values were rounded to two significant figures. ΔBIC is the Bayesian Information Criterion value relative to the lowest value in that row, where a lower value indicates that the model better represents the available information. Bolded values in the BIC columns indicate that the model for that column was kept in consideration for representing the data provided by the expert panelist in that row, and grey values indicate that the model was eliminated from consideration, generally because its value was more than six greater than the lowest BIC value in that row. ^a indicates that the Beta Poisson model fit produced a curve virtually identical to the exponential model, so it was redundant to keep it in consideration. *Exact* entries indicate that the Log-probit model fit the expert panelist values in that row exactly (which results in a BIC value of negative infinity), so the other two models in that row are not applied (N/A). Abbreviations: Exp = Exponential model; Lp = Log-probit model; BP = Beta Poisson model.

Figure J-11

Plot of all retained dose response curves used to estimate probability of infection for each dose. Solid curves were weighted with 1/8 probability; dashed curves were weighted with 1/16 probability; dotted curves were weighted with 1/24 probability.

Table J-11d. Results for retained expert-derived JUNV dose-response models

Expert	Model	ID ₅₀	ID ₁₀	ID ₁	ID _{0.1}	ID _{0.01}

	BP	93	10	0.94	0.093	0.0093
Median (Min–Max)		96 org. (14–1000)	14 (2.1–100)	1.6 (0.20–15)	0.19 (0.020–3.9)	0.049 (0.0020–1.3)

Results are listed for the models that were retained after applying the Bayesian information criterion for model comparison. Each ID_x result refers to the expected inhaled dose estimated to result in infection of x% of exposed individuals. For example, ID_{0.1} refers to the dose estimated to result in infection of 0.1%, or one in one thousand individuals. The medians were calculated after weighing each of the eight experts equally and weighing each model equally within each expert if more than one was retained. Abbreviations: org. = organisms, Exp = exponential, LP = log-probit and BP = beta Poisson.

J.3.11.6 Other Considerations

The units of exposure for events analyzed in this RA for JUNV are in terms of PFU (plaque forming units). These units do not measure the absolute number of active virions in a sample, because individual virions may aggregate or clump to infect a cell or to form one plaque and because a given assay may not be entirely sensitive to detecting all virions that would have the ability to infect cells in a different medium or host. The exposures in the NHP experiment that was assessed in Section J.3.11.3 were measured in units of PFU, so it is appropriate to evaluate information derived from these data for the exposure estimates.

The expert panelists were asked to provide their ID estimates in terms of number of organisms. It is assumed that the expert values represent numbers of potentially infectious units, as estimated by PFU, and that it is appropriate to apply the curves derived from their estimates to the exposure estimates. It is

possible that this assumption is non-conservative if the assays used to derive the estimated inventories did not count all the organisms with potential to infect a human as envisioned by the experts. One study in the literature performed real-time PCR and reported that as little as 0.0001 PFU can be detected by PCR. These data are of limited use because many of those genomes are likely not incorporated into viral particles, and therefore are regarded as posing no threat to a potential host. Furthermore, it is likely that even many virions with an incorporated genome may be otherwise defective or lack the ability to infect host cells. Therefore, the potential magnitude of non-conservatism resulting from the assumption that numbers of organisms as envisioned by any particular expert are adequately measured by PFU is unknown.

J.3.11.7 Summary of Approach

The following summarizes the dose-response estimates for JUNV derived in this section. ID estimates derived from these models are compared in Table J-11e.

- Literature-based dose-response information: the exponential model was evaluated in light of NHP (*Macaca mulatta*) dose-response data and it was determined that parameter values for $r > 0.0064$, would not be inconsistent with the data. It was not possible to derive a best-fit curve from the data.
- Range of dose-response models derived from the expert-provided values: the distribution of estimates shown in Table J-11d, with the model or set of models derived from each expert weighted equally.

Table J-11e. ID estimates and associated ranges for JUNV.

Model	ID ₅₀	ID ₁₀	ID ₁	ID _{0.1}
Literature-based	< 110 PFU	< 16	< 1.6	< 0.16
Expert-based	96 org. (14–1000)	14 (2.1–100)	1.6 (0.20–15)	0.19 (0.020–3.9)

Each ID_x result refers to the expected inhaled dose estimated to result in infection of x% of exposed humans. The literature-based values are upper bounds listed here for comparison purposes. The expert-based ranges are the minimum and maximum values from Table J-11d. Abbreviations: PFU = plaque forming units; org. = organisms.

The expert-based estimates shown in Table J-11e are applied to the exposure estimates in the initial infection portions of this RA to determine the implications for the overall risk posed by JUNV. The

median point estimates (in bold) are close to the literature-based upper bounds estimated from NHP data, which means that about half the weight of the expert based range is above that estimated upper bound. Those estimates above the median are not necessarily inaccurate, as it is possible that humans are not as susceptible to infection from JUNV aerosols as are *Macaca mulatta*. The part of the distribution that lies below the literature-based upper bound can serve to represent the possibility that human susceptibility to JUNV is consistent with what was observed among NHPs.

J.3.12 Tick-Borne Encephalitis Virus, Far Eastern Subtype

(Formerly called Tick-borne encephalitis complex (Russian spring summer encephalitis virus))

The Far Eastern sub-type of tick-borne encephalitis virus (TBEV-FE) is a highly infectious, tick-borne virus that has infected humans in both natural and laboratory settings, as described in Chapter 3 and Appendix C. This section synthesizes the available dose-response information and derives a range of dose-response estimates to be applied to the exposure results from each of the event sequence analyses.

J.3.12.1 Routes of Exposure

For TBEV-FE, the primary natural route of exposure and infection for humans is assumed to be through bites from infected ticks. Infection has also been linked to ingestion of contaminated animal products. Infection from inhalational exposure has also occurred in laboratory settings. Infections resulting from laboratory activities are assumed to be possible via inhalation, ingestion, direct contact, puncture, and animal-related (NHP, rodent, and tick) routes. The inhalational route is the primary focus of the dose-response assessment in this section, in support of the events analyzed in this RA that lead to aerosol releases in the laboratory or outside the NEIDL. Non-inhalational routes of exposure and their potential consequences are considered separately and as needed in conjunction with relevant events.

J.3.12.2 Vaccine and Prophylaxis

A vaccine is available in some countries where the disease is endemic, but it is not currently available in the United States. For this RA, it is assumed that no potentially exposed laboratory worker, facility worker, or member of the general public would be vaccinated against infection or disease with TBEV-FE. This is a conservative assumption, as it is possible that some individuals (especially laboratory workers) would be partially protected from an administered vaccine that may become FDA-approved or that may be available before official FDA-approval, such as those classified as an IND, in the future.

It is also assumed that no prophylactic treatment would be available to prevent infection in exposed individuals. There is no specific drug therapy that has been shown to be effective against TBE disease after infection occurs in humans.

J.3.12.3 Dose-Response Information from the Literature

There are no human dose-response data available for TBEV-FE. Evidence from LAI suggests that humans may have become infected through inhaling aerosolized particles containing TBEV of various sub-types, but the amount of virus inhaled by humans who became infected is not known.

As described in Chapter 3 and Appendix C, experiments on laboratory animal infection with TBEV have been generally ineffective in reproducing aspects of human disease. The example in the literature that might be most relevant to inhalational exposure of humans to TBEV-FE is a study (Hambleton 1983) in which rhesus monkeys (*Macaca mulatta*) were exposed via the intranasal route to TBEV-CE (Central European sub-type) and exhibited symptoms similar to those seen in humans. Ten monkeys were exposed intranasally to very high doses ranging from 300 million to 800 million PFU. Of these ten, six experienced severe clinical symptoms leading to death, two appeared to have sub-clinical infection, and two were sacrificed early. An additional five animals were exposed to similarly high doses via the intravenous route, presumably closer to the natural route of infection in humans (tick bite), but none of these animals showed clinical symptoms of disease.

J.3.12.4 Literature-Based Dose-Response Estimate

This section consists of a discussion of the dose-response data and evidence for TBEV-FE outlined in the previous section and discusses why a literature-based dose-response estimate is not used for this RA.

Dose-response literature is extremely sparse for TBEV-FE, especially for inhalational exposure. The one animal study described in Section J.3.12.3 (Hambleton 1983) is of very limited use. First, the susceptibility of rhesus monkeys to TBEV appears to be of a different nature than that of humans, as monkeys that were exposed to high doses via the route closest to the natural route of infection in humans did not develop disease. Second, the doses applied were extremely high and not described in enough detail on which to base a dose-response model, which would have to extrapolate down many orders of magnitude to shed any light on what the probability of infection might be at exposure levels relevant for this RA.

It is noted that laboratory infections of humans did occur via the inhalational route in the past, which suggests that humans may be susceptible to relatively low doses by that route. However, it is impossible

1 to derive quantitative estimates from this information. Therefore, a literature-based dose response model
2 is not applied to TBEV-FE exposure estimates for this RA.

4 **J.3.12.5 Dose-response Estimates Derived from Expert Panel**

5 In the procedure described previously, dose-response curves were fit to the ID₁₀, ID₅₀, and ID₉₀ estimates
6 provided by each expert on the Delphi panel. The results of this model fitting procedure for TBEV-FE are
7 displayed in Table J–12a, including which models were retained from each expert according to the BIC.

8 Fourteen curves were retained for application in this RA, and plots of those curves are shown in Figure J–
9 12. ID estimates provided by the retained curves are shown in Table J–12b.

Table J-12a: Dose response model fitting for TBEV-FE

Expert	ID ₁₀ ID ₅₀ ID ₉₀	Exp. model	Log-probit model		Beta Poisson model		$\Delta\text{BIC}^{\text{Exp}}$	$\Delta\text{BIC}^{\text{Lp}}$	$\Delta\text{BIC}^{\text{BP}}$
		r	m	ID ₅₀	α	β			
1	1,000 5,000 50,000	8.8×10^{-5}	0.66	6,300	1.3	9.3×10^3	5.2	0	1.7

8	Exp	200	30	2.9	0.29	0.029
	LP	160	16	2.4	0.62	0.20
	BP	150	15	1.3	0.13	0.013
Median (Min–Max)		200 org. (71–10000)	20 (10–1200)	3.1 (1.0–180)	0.78 (0.10–56)	0.25 (0.010–22)

Results are listed for the models that were retained after applying the Bayesian information criterion for model comparison. Each ID_x result refers to the expected inhaled dose estimated to result in infection of x% of exposed individuals. For example, ID_{0.1} refers to the dose estimated to result in infection of 0.1%, or one in one thousand individuals. The medians were calculated after weighing each of the eight experts equally and weighing each model equally within each expert if more than one was retained. Abbreviations: org. = organisms, Exp = exponential, LP = log-probit and BP = beta Poisson.

J.3.12.6 Other Considerations

The units of exposure for events analyzed in this RA for TBEV-FE are in terms of MID₅₀ (median mouse infective dose). The expert panelists were asked to provide their ID estimates in terms of number of organisms. It is assumed that the expert values represent numbers of potentially infectious units, as estimated by plaque-forming units (PFU). It is likely that the exposure estimates would be lower in terms of PFU, because the estimated inventory concentration (1×10^8 MID₅₀ / ml), which is proportional to the exposure estimates, was chosen in those units because titers in other units, including PFU, were generally found to be lower in the literature. However, there is at least one example of up to 10^8 PFU / mL being achieved for TBEV in tick cell lines (Ruzek 2008). Therefore, it is conservatively assumed that it is appropriate to apply the expert-derived dose-response estimates to the exposure estimates in units of MID₅₀.

It is possible that the assumption that the expert ID estimates are representative of PFU is non-conservative if the assays used to derive the estimated inventories did not count all the organisms with

potential to infect a human as envisioned by the experts. No studies were found in the literature that attempted to quantify the number of virions represented by one PFU or one MID₅₀. Therefore, the potential magnitude of non-conservatism resulting from the assumption that numbers of organisms as envisioned by any particular expert are adequately measured by PFU is unknown.

J.3.12.7 Summary of Approach

The following summarizes the two sets of dose-response estimates for TBEV-FE to be applied to exposure data for this RA. ID estimates derived from these models are compared in Table J–12c.

- Literature-based dose-response model: none
- Range of dose-response models derived from the expert-provided values: the distribution of estimates shown in Table J–12b, with the model or set of models derived from each expert weighted equally.

Table J–12c. ID estimates and associated ranges for TBEV-FE.

Model	ID ₅₀	ID ₁₀	ID ₁	ID _{0.1}	ID _{0.01}
Expert-based	200 org. (71–10000)	20 (10–1200)	3.1 (1.0–180)	0.78 (0.10–56)	0.25 (0.010–22)

Each ID_x result refers to the expected inhaled dose estimated to result in infection of x% of exposed humans. The literature-based ranges are the 95% intervals derived from the bootstrap parameter distribution; the actual range of values applied to the RA may be wider. The expert-based ranges are the minimum and maximum values from Table J–12b. Abbreviations: org. = organisms.

The estimates shown in Table J–12c are applied to the exposure estimates in the initial infection portions of this RA to determine the implications of each estimate for the overall risk posed by TBEV-FE. The literature on TBEV dose-response is not extensive enough to make an evaluation of these ID estimates. However, the fact that LAI have occurred via exposure to aerosols imply that relatively low doses might be able to cause infection in humans, which appears to be adequately captured by the range of estimates shown here.

J.3.13 Nipah Virus

Nipah virus (NIPV) is a highly infectious, zoonotic virus that has infected humans, causing encephalitis and/or respiratory disease, as described in Chapter 3 and Appendix C. This section synthesizes the available dose-response information and derives a range of dose-response estimates to be applied to the exposure results from each of the event sequence analyses.

J.3.13.1 Routes of Exposure

For NIPV, the primary natural routes of exposure and infection for humans are assumed to be through direct contact with or ingestion or inhalation of excretions from infected animals. Bodily fluids of infected humans may cause infection in contacts as well. Infections resulting from laboratory activities are assumed to be possible via inhalation, ingestion, direct contact, puncture, and animal-related (NHP and rodent) routes. The inhalational route is the primary focus of the dose-response assessment in this section, in support of the events analyzed in this RA that lead to aerosol releases in the laboratory or outside the NEIDL. Non-inhalational routes of exposure and their potential consequences are considered separately and as needed in conjunction with relevant events.

J.3.13.2 Vaccine and Prophylaxis

There are currently no vaccines available for NIPV. Animal models on which vaccines may be tested are currently in early stages of development (Bossart 2009, Geisbert 2010). For this RA, it is assumed that no potentially exposed laboratory worker, facility worker, or member of the general public would be vaccinated against infection or disease with NIPV. This is a conservative assumption, as it is possible that some individuals (especially laboratory workers) would be partially protected from an administered vaccine that may become FDA-approved or that may be available before official FDA-approval, such as those classified as an IND, in the future.

There are no prophylactic treatments that have been shown to protect against NIPV infection in humans after exposure. A neutralizing human monoclonal antibody was shown to protect ferrets from disease after exposure to otherwise lethal doses (Bossart 2009). It is conservatively assumed that no such treatments would be available to exposed laboratory workers or members of the public.

J.3.13.3 Dose-Response Information from the Literature

There are no human dose-response data available for NIPV. Epidemiological evidence suggests that humans may have become infected through inhaling aerosolized particles containing NIPV, but the amount of virus inhaled by humans who became infected is not known. In the absence of human data, studies on NIPV infectivity in animals provide the best-available information through which dose-response information potentially relevant for humans might be obtained.

As described in Chapter 3 and Appendix C, several animal species have been tested in laboratory settings for susceptibility to NIPV. The two most promising animal models for representing human infection and disease are the ferret (Bossart 2009) and the African green monkey (Geisbert 2010).

Bossart et al. (2009) exposed ferrets to different doses of NIPV oral-nasally and, among unprotected animals, observed the data shown in Table J–13a. The authors stated an ID₅₀ estimate of 500 CCID₅₀ based on one out of two animals becoming infected at that dose.

Table J–13a. Ferret oral-nasal dose-response data (Bossart 2009) for NIPV.

Challenge Dose (CCID ₅₀)	Number exposed	Number infected
50	2	0
500	2	1
5000	4	4
50,000	2	2

Data from Bossart et al. (2009). Dose units were reported in median tissue culture infectious dose (TCID₅₀), which is referred to as CCID₅₀ in this RA. Infected animals developed disease and were euthanized. Other animals exhibited no symptoms, did not shed detectable virus, and did not seroconvert.

Geisbert et al. (2010) exposed eight African green monkeys to doses ranging from 2500 plaque-forming units (PFU) to 1,300,000 PFU administered intratracheally or intratracheally and orally. All eight animals were infected and became clinically ill. All animals succumbed to disease or were euthanized except for one animal, exposed to 7000 PFU intratracheally and orally, which experienced severe clinical illness but eventually recovered after long convalescence.

J.3.13.4 Literature-Based Dose-Response Estimate

This section consists of a discussion of the dose-response data and evidence for NIPV outlined in the previous section and provides the literature-based dose-response estimate to be used for this RA.

The dose-response data in Table J–13a for ferrets, one of two animals proposed as the best available platforms for evaluation of potential immunization and treatment of humans (Bossart 2009, Geisbert 2010), is amenable to dose-response model fitting. The exponential model was fit to the data and the best-fit parameter results in very low optimal deviance. The model fitting result and IDs estimated by the model at varying probabilities are shown in Table J–13b.

**Table J–13b. Model fitting results and ID estimates (with 95% confidence intervals) for ferrets from
NIPV oral-nasal dose-response data (Bossart 2009)**

Model	Optimal param. value	Optimal deviance	$\chi^2_{0.95}$, df = 3	ID ₅₀	ID ₁₀	ID ₁	ID _{0.1}
Exp	$r = 0.001$	0.3	7.8	500 CCID₅₀ (100–1000)	80 (20–200)	8 (2–20)	0.8 (0.2–2)

Dose-response model fitting to the NHP data from Table J–13a. Exp = exponential. Model parameter is defined in Section J.2.5.1. Fit acceptability was confirmed if the deviance at the optimal parameter values was less than the corresponding 95th percentile chi-squared statistic with degrees of freedom (df) equal to 3, the number of distinct doses minus the number of parameters. Each ID_x result refers to the expected oral-nasal dose estimated to result in death of x% of exposed individuals under the model. Estimates are rounded to one significant figure. Units of dose are median cell culture infectious dose (CCID₅₀). Intervals under the LD estimates are 95% confidence intervals based on model fits to bootstrap replicates from the data set.

The dose-response data from African green monkeys (Geisbert 2010) are not amenable to dose-response model fitting because 100 percent of animals exposed were infected. The dose range administered to the monkeys in this study was 2500–1,300,000 PFU. Assuming that those doses would have been roughly equal or higher in units of CCID₅₀, these results are consistent with the exponential dose response model in Table J–13b, which estimates a greater than 95 percent probability of infection at a dose of 2500 CCID₅₀. The doses administered to the monkeys appear to have been too high to shed any additional light on the low-dose infectivity of NIPV.

Given that the ferrets in the Bossart et al. (2009) study were exposed oral-nasally, which is a reasonable surrogate for inhalational exposure that might occur as a result of an aerosol release from a laboratory, that ferrets respond to NIPV infection quite similarly to humans, and that the data cover the low-dose end of a potential dose-response curve, the ferret data-based model in Table J–13b is retained as the literature-based model to be applied to exposure estimates for this RA.

J.3.13.5 Dose-Response Estimates Derived from Expert Panel

In the procedure described previously, dose-response curves were fit to the ID₁₀, ID₅₀, and ID₉₀ estimates provided by each expert on the Delphi panel. The results of this model fitting procedure for NIPV are displayed in Table J–13c, including which models were retained from each expert according to the BIC. Twelve curves were retained for application in this RA, and plots of those curves are shown in Figure J–13. ID estimates provided by the retained curves are shown in Table J–13d.

Table J–13c: Dose response model fitting for Nipah virus

Expert	ID ₁₀ ID ₅₀ ID ₉₀	Exp. model	Log–probit model		Beta Poisson model		$\Delta\text{BIC}^{\text{Exp}}$	$\Delta\text{BIC}^{\text{Lp}}$	$\Delta\text{BIC}^{\text{BP}}$

Fitted parameters for three dose response models to each set of three data points from each expert panelist. Optimal parameter values were rounded to two significant figures. ΔBIC is the Bayesian Information Criterion value relative to the lowest value in that row, where a lower value indicates that the model better represents the available information. Bolded values in the BIC columns indicate that the model for that column was kept in consideration for representing the data provided by the expert panelist in that row, and grey values indicate that the model was eliminated from consideration, generally because its value was more than six greater than the lowest BIC value in that row. ^a indicates that the Beta Poisson model fit produced a curve virtually identical to the exponential model, so it was redundant to keep it in consideration. *Exact* entries indicate that the Log-probit model fit the expert panelist values in that row exactly (which results in a BIC value of negative infinity), so the other two models in that row are not applied (N/A). Abbreviations: Exp = Exponential model; Lp = Log-probit model; BP = Beta Poisson model.

Figure J-13

Plot of all retained dose response curves used to estimate probability of infection for each dose. Solid curves were weighted with 1/8 probability; dashed curves were weighted with 1/16 probability; dotted curves were weighted with 1/24 probability.

Table J–13d. Results for retained expert-derived NIPV dose-response models

Expert	Model	ID ₅₀	ID ₁₀	ID ₁	ID _{0.1}	ID _{0.01}
1	1	7900	1200	110	11	1.1
	2	6300	890	180	56	22
	3	6700	800	73	7.3	0.73
2	1	500	75	7.2	0.72	0.072
3	2	1000	100	15	3.9	1.3
4	2	1000	100	15	3.9	1.3
5	2	1000	100	15	3.9	1.3
6	2	1000	100	15	3.9	1.3
7	2	25000	1100	88	14	3.0
	3	18000	1500	130	13	1.3
8	2	1100	140	25	7.2	2.6
	3	1200	130	12	1.2	0.12
Median (Min–Max)		1000 org. (500–25000)	100 (75–1400)	15 (7.2–180)	3.9 (0.72–56)	1.3 (0.072–22)

Results are listed for the models that were retained after applying the Bayesian information criterion for model comparison. Each ID_x result refers to the expected inhaled dose estimated to result in infection of x% of exposed individuals. For example, ID_{0.1} refers to the dose estimated to result in infection of 0.1%, or one in one thousand individuals. The medians were calculated after weighing each of the eight experts equally and weighing each model equally within each expert if more than one was retained. For the models, Exp = exponential, LP = log-probit and BP = beta Poisson.

It is noted that the estimates derived from Expert 2 are very close to the estimates derived from the chosen dose-response model from the literature. While no published NIPV dose-response models by this expert or any other was found in the literature, it is presumed that the expert independently carried out an analysis of the Bossart et al. (2009) data set in a similar fashion to what has been presented here.

J.3.13.6 Other Considerations

The units of exposure for events analyzed in this RA for NIPV are in terms of PFU (plaque forming units) or CCID₅₀ (median cell culture infective dose). It is assumed that the estimated inventory concentration of NIPV that would be used at the NEIDL is an appropriate estimate under both units of measure. These units do not measure the absolute number of virions in a sample, because individual virions may aggregate or clump to infect a cell or to form one plaque and because a given assay may not be entirely sensitive to detecting all virions that would have the ability to infect cells in a different medium or host. The exposures in the ferret experiments that form the basis for the literature-based dose-response estimates were measured in units of CCID₅₀, so it is appropriate to apply the curves derived from these data to the exposure estimates.

The expert panelists were asked to provide their ID estimates in terms of number of organisms. It is assumed that the expert values represent numbers of potentially infectious units, as estimated by PFU, and that it is appropriate to apply the curves derived from their estimates to the exposure estimates. It is possible that this assumption is non-conservative if the assays used to derive the estimated inventories did not count all the organisms with potential to infect a human as envisioned by the experts. Studies in the literature have reported viral genome copies : PFU ratios in samples of NIPV ranging from as low as 20:1 to as high as 760,000:1, and several results in between (Guillaume 2004, Weingartl 2005, Chang 2006). Aside from the large uncertainty and/or variability implied by these data, they are of limited use because many of those genomes are likely not incorporated into viral particles, and therefore are regarded as posing no threat to a potential host. Furthermore, it is likely that even many virions with an incorporated genome may be otherwise defective or lack the ability to infect host cells. Therefore, the potential magnitude of non-conservatism resulting from the assumption that numbers of organisms as envisioned by any particular expert are adequately measured by PFU is unknown.

J.3.13.7 Summary of Approach

The following summarizes the two sets of dose-response estimates for NIPV to be applied to exposure data for this RA. ID estimates derived from these models are compared in Table J–13e.

- Literature-based dose-response model: the exponential model with $r = 0.001$, derived for ferret oral-nasal dose-response data (Bossart 2009). Use a distribution of r values derived from bootstrap replicates of the data set, which results in a 95 percent range of (0.0006 to 0.01), for uncertainty and sensitivity analyses.
- Range of dose-response models derived from the expert-provided values: the distribution of estimates shown in Table J–13d, with the model or set of models derived from each expert weighted equally.

Table J–13e. ID estimates and associated ranges for NIPV.

Model	ID ₅₀	ID ₁₀	ID ₁	ID _{0.1}
Literature-based	500 CCID₅₀ (100–1000)	80 (20–200)	8 (2–20)	0.8 (0.2–2)
Expert-based	1000 org. (500–25000)	100 (75–1400)	15 (7.2–180)	3.9 (0.72–56)

Each ID_x result refers to the expected inhaled dose estimated to result in infection of x% of exposed humans. The literature-based ranges are the 95% intervals derived from the bootstrap parameter distribution; the actual range of values applied to the RA may be wider. The expert-based ranges are the minimum and maximum values from Table J–13d. Abbreviations: CCID₅₀ = median cell culture infective dose; org. = organisms.

Both sets of estimates shown in Table J–13e are applied to the exposure estimates in the initial infection portions of this RA to determine the implications of each estimate for the overall risk posed by NIPV.

K. Initial Infection

K.1 Introduction

Initial infections analyses for this risk assessment (RA) consist of qualitative and quantitative estimates of potential infection and health effects in those exposed to a pathogen as a direct result of each of the events carried forward from the event sequence analyses. A distinction is made with regard to *initial* infection, addressed in this appendix as that occurring after direct exposure to a pathogen as a result of a release, and *secondary* infection that results from exposure to an already infected individual. Secondary infections are addressed in Appendix L.

The dose-response analysis (Appendix J) provides estimates for the probability of infection resulting from inhalational exposure to different amounts (doses) of each pathogen. This appendix links these dose-response estimates with the exposure estimates from the event sequence analyses to provide estimates for the frequency with which initial infections might occur as a result of NEIDL-related events. This appendix also discusses potential health effects, morbidity, and mortality that might result in those becoming infected.

The initiating event for most exposures considered in this RA and subsequent initial infections is an event involving a laboratory accident, which has the potential to result in a laboratory-associated infection (LAI). A special case of initial infection is where the individual acquires the pathogen directly from an infected animal or arthropod that was inadvertently released from the laboratory/facility. Yet another special case of initial infections is where there is a large scale disaster such as an earthquake resulting in direct exposure of pathogen to members of the public.

K.2 Methodology

The estimation of initial infections is based on the following:

- i. Outputs of the event sequence analyses that provide an estimate or range of
 - a. The frequency categories of the incidents
 - b. The number of individuals exposed in the three categories—laboratory workers, facility workers, and members of the public
 - c. The route of exposure
 - d. The amount of exposure (dose) per exposed individual

- ii. Dose-response curves for each pathogen based on estimates of human infectious doses (HID) for the 13 pathogens (see Appendix J)
 - a. Literature-based estimates derived from published models and from models fit to human and/or animal data for the RA
 - b. Expert-based estimates of HID from expert opinion using a modified Delphi method
- iii. Mitigation strategies available for each pathogen
 - a. Vaccine status of the exposed individual, if there is a vaccine available for the particular pathogen
 - b. Availability of post-exposure prophylaxis to the exposed individual; these are usually medications, though occasionally vaccines may be administered post-exposure
- iv. Population susceptibility to infection
 - a. Estimates of the portion of the population exposed from each event sequence belonging to medically vulnerable sub-populations (MVSP)
 - b. Estimates of the increased susceptibility to infection of MVSP members as compared to healthy individuals
- v. Health consequences to the initially infected individual
 - a. Estimates of morbidity in those becoming infected and experiencing subsequent disease symptoms
 - b. Estimates of mortality resulting from infection and disease

The outputs of the initial infections calculations are in the form of probabilistic estimates of the number of initial infections for each pathogen that might occur from each event sequence. These estimates are combined with the estimated frequency of occurrence of each incident to derive estimated frequencies of the occurrence of initial infections and associated consequences. These estimates are subsequently extended to potential further consequences due to secondary transmission in Appendix L.

When developing the calculations, it is important to distinguish *uncertainty* and *variability*. Uncertainty refers to the lack of knowledge of the true value of parameters. Variability refers to the effect of chance and inherent unpredictability of the way events might occur (stochasticity). In the estimation of initial infections, the effect of uncertainty for some key unknown values was assessed by systematically

comparing results under different assumptions for their values, while the effect of variability was assessed by performing probabilistic calculations under each tested scenario.

K.2.1 Needlestick

This section describes the methodology for generating estimates for initial infections resulting from Needlestick events described in Chapter 4 and Appendix F.

Chapter 4 described four distinct sub-events, depending on the setting of the event (BSL-3 or BSL-4 laboratories) and whether or not the event is detected and reported. The initial infections analyses are primarily concerned with consequences from potential LAI's without prompt detection and reporting because those events pose potential risk to the public through secondary transmission. Therefore, the events that assume prompt detection and reporting are not carried forward for detailed analysis in this appendix. The frequency categories assigned to the other two sub-events are listed in Table K-1. An explanation of how the category was determined for each event is provided in Chapter 4.

Table K-1. Frequency categories for needlestick events.

Event	Frequency category
Needlestick in BSL-3 laboratory <i>without</i> prompt detection and reporting	B < 1 per 100 years > 1 per 10,000 years
Needlestick in BSL-4 laboratory <i>without</i> prompt detection and reporting	B < 1 per 100 years > 1 per 10,000 years

As described in Chapter 4 and further detailed in Appendix F, it is conservatively assumed that every needlestick occurring under each scenario in Table K-1 would deliver a sufficiently high dose to cause an infection in the laboratory worker. Therefore, no further analysis on the likelihood of initial infections for needlestick events is provided in this appendix. The frequency categories assigned to each sub-event are carried forward and assumed as the frequency categories for one initial infection occurring in a laboratory worker. The frequency estimates for events without prompt detection and reporting also serve as estimates for the frequency with which a needlestick-infected laboratory worker would leave the facility and interact with contacts. Potential consequences following this scenario are discussed in Chapter 9 and Appendix L.

The results section for Needlestick events (Section K.3.1 below) includes descriptions of potential health consequences for a laboratory worker infected via needlestick for each pathogen. Section K.3.1 also includes estimates for the frequency of mortalities among laboratory workers infected via needlestick without prompt detection and reporting.

K.2.2 BSL-3 Centrifuge Infectious Aerosol Release

This section describes the methodology for generating estimates for initial infections resulting from *BSL-3 Centrifuge Infectious Aerosol Release* events described in Chapter 4 and Appendix F.

This event involves only those pathogens that may be studied under BSL-3 laboratory conditions (i.e., 7 of 13 pathogens). Centrifuge release scenarios involving BSL-4 pathogens are not carried forward to the initial infection analyses because the analysis described in Chapter 4 and Appendix F determined that it would not be credible for an aerosol exposure to go undetected in a BSL-4 laboratory. For the BSL-3 release scenario analyzed in this section, all potentially exposed individuals are laboratory workers. This section does not discuss risk to the public as a result of a centrifuge release. The potential consequences of laboratory workers leaving the facility after becoming infected and interacting with contacts in the general public are discussed in Chapter 9 and Appendix L.

The potential route of exposure for laboratory workers during or after a centrifuge release is assumed to be through direct contact, ingestion, or inhalation. Therefore, the dose-response information generated in Appendix J, which focuses primarily on inhalational exposure, can be applied. The centrifuge release information provided in Appendix F and the dose-response information provided in Appendix J are synthesized in Section K.3.2 of this appendix for each of the seven BSL-3 pathogens.

The remainder of this section describes the methodology for generating quantitative estimates of the frequency of centrifuge release events that lead to one or more initial infections from each pathogen, as well as the uncertainty in the estimations and the sensitivity of the estimations to uncertainties in the input values. *As this RA specifically considers centrifuge release scenarios that are undetected or unreported*, the initial infections results can also serve as estimates for the frequency of infected laboratory workers leaving the facility after a centrifuge incident, with subsequent potential to transmit to the public.

K.2.2.1 Overall assumptions

The following assumptions were made in the calculations, though deviations from these assumptions were not tested.

- The true frequency of centrifuge release is constant over time and is within the range specified in Chapter 4. Note that assuming a constant frequency does not mean that incidents are assumed to happen at regularly spaced intervals.
- The number of workers potentially exposed after an incident is variable but always within the range 1–4.
- The expected dose received by each worker is variable but always within the ranges specified in Chapter 4.
- The dose received by one worker is independent of the dose received by another worker. This assumption might be violated because the dose is affected by variability in the incident itself, which would have a common effect on all workers in the room. However, it is reasonable to assume that much of the variability in dose received depends on, for example, where the worker is positioned in the room relative to the centrifuge and air flow or the worker's personal protective equipment and actions.
- A true dose-response curve exists for each pathogen, is applicable to each potentially exposed person, and is within the range of dose-response curves derived in Appendix J.

K.2.2.2 Input values

This section specifies the values, distributions, and functions that are used in the calculations. There are two types of calculations presented for each pathogen—a *central estimate example* and *uncertainty results*.

For the central estimate example, a single value, distribution, or function is selected for each of the inputs. It is important to note that the results calculated from these central estimate inputs are not intended to be used as if they are certain predictions of what the frequency of infections would be at the NEIDL. This is because many of the inputs to the calculations are associated with rather wide uncertainty ranges. Instead, these results serve to illustrate the steps of the calculations and to provide point estimates near the center of the uncertainty range. For the uncertainty results, each input is assigned a range of values, distributions, or functions, and various sets of inputs are drawn randomly to generate a range of outputs.

1 The central estimate inputs and uncertainty ranges are specified as follows.

2
3 **Number of lab workers potentially exposed (w).** The number of workers w present in the
4 biocontainment area of a potential centrifuge release is assumed to fall in the range 1–4, as described in
5 Chapter 4. Assumptions regarding this input are important in calculations of the likelihood of one or more
6 more initial infections occurring.

7
8 • **Central estimate example: $w = 2$**

9 For the central estimate, it is assumed that there would be exactly two workers
10 present in the biocontainment area of a centrifuge during a potential release, with no variability.

11
12 • **Uncertainty range:**

13 In reality, there is variability in the exact number of people within the range 1–4 who would
14 potentially be exposed by any given centrifuge release. This means, for example, that at some
15 times there could be as many as four workers in the room where a release occurs, while at other
16 times there could be one, two, or three. This variability is described quantitatively through the use
17 of a probability distribution; that is, the probability that the number of workers in the room will be
18 1, 2, 3, or 4 at any given time. Specifically, we define a probability mass function $f(w)$, which is
19 the probability that the number of workers in the room is w . Multiple distributions were tested in
20 the analysis. A realistic distribution could be skewed toward the lower or higher end of the range.
21 Three distributions, f_1 , f_2 , and f_3 shown in Table K–2, were used to generate the uncertainty
22 results. The distribution equivalent to the central estimate example is also included in that table
23 for reference.

Table K–2: Candidate distributions for the number of workers in a room during a potential centrifuge release.

Distribution	Prob ($w = 1$)	Prob ($w = 2$)	Prob($w = 3$)	Prob($w = 4$)	Average w
<i>Central estimate example</i>	0	1	0	0	2
$f_1(w)$	0.5	0.3	0.2	0	1.7
$f_2(w)$	0.25	0.25	0.25	0.25	2.5
$f_3(w)$	0	0.2	0.3	0.5	3.3

The central estimate example row in Table K–2 demonstrates the assumption that there will always be exactly two laboratory workers potentially exposed during a release (no variability). The other three distributions in Table K–2 assume variability in the number of laboratory workers. For example, distribution f_3 assumes that there is no chance that only one laboratory worker would be in the room during a release, a 20% chance that there would be two laboratory workers, a 30% chance that there would be three laboratory workers, and a 50% chance that there would be four laboratory workers. These probabilities lead to an estimated average of 3.3 laboratory workers in the room at any given time. For the uncertainty analysis, it is assumed that the true distribution of the number of laboratory workers is equally likely to be f_1 , f_2 , or f_3 .

Amount of exposure per worker (d). The amount of exposure is the expected dose inhaled by a laboratory worker, which is denoted d . The value of d for each laboratory worker is assumed to fall in the ranges listed in Chapter 4 for each pathogen. All the ranges are given from $d = 0$ to $d = d_{\max}$, where d_{\max} depends on the pathogen and whether or not the laboratory worker has full or partial respiratory protection. Assumptions about the likelihood of inhaling various doses within the range are important in determining the probability that a worker becomes infected.

- **Central estimate example:**

The central estimate assumes that there is variability in the expected dose within the range 0 to d_{\max} that a worker would receive during any given incident. By random chance, one laboratory worker might inhale a dose close to d_{\max} , another might inhale a dose close to zero, and a third might inhale a dose in between. The central estimate example employs a simple probability

distribution to characterize this variability. Specifically, it is assumed that for each laboratory worker, there is a 20% probability that the dose d is 0, a 20% probability that d is one-fourth of d_{\max} , a 20% probability that d is one-half of d_{\max} , a 20% probability that d is three-fourths of d_{\max} , and a 20% probability that the dose is d_{\max} .

- **Uncertainty range**

To describe the different dose distributions tested in the uncertainty analysis, the following notation is introduced. The probability mass function $g(d)$ is the probability that the expected dose received is d . Multiple distributions were tested as part of the uncertainty analysis. A realistic distribution could be skewed toward either end of the range. The three alternative distributions described below were tested.

First, each dose range is split into $N = 1000$ evenly-spaced doses d_i from $d_1 = 0$ to $d_{1000} = d_{\max}$ (note that for the central estimate $N = 5$ was used). Non-integer values of d are acceptable as the input to the dose-response models is the *expected* dose, while the dose-response equations calculate the average probability of infection over possible integer numbers of dose units around the expected value. Next, the value M is defined as $M = N(N - 1)/2$. Using these definitions, the three distributions are as follows:

$$g_1(d_i) = (N - i)/M$$

$$g_2(d_i) = 1/N$$

$$g_3(d_i) = (i - 1)/M$$

The g_1 distribution is a discretized triangular distribution that assigns higher probability to the received dose being in the lower part of the dose range. The g_2 distribution is a uniform distribution over the range 0 to d_{\max} , inclusive. The g_3 distribution is a discretized triangular distribution that assigns higher probability to the received dose being in the higher part of the dose range. All three distributions are weighted equally in the uncertainty analysis.

It is unlikely that the true distribution of doses received over many releases would resemble the form of any of these three examples. However, the three distributions are useful test cases for the

range of possibilities for distributions that are skewed toward either end of the dose range and especially for testing the sensitivity of the outcome to uncertainty in the dose distribution. Note that because the upper limit of each dose range was selected as a conservative upper bound, the g_1 distribution, which places the lowest weight on higher doses, is presumed to be closest to what the true distribution would be over many incidents. Because g_2 and g_3 are given equal weight to g_1 , the uncertainty analysis places a conservative amount of weight on dose distributions that most likely overestimate the average exposure level.

Probability of partial respiratory protection (p_f). It was assumed, and as stated in Appendix F, that there is a 1% chance that one out of four workers would have partial rather than full respiratory protection. This would result in a two order of magnitude increase in exposure should a centrifuge release occur.

- **Central estimate example: $p_f = 0.0025$**

The assumption from Appendix F is carried forward to the calculations used in this chapter, where it is assumed that there is a 0.25% chance that any given worker will have partial rather than full respiratory protection during a centrifuge release (resulting in about a 1% chance that one out of four will have partial protection). Therefore, it is assumed that the probability $p_f = 0.0025$ that an exposed worker will receive a dose in the range estimated for the *BSL-3 Centrifuge Infectious Aerosol Release with Partial Respiratory Protection* event and a probability $1 - p_f = 0.9975$ that an exposed worker will receive a dose in the range estimated for the *BSL-3 Centrifuge Infectious Aerosol Release with Full Respiratory Protection* event.

- **Uncertainty analysis**

Variations from the central estimate example assumption were not tested in the uncertainty analysis. The assumption in Appendix F from which the value of p_f was derived was selected conservatively, which means that the *true* value of p_f is presumed to be lower than 0.0025. Therefore, if lower values of p_f were applied, the calculations would result in lower risk than the results presented here.

Probability of infection given the expected dose, or dose-response curve ($p(d)$). As described in Appendix J, a dose-response curve $p(d)$ describes the probability p of infection given an expected dose d

inhaled by a worker. For most pathogens, both a literature-based curve and an expert-based curve were generated, along with uncertainty ranges for each.

- **Central estimate example**

The best fit literature-based dose-response curve was used in the central estimate example for each pathogen. For one BSL-3 pathogen (1918 H1N1 influenza virus), a literature-based curve was not derived. In this case, a middle-range curve derived from the set of estimates from one expert was employed for the central estimate example. Table K-3 shows the model used for each of the seven BSL-3 pathogens. Full descriptions of the models are provided in Appendix J.

Table K-3. Central estimate example dose-response curves for each BSL-3 pathogen.

Pathogen	Model	Parameter value(s)	Units of dose	Source
<i>B. anthracis</i>	Exponential	$r = 2.6 \times 10^{-5}$	CFU ^a	Literature-based model
<i>F. tularensis</i>	Exponential	$r = 0.063$	CFU	Literature-based model
<i>Y. pestis</i>	Beta Poisson	$\alpha = 0.065$ $\beta = 8000$	CFU	Literature-based model
1918 H1N1V	Log-Probit	$m = 0.41$ $ID_{50}^b = 930$	PFU ^c	Expert-based model ^d
SARS-CoV	Exponential	$r = 0.0025$	PFU	Literature-based model
RVFV	Exponential	$r = 0.072$	MICLD ₅₀ ^e	Literature-based model
ANDV	Exponential	$r = 0.011$	CCID ₅₀ ^f	Literature-based model

^a Colony forming units

^b Infectious dose to 50% of exposed individuals

^c Plaque forming units

^d The log-probit model with parameters fit to the ID estimates of Expert 3 from the modified Delphi process. This model was selected for use because it leads to ID estimates that equal the median of the range of expert-derived estimates for the ID₁₀ and lower in Appendix J, Table K-4e. An expert-based model example was selected because no literature-based model was derived for 1918 H1N1V.

^e Mouse intracerebral lethal dose 50% (the dose that kills 50% of mice following intracerebral inoculation)

^f Cell culture median infectious dose

- **Uncertainty range**

Both the literature-based range and the expert-based range were tested separately as part of the uncertainty analysis for each pathogen. For literature-based dose-response estimates, a range of parameter values, derived from bootstrap resampling of the data set from which the dose-response

model was derived, was used for the uncertainty analysis. For expert-based dose-response estimates, the full distribution of expert-derived curves was applied for the uncertainty analysis. The method for deriving each of these distributions is described in Appendix J.

Frequency of a centrifuge release (λ_{release}). The expected frequency of the occurrence of a centrifuge release (average number of releases per time) is denoted λ_{release} . The frequency range assigned to a centrifuge release in Chapter 4 is comprised of those values in the A frequency category, as follows:

$$1 \text{ per } 100 \text{ years} < \lambda_{\text{release}} < 1 \text{ per year}$$

- **Central estimate example:** $\lambda_{\text{release}} = 1 \text{ per } 50 \text{ years}$

The central estimate frequency was selected such that the average return period is half of the maximum return period of the range (half of 100 years).

- **Uncertainty range**

Individual frequencies from throughout the range given in Chapter 4 were tested as part of the uncertainty analysis. Specifically, for each calculation, a return period for a release was drawn from a uniform distribution over the given range. The incident frequency was then calculated by taking the inverse of the return period.

K.2.2.3 Calculations

The following steps describe the calculations performed that lead to the results for each combination of test cases. Step-by-step examples of these calculations for the central estimate example inputs are shown in conjunction with each pathogen in the results section.

- **Expected probability of infection per worker (q)**

Let the selected dose-response curve be $p(d)$. Let $g(d)$ be the probability mass function of the expected dose received per worker (i.e., the probability that the expected dose is d). Each dose range was split into N evenly-spaced doses d_i from $d_1 = 0$ to $d_N = d_{\text{max}}$. The equation for q is then

$$q = \sum_{i=1}^N p(d_i)g(d_i).$$

As described in Section K.2.2.2 above, the value $N = 5$ is used for the central estimate example while $N = 1000$ for the uncertainty analysis. Note that there are two values of q for each

pathogen—one pertaining to the dose range for exposure with full respiratory protection and one pertaining to the dose range for exposure with partial respiratory pathogen.

- **Probability of x initial infections per incident (μ_x)**

Let q_1 and q_2 be the expected probability of infection for an exposed worker with full respiratory protection and with partial respiratory protection, respectively. Then the expected probability for a worker to both have full respiratory protection and be infected is $p_1 = (1 - p_f)q_1$; the expected probability for a worker to both have partial respiratory infection and be infected is $p_2 = p_f q_2$; and the overall expected probability of infection for a particular worker is $p_T = p_1 + p_2$.

Let $f(w)$ be the probability mass function of the number of workers in the room at the time of the incident. The equations for μ_x are provided below. Note that the equations are written for p_T , which is replaced by p_1 and p_2 for calculating the μ_x values specific to *with full respiratory protection* and *with partial respiratory protection* infections.

$$\begin{aligned}\mu_0 &= (1 - p_T)^2 f(2) + (1 - p_T)^3 f(3) + (1 - p_T)^4 f(4) \\ \mu_1 &= 2p_T(1 - p_T)f(2) + 3p_T(1 - p_T)^2 f(3) + 4p_T(1 - p_T)^3 f(4) \\ \mu_2 &= (p_T)^2 f(2) + 3(p_T)^2(1 - p_T)f(3) + 6(p_T)^2(1 - p_T)^2 f(4) \\ \mu_3 &= (p_T)^3 f(3) + 4(p_T)^3(1 - p_T)f(4) \\ \mu_4 &= (p_T)^4 f(4)\end{aligned}$$

- **Frequency of an x -infection event per year (λ_x)**

Let λ_{release} be the estimated frequency of a centrifuge release. To obtain the frequency of an event resulting in x infections, the release frequency is multiplied by the probability of x initial infections per incident, μ_x

$$\lambda_x = \mu_x \lambda_{\text{release}}$$

K.2.2.4 Uncertainty analysis

All the uncertainties described above contribute to the overall uncertainty in estimating the frequency of initial infections. In order to efficiently evaluate the effects of these compounding uncertainties, random combinations of the above values and distributions were generated using Latin hypercube sampling, which ensures that all the sets of input data are representative of the full variability of the input values (McKay et al. 1979; Blower and Dowlatabadi 1994). For each combination of input data (i.e., distribution of the number of workers, distribution of the dose received by each worker, dose-response curve, and

incident frequency), the calculations described above were performed to estimate the frequency of initial infections for each pathogen, taking into account the variabilities described by the distributions.

A total of 10,000 input combinations were generated for each pathogen, and each combination results in a different set of frequencies λ_x (frequency of a centrifuge release resulting in x initial infections). These values were re-organized to compute estimated frequencies of releases leading to x or more initial infections. Results were tallied according to how many of the 10,000 output values fell into each of the frequency categories described in Chapter 4.

K.2.2.5 Sensitivity analysis

Sensitivity analysis is performed using partial rank correlation (PRC), a nonparametric technique for statistically evaluating the independent effects of each input parameter on the outcome value (Iman and Conover 1980). The technique is intended for assessing input variables that have a monotonic correlation with the output variable; that is, as the input parameter increases across its range of values while other parameters are held constant, the output variable should tend to increase or decrease across the entire range with no reversal in trend. Each uncertain input parameter is assigned a partial rank correlation coefficient (PRCC) that quantifies degree of monotonicity, or the extent to which an increase in the input variable causes an increase (positive PRCC) or decrease (negative PRCC) in the output variable. PRCC values for different input parameters can be compared to determine the relative contribution to the uncertainty in the output value from the uncertainty in each input parameter value.

For the centrifuge events, PRCC values were calculated for four input values, the distribution for the number of exposed workers (range 1 to 3); the distribution for the amount of exposure (range 1 to 3); the index of the dose-response curve, where the index is the rank-order according to the average probability of infection it predicts; and the frequency of the centrifuge release (range 10^{-2} to 1 per year). Each of the four values are positively correlated with the output value of the rate of infections per time. The PRCC values were calculated against the output variable to evaluate the relative importance of the uncertainty in the four values in contributing to the uncertainty in the infection rate. The PRCC calculations were performed using the R function pcc.

K.2.3 Earthquake Release

This section describes the methodology for generating estimates for initial infections resulting from earthquake release events described in Chapter 4 and Appendix F.

This event is relevant to all 13 pathogens analyzed in this RA. All potentially exposed individuals are assumed to be members of the public. This section discusses only initial infections; that is, members of the public directly exposed to an aerosol released from NEIDL. The secondary transmission sections of this RA discuss the potential consequences of initially infected individuals interacting with public contacts.

The potential route of exposure for members of the public from this event is assumed to be through inhalation. Therefore, the dose-response information generated in Appendix J, which focuses primarily on inhalational exposure, can be applied. The earthquake release information provided in Appendix F and the dose-response information provided in Appendix J are synthesized in Section K.3.4 of this appendix for each of the 13 pathogens.

The remainder of this section describes the methodology for generating quantitative estimates of the frequency of earthquake release events that lead to one or more initial infections or mortalities from each pathogen, as well as the uncertainty in the estimations and the sensitivity of the estimations to uncertainties in the input values. The initial infections results subsequently serve as inputs to secondary transmission analyses.

K.2.3.1 Overall assumptions

The following assumptions were made in the calculations, and deviations from these assumptions were not tested:

- The true frequency of an earthquake release is constant over time and is within the range specified in Chapter 4. Note that assuming a constant frequency does not mean that incidents are assumed to happen at regularly spaced intervals.
- A true dose-response curve exists for each pathogen, is applicable to each potentially exposed person, and is within the range of dose-response curves derived in Appendix J.

K.2.3.2 Input values

This section specifies the values, distributions, and functions that are used in the calculations. There are two types of calculations presented for each pathogen—a *central estimate example* and *uncertainty results*.

For the central estimate example, a single value, distribution, or function is selected for each of the inputs. It is important to note that the results calculated from these central estimate inputs are not intended to be used as if they are certain predictions of what the frequency of infections would be at the NEIDL, as many of the inputs to the calculations are associated with rather wide uncertainty ranges. Instead, these results serve to illustrate the steps of the calculations and to provide point estimates near the center of the uncertainty range.

For the uncertainty results, certain inputs are assigned a range of values, distributions, or functions, and various sets of inputs are drawn randomly to generate a range of outputs. The process for generating sets of inputs is described in more detail in Section K.2.3.4 below.

The central estimate inputs and uncertainty ranges are specified as follows.

Number of people potentially exposed in each annular ring (N_r). Appendix F provides average population estimates for the potentially exposed population in each annular ring at various radii out from the release site, for all three sites. For a particular site, the population in annular ring r (for $r = 1-10$, extending out from the release point) is denoted N_r . Assumptions about this input are important in calculations of the likelihood of one or more more initial infections occurring.

- **Central estimate example:**

For the central estimate example, the population numbers N_r from Appendix F are applied as the expected number of people potentially exposed in each annular ring. It is assumed that there is variability in each of these numbers that is described by the Poisson distribution with mean N_r . Note that this variability distribution is not intended to reflect the true population variability at each site, which in reality varies across both time and space and is likely to be quite complicated. The Poisson distribution is used to handle fractional average population estimates so that the probabilistic outputs required for the results can be calculated.

- **Uncertainty range:**

Variations from the central estimate example assumption were not tested in the uncertainty analysis. It is presumed that the census data and other sources of population estimates used to derive values of N_r are reasonably accurate, especially when compared to other uncertain inputs. More importantly, the central estimate is a conservative estimate of the average number of people

at risk of exposure because it assumes that each person in a particular sector of the annular ring is exposed to an average dose from the centerline of the aerosol plume. In reality, only a fraction of the population in a given annular ring would receive that level of exposure. Therefore, it is presumed that N_r is more likely to overestimate than underestimate the *true* average population at risk in each annular ring.

Amount of exposure per person in each annular ring (d_r). The amount of exposure is the expected dose inhaled by a person in annular ring r , which is denoted d_r . Exposure amounts at various radii from the release point along the centerline of the plume are provided in Appendix F.

- **Central estimate example:**

For the central estimate example, the centerline exposure estimates d_r from Appendix F at the radial midpoint of each annular ring are applied as the expected dose inhaled by each person in the annular ring, with no variability.

- **Uncertainty range**

Two different sets of exposure estimates were provided in Appendix F, called beyond design basis (BDB) release and maximum reasonably foreseeable (MRF) release. Central estimate results are presented for each case in this Appendix, which give a rough measure of an uncertainty range for probable outcomes. Additional variations from each central estimate example were not tested in the uncertainty analysis. For the MRF release scenario, the values d_r arise from a large number of conservative assumptions, as discussed in Appendix F. Therefore, the results under the MRF assumption are presumed to represent the maximum results across an uncertainty range.

Probability of infection given the expected dose, or dose-response curve ($p(d)$). As described in Appendix J, a dose-response curve $p(d)$ describes the probability p of infection given an expected dose d inhaled by a worker. For most pathogens, both a literature-based curve and an expert-based curve were generated, along with uncertainty ranges for each.

- **Central estimate example**

The best fit literature-based dose-response curve was used in the central estimate example for each pathogen. For three pathogens (1918 H1N1 influenza virus; Junin virus; and tick-borne encephalitis virus, Far Eastern subtype), a literature-based curve was not derived. In these cases, a middle-range curve derived from the set of estimates from one expert was employed for the

central estimate example. The models selected for the BSL-3 pathogens were the same ones selected for the central estimate examples of the BSL-3 centrifuge infectious aerosol release (see Table K–3). Table K–4 below summarizes the models selected for the BSL-4 pathogens.

Table K–4. Central estimate example dose-response curves for each BSL-4 pathogen.

Pathogen	Model	Parameter value(s)	Units of dose	Source
EBOV	Exponential	$r = 0.16$	PFU ^a	Literature-based model
MARV	Exponential	$r = 0.16$	PFU ^a	Literature-based model
LASV	Exponential	$r = 0.039$	PFU	Literature-based model
JUNV	Exponential	$r = 0.0070$	PFU	Expert-based model ^b
TBEV-FE	Log-Probit	$m = 0.56$ $ID_{50} = 200$	PFU	Expert-based model ^c
NIPV	Exponential	$r = 0.0013$	CCID ₅₀	Literature-based model

^a The units of the earthquake release exposure estimates for EBOV and MARV are CCID₅₀, and these numbers are converted to PFU using a factor of 1/12 before the given dose-response model is applied, as described in Appendix J.

^b For JUNV, the exponential fit to the ID estimates of Expert 3 was applied because the derived estimates most closely tracked median expert estimates, or were slightly lower than the median at the lowest ID levels (see Appendix J, Table J–11d).

^c For TBEV-FE, the log-probit fit to the ID estimates of Experts 5 and 6 was applied because the derived estimates were equal to the median expert estimates at every ID point, as shown in Appendix J, Table J–12b.

• Uncertainty range

Both the literature-based range and the expert-based range were tested separately as part of the uncertainty analysis for each pathogen. For literature-based dose-response estimates, a range of parameter values, derived from bootstrap resampling of the data set from which the dose-response model was derived, was used for the uncertainty analysis. For expert-based dose-response estimates, the full distribution of expert-derived curves was applied for the uncertainty analysis. The method for deriving each of these distributions is further described in Appendix J.

Case fatality rate (m). The case fatality rate, m (for mortality), is the probability that a person infected with the pathogen would subsequently die from illness caused by the infection. Case fatality rates observed and estimated for each pathogen are reviewed in Chapter 3 and Appendix C.

- **Central estimate example**

The assumed case fatality rate for each pathogen is listed in Table K–4.

Table K–4. Central estimate example case fatality rate for each BSL-4 pathogen.

Pathogen	Case fatality rate (<i>m</i>)	Pathogen	Case fatality rate (<i>m</i>)
<i>B. anthracis</i>	45%	EBOV	90%
<i>F. tularensis</i>	2%	MARV	100%
<i>Y. pestis</i>	15%	LASV	2%
1918 H1N1V	2.5%	JUNV	1%
SARS-CoV	10%	TBEV-FE	40%
RVFV	2%	NIPV	70%
ANDV	50%		

- **Uncertainty range**

No alternate case fatality rate estimates were tested. For pathogens for which a range of case fatality rates were found in the literature, the upper end of the range was applied in the central estimate example; thus, those values might overestimate but are unlikely to underestimate the average case fatality rate in the event of a release leading to infections.

Frequency of an earthquake release (λ_{release}). The expected frequency of the occurrence of an earthquake release (average number of releases per time) is denoted λ_{release} . The frequency range assigned to an earthquake release consists of those values in the C frequency category, as follows:

$$1 \text{ in } 1 \text{ million years} < \lambda_{\text{release}} < 1 \text{ in } 10,000 \text{ years}$$

- **Central estimate example:** $\lambda_{\text{release}} = 1 \text{ in } 100,000 \text{ years}$

The central estimate frequency was selected such that the average return period is halfway between the boundaries of the frequency category on a logarithmic scale.

- **Uncertainty range**

Individual frequencies from throughout the range given in Chapter 4 were tested as part of the uncertainty analysis. Specifically, for each calculation, a return period for the incident was drawn from a uniform distribution on a logarithmic scale; that is, a number x was drawn from a uniform distribution on the range 4 to 6, and then λ_{release} was calculated as $1/10^x$. This choice of distribution puts a conservative amount of weight on higher frequencies within the range.

K.2.3.3 Calculations

The following steps describe the calculations performed that lead to the results for each combination of test cases. Step-by-step examples of these calculations for the central estimate example inputs are shown in conjunction with each pathogen in the results section.

- **Expected probability of infection per person in each annular ring ($p(d_r)$)**

Let d_r be the expected dose assumed for each person in annular ring r , and let $p(d)$ be the selected dose-response curve. Then the expected probability of infection per person in annular ring r is $p(d_r)$. The formula is applied to each annular ring separately.

- **Probability of x initial infections in annular ring r per release (μ_x^r)**

Under the assumption that the number of people potentially exposed in each annular ring is Poisson distributed with mean N_r , the following formulas are applied for the probability of zero, one, or two initial infections in annular ring r :

$$\begin{aligned}\mu_0^r &= e^{-p(d_r)N_r} \\ \mu_1^r &= p(d_r)N_r e^{-p(d_r)N_r} \\ \mu_2^r &= \frac{1}{2}[p(d_r)N_r]^2 e^{-p(d_r)N_r}\end{aligned}$$

- **Probability of x deaths in annular ring r per release (δ_x^r)**

The assumed case fatality rate m is multiplied by the expected, per-person probability of infection $p(d_r)$ to estimate the per-person probability of death in each annular ring. This product is then applied to the same formulas provided in the previous bullet to get the probability of zero, one, or two deaths in each annular ring r :

$$\begin{aligned}\delta_0^r &= e^{-p(d_r)mN_r} \\ \delta_1^r &= p(d_r)N_r e^{-p(d_r)mN_r}\end{aligned}$$

$$\delta_2^r = \frac{1}{2}[p(d_r)N_r]^2 e^{-p(d_r)mN_r}$$

• **Probability of x or more total initial infections, per release ($\mu_{\geq x}$)**

The μ_x^r values across all annular rings were used to calculate $\mu_{\geq x}$, the probability that a release results in x or more total infections (across all 10 annular rings). The formulas are as follows:

$$\begin{aligned}\mu_{\geq 1} &= 1 - \prod_{r=1}^{10} \mu_0^r \\ \mu_{\geq 2} &= \mu_{\geq 1} - \sum_{r_1=1}^{10} \left(\mu_1^{r_1} \prod_{r_2 \neq r_1} \mu_0^{r_2} \right) \\ \mu_{\geq 3} &= \mu_{\geq 2} - \sum_{s_1=1}^{10} \left(\mu_2^{s_1} \prod_{r_2 \neq s_1} \mu_0^{r_2} \right) - \sum_{r_1=1}^9 \left(\sum_{r_2=r_1+1}^{10} \left(\mu_1^{r_1} \mu_1^{r_2} \prod_{\substack{r_3 \neq r_1 \\ r_3 \neq r_2}} \mu_0^{r_3} \right) \right)\end{aligned}$$

These formulas are sufficient for most pathogens and scenarios, as the estimated probability of three or more infections is small enough that calculating probabilities of a higher number of infections would not add useful information. For any scenario in which the probability of more than three infections is potentially significant, probabilities of higher numbers of initial infections are estimated through simulations because the exact formulas become unwieldy for higher values of x . For the simulations, 100,000 random population values are drawn for each annular ring from a Poisson distribution with mean N_r , and using each of those values along with the probability $p(d_r)$, a random number of initial infections is drawn from a binomial distribution. Next, the simulated numbers of infections are totaled and tabulated to estimate the values of $\mu_{\geq x}$ for selected values of x .

- Probability of x or more total deaths, per release ($\delta_{\geq x}$). The same formulas in the previous bullet point apply, replacing μ with δ .
- Frequency of an x -or-more-infection or x -or-more-death event per year ($\lambda_{\geq x}$). Let λ_{release} be the estimated frequency of an earthquake release event. To obtain the frequency of an event resulting in x or more initial infections or deaths, the release frequency is multiplied by the probability of x or more initial infections per release, $\mu_{\geq x}$, or the probability of x or more deaths per release, $\delta_{\geq x}$

$$\lambda_{\geq x} = \mu_{\geq x} \lambda_{\text{release}} \text{ (for infections)}$$

$$\lambda_{\geq x} = \delta_{\geq x} \lambda_{\text{release}} \text{ (for deaths)}$$

Example Calculations

The following example serves to illustrate the steps of the calculations described above. The input values are taken from the following scenario: maximum reasonably foreseeable release of *B. anthracis* at the urban site. Central estimate assumptions for each of the input values have been described previously. Step-by-step calculations and results under these input values are summarized as follows. See Section K.3.3 for full results from all pathogens at each site and under each release scenario.

**Table K–5. Central estimate, annular ring-specific calculations for urban site earthquake MRF
release of *B. anthracis***

Annular ring (r)	Dose (CFU) per person (d_r)	Infection probability per person ($p(d_r)$)	Potentially exposed population (N_r)	Conditional Probability of x initial infections, given a MRF release (μ_x^r)
1	2.9×10^{-2}	7.5×10^{-7}	31	$x = 0$: 0.999977 $x = 1$: 2.3×10^{-5} $x = 2$: 2.7×10^{-10}
2	3.1×10^{-3}	8.1×10^{-8}	108	$x = 0$: 0.9999913 $x = 1$: 8.7×10^{-6} $x = 2$: 3.8×10^{-11}
3	1.1×10^{-3}	2.9×10^{-8}	196	$x = 0$: 0.9999944 $x = 1$: 5.6×10^{-6} $x = 2$: 1.6×10^{-11}
4	6.2×10^{-4}	1.6×10^{-8}	372	$x = 0$: 0.9999940 $x = 1$: 6.0×10^{-6} $x = 2$: 1.8×10^{-11}
5	4.1×10^{-4}	1.1×10^{-8}	376	$x = 0$: 0.9999960 $x = 1$: 4.0×10^{-6} $x = 2$: 8.1×10^{-12}
6	3.0×10^{-4}	7.8×10^{-9}	178	$x = 0$: 0.9999986 $x = 1$: 1.4×10^{-6} $x = 2$: 9.5×10^{-13}
7	2.3×10^{-4}	5.9×10^{-9}	165	$x = 0$: 0.9999990 $x = 1$: 9.8×10^{-7} $x = 2$: 4.8×10^{-13}
8	1.8×10^{-4}	4.7×10^{-9}	250	$x = 0$: 0.9999988 $x = 1$: 1.2×10^{-6} $x = 2$: 7.0×10^{-13}
9	1.5×10^{-4}	3.9×10^{-9}	310	$x = 0$: 0.9999988 $x = 1$: 1.2×10^{-6} $x = 2$: 7.2×10^{-13}
10	1.2×10^{-4}	3.2×10^{-9}	215	$x = 0$: 0.9999993 $x = 1$: 7.0×10^{-7} $x = 2$: 2.4×10^{-13}

The results in Table K–5 provide information about what the example dose-response function $p(d)$ estimates for the probability that infections would occur among people in each annular ring. For example, in $r = 1$ (between 30 and 100 meters [m] from the release source), assuming the average dose inhaled per person is 0.029 CFU, the dose-response model estimates a 7.5×10^{-7} probability of infection per person.

Next, using this probability and the estimate of 31 people potentially exposed in the annular ring on average, the formulas given in Section K.2.2.3 lead to the estimated probabilities in the third column. For example, the probability that 1 infection occurs out of an average of 31 people in annular ring 1 is estimated to be 2.3×10^{-5} , or about a 1 in 40,000 chance. The probability of two infections occurring in annular ring 1 is estimated to be 2.7×10^{-10} , or about a 1 in 4 billion chance.

The calculations in Table K-5 are repeated for case fatality rates. Each $p(d_r)$ value in the third column is multiplied by the assumed case fatality rate for *B. anthracis* infection ($m = 0.45$), and each of these products is used to calculate δ_x^T using the formulas supplied in this section.

Table K-6. Central estimate overall calculations for urban site earthquake MRF release of *B. anthracis*

Number of initial infections overall (x)	Probability x or more initial infections overall ($\mu_{\geq x}$)	Frequency of release leading to x or more initial infections ($\lambda_{\geq x}$)
1 or more	5.3×10^{-5}	$5.3 \times 10^{-10}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
2 or more	1.4×10^{-9}	$1.4 \times 10^{-14}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
3 or more	2.5×10^{-14}	$2.5 \times 10^{-19}/\text{year} = 1 \text{ in } > 10 \text{ million years}$

The probability of x or more initial infections overall is calculated based on the annular ring-specific probabilities from Table K-5 and the formulas provided in this section. For example, the probability of one or more infections is one minus the probability that there are no infections in any of the 10 annular rings, which is the product of the ten $x = 0$ probabilities in the last column of Table K-5. Next, the frequency of a release leading to x or more infections is calculated by multiplying $\mu_{\geq x}$ by $10^{-5}/\text{year}$, which is the assumed frequency of an earthquake release for the central estimate example.

These calculations are repeated in the same fashion for the frequency of an earthquake release leading to x or more deaths.

K.2.3.4 Uncertainty analysis

For each combination of input data (dose-response curve and earthquake release frequency), the calculations described above were performed to estimate the frequency of initial infections for each

pathogen. The combinations of inputs were generated using the Latin hypercube sampling scheme described in Section K.2.2.4 above.

A total of 10,000 input combinations were generated for each pathogen, and each unique combination results in a set of frequencies $\lambda_{\geq x}$ (frequency of an earthquake release resulting in x or more initial infections). Results were tallied according to how many of the 10,000 output values fell into each of the frequency categories described in Chapter 4.

K.2.4 Medically Vulnerable Sub Populations

The methodology for the initial infections analyses described in the sections above uses an assumption that the dose-response and case fatality estimates are applicable to all potentially exposed populations. This assumption might be violated for a population that has a different profile of vulnerability to disease and/or death than did the populations on which the dose-response and case fatality estimates were based. For this RA, the issue of population vulnerability is investigated by evaluating populations at the three sites for the presence of five medically vulnerable sub populations (MVSP), and as discussed in Appendix I for children under 5, adults over 65, people with diabetes, people with HIV/AIDS, and pregnant women.

The dose-response models applied in the previous sections of this appendix are assumed to be applicable to human populations containing MVSP to some extent. The derivation and justification of the models, discussed in detail in Appendix J, included consideration of the possibility that some potentially exposed individuals might be more susceptible to infection at a given dose than others. Although the literature-based models were mostly derived from experimental human and/or animal data in which exposed groups might have been more homogeneous than a general human population, the justification for applying non-threshold models to these data was partly based on the fact that the models would be applied to human populations in which some individuals might be especially susceptible to low doses because of immune status or some previous or concurrent health condition. The expert-based dose-response models were based on the outcome of a modified Delphi process in which it was not specified to the experts that their estimates should be based on healthy individuals only; presumably, the experts took into consideration the susceptibility profile of a typical human population in arriving at their infectious dose estimates. For case fatality estimates, the baseline rates assumed for each pathogen are based on data observed in human outbreaks that occurred among populations containing many, if not all, of the MVSP considered in this RA.

Despite that the dose-response and case fatality estimates are already assumed to encompass MVSP, it is worth considering whether particular potentially exposed populations considered for this RA contain an atypical proportion of individuals belonging to certain MVSP, and whether this proportion of MVSP is sufficiently different from the norm to warrant adjusting the baseline initial infections and case fatality estimates.

The quantitative analysis described in the following sub-sections is only applied to the earthquake release scenarios in which the potentially exposed group (members of the public surrounding NEIDL) might contain MVSP of higher or lower proportion than a typical human population. As discussed in Appendix I, the population of laboratory workers, who are the potentially exposed group for the needlestick and centrifuge events, might include proportions of some, but not all, of the five MVSP. It is surmised that the population of laboratory workers assigned to work with BSL-3 or BSL-4 pathogens would have a lower proportion of each MVSP, and of unhealthy or immunocompromised individuals in general, than the proportions occurring in the overall population. Therefore, it is acknowledged that the dose-response models applied in the centrifuge initial infections analysis may overestimate the risk to laboratory workers in this regard, though no attempt is made to quantify the potential degree of overestimation. The needlestick analysis included the assumption that every exposure would lead to an infection, regardless of whether the exposed worker is a member of an MVSP.

K.2.4.1 Overall assumptions

The following assumptions are made in order to quantitatively investigate possible effects of MVSP on the initial infections results for the earthquake release scenarios:

- A given dose-response curve being assumed for a particular pathogen is relevant for a population comprised of MVSP at proportions in line with the overall U.S. population.
- The probability that a given exposed individual is a member of a MVSP is equal to the portion of the local population that is assumed to belong to that MVSP.
- For the purposes of the RA, no individuals were considered as members of more than one of the five MVSP. The RA acknowledges that if an individual were to be a member of more than one MVSP, it is likely that their susceptibility would be greater as compared to an individual who is a member of a single MVSP. It is assumed that accounting for individuals belonging to multiple MVSP would not change the overall results significantly. The possible effects of uncertainties in assumption about MVSP susceptibility on the results are discussed in Section K.3.5.

- The portion of a population that is not a member of any of the five designated MVSP has average susceptibility status in line with *healthy adults* for purposes of comparatively quantifying estimates of the increased susceptibility of MVSP. This is a necessary assumption for conducting the calculations to investigate the potential effects of the presence of the five MVSP; it is acknowledged that the five MVSP do not encompass all individuals who might have increased susceptibility to disease.
- If person A is $x\%$ more susceptible to disease than person B, that is assumed to mean that the probability of person A being infected at a given expected dose d is the same as the probability of person B being infected at an expected dose $x\%$ higher than d .

K.2.4.2 Input values

This section specifies the values that are used in the calculations. For this part of the analysis, only single point estimates are applied for each input. While uncertainties do exist for these inputs, the given values are sufficient for the purpose of this exercise, which is to explore the potential role that MVSP proportions might play at each site in affecting the initial infections estimates. Some qualitative discussion of the effects of input uncertainties is included in the results section.

First, the index k is defined, which represents an index for the five MVSP described in Appendix I, as follows:

- $k = 1$ for children under 5 years of age
- $k = 2$ for adults over 65
- $k = 3$ for people with diabetes
- $k = 4$ for people with HIV/AIDS
- $k = 5$ for pregnant women

Given this index, the following inputs are defined and specified.

Proportion of U.S. and local populations belonging to MVSP k (x_k, y_k). Appendix I provides estimates for proportions of each MVSP according to U.S. data and data and estimates from areas near the three sites. The assumed U.S. proportions are termed x_k , for $k = 1$ to 5, and the values are taken directly from Table 1 in Appendix I. The assumed urban resident proportions are taken from the column in Table 1 of Appendix I that estimates the proportion of each MVSP residing in zip code 02118, which covers the area

around the NEIDL site for which exposure estimates are provided for the earthquake release events. For the non-resident portion of the urban population estimates, the Massachusetts statewide MVSP estimates were assumed, based on the assumption that daytime students, workers, and other visitors and passersby in the vicinity of the NEIDL location typically reside in a wide area around the city. For certain MVSP, the non-resident MVSP estimates are conservatively high; for example, there would be no children under 5 years of age among BU students, faculty, and employees at BUMC, which comprise a large portion of the non-resident population estimates. Therefore, the estimated urban non-resident proportion of children under 5 years of age and, perhaps to a lesser extent, adults over 65 are conservatively high. The suburban site estimates were taken from the Tyngsborough, MA data listed in Table 1 of Appendix I. The rural site estimates were calculated by combining the data from Peterborough, NH and Hancock, NH listed in Table 1 of Appendix I. Table K-7 specifies the values applied in this analysis

Table K-7: Inputs for MVSP population values^a

MVSP (k)	Proportion of MVSP in U.S. population (x_k)	Proportion of MVSP in local population (y_k)			
		Urban resident	Urban non- resident	Suburban	Rural
1: Children under 5	0.069	0.039	0.063	0.055	0.058
2: Adults over 65	0.126	0.079	0.135	0.082	0.217
3: People with diabetes	0.057	0.126	0.074	0.078	0.066
4: People with HIV/AIDS	0.0045	0.016	0.0028	0.0020	0.0011
5: Pregnant Women	0.01	0.01	0.01	0.01	0.01

^a See Appendix I for sources of these estimates

Increased susceptibility of MVSP k to pathogens (q_k). Appendix I includes a discussion of evidence for increased susceptibility to the 13 pathogens of members of the 5 MVSP. The quantitative estimates from experts on the Delphi panel, which were estimates of percentage increase in susceptibility to disease and mortality for viruses and bacteria of each MVSP compared to healthy adults (denoted q_k), are also listed in Appendix I. For this analysis, the maximum estimate from each set of expert estimates was applied to reduced the possibility of producing non-conservative results. These values are listed in Table K-8.

Table K-8: Inputs for MVSP relative susceptibility values^a

MVSP (<i>k</i>)	Increased susceptibility compared to healthy adult (q_k)			
	to disease from bacteria	to mortality from bacteria	to disease from viruses	to mortality from viruses
1: Children under five	0.33	0.2	0.33	0.2
2: Adults over 65	0.5	0.5	0.5	0.5
3: People with diabetes	0.3	0.25	0.25	0.25
4: People with HIV/AIDS	0.4	0.3	0.4	0.3
5: Pregnant Women	0.3	0.2	0.5	0.2

^a See Appendix I for sources of these estimates. The q_k numbers are the maximum values from the expert estimates.

K.2.4.3 Calculations

The following steps describe the calculations performed that lead to the results presented in Section K.3.5.

Probability of infection or death for MVSP k relative to a healthy adult

The following terms are defined:

- $p_h(d)$ is the infection probability of a healthy adult inhaling a dose with expected number of organisms d .
- $p_k(d)$ is the infection probability of a person belonging to MVSP k inhaling a dose with an expected number of organisms d .

Next, the relationship between p_h and q_k under the assumptions listed in Section K.2.4.1 above is expressed mathematically as

$$p_k(d) = p_h((1 + q_k)d).$$

Because the three dose-response forms used in this risk assessment are non-linear, the amount that p changes for a given value of q will be different depending on which particular model is being assumed. Under the stated assumptions, formulas under each model for calculating p_k for given values of p_h and q_k at the same exposure are expressed below.

Exponential model: $p_k = 1 - (1 - p_h)^{1+q_k}$

Log-probit model: $p_k = \Phi[\Phi^{-1}(p_h) + m \ln(1 + q_k)]$

Beta Poisson model: $p_k = 1 - [1 + ((1 - p_h)^{-1/\alpha} - 1)(1 + q_k)]^{-\alpha}$

These formulas are also applied for estimates of increased susceptibility to mortality, wherein p stands for the probability of death given infection.

Probability of infection or death for a healthy adult

The value of p_h for a pathogen at a given dose or for mortality is not obvious because the baseline dose-response curves and case fatality rates are assumed to be applicable for a heterogeneous population containing both healthy and unhealthy individuals, as discussed above. To make use of the above formulas, p_h must first be calculated, which is possible under the stated assumptions, and as described below.

The following additional term is defined as follows:

- p is the average probability of either infection at a given dose or mortality (assumed to be applicable to a general U.S. population).

Next the value of p can be expressed in terms of x_k , p_h , and q_k . First, p is broken down into its components, the probabilities assigned to each of the six groups (five MVSP plus everyone else) multiplied by the portion of the U.S. population in each group, as follows:

$$p = \sum_{k=1}^5 p_k x_k + p_h \left(1 - \sum_{k=1}^5 x_k \right)$$

Here, p_k depends on p_h and q_k and is defined according to which dose-response model is being assumed, as described above. For example, if the exponential model is being assumed, the equation becomes

$$p = \sum_{k=1}^5 [1 - (1 - p_h)^{1+q_k}] x_k + p_h \left(1 - \sum_{k=1}^5 x_k \right)$$

In the above equation, the value of p is given, as are all the parameters on the right-hand side, except p_h . The value of p_h is determined for specific examples using a numerical root finder.

Adjusted average probability of infection or death at a given site

Using the values of p_h and p_k , for $k = 1$ to 5, as derived above for a particular dose or for mortality, the average probability of infection or death at a given site is calculated using the MVSP population values y_k for that site

$$p = \sum_{k=1}^5 p_k y_k + p_h \left(1 - \sum_{k=1}^5 y_k \right)$$

Adjusted probability of x or more infections or deaths resulting from earthquake release

The adjusted probabilities p calculated using the preceding equation are applied to the earthquake release calculations described in Section K.2.3.3. The results are then compared to the baseline results for representative pathogens and scenarios.

Probability of x or more infections or deaths among each individual MVSP resulting from earthquake release

For each MVSP k , the potentially exposed population estimates from the earthquake analysis at each site are multiplied by the y_k values for that site to estimate the potentially exposed MVSP. Next, the corresponding p_k values, calculated as described above, are applied in conjunction with these population estimates to the earthquake release calculations described in Section K.2.3.3. This process is repeated using the values x_k instead of y_k , for the purpose of comparing what the estimated risk to the MVSP population at each site would be if the population proportions were consistent with U.S. averages.

Example calculations

As an example, the probability of infection with *F. tularensis* at an expected inhaled dose of 1 CFU is considered. The literature-based dose-response model derived in Appendix J (an exponential model) produces an estimate for the probability of infection of about 6.1% at this dose. Again, this is assumed to be an average probability of infection across a population containing MVSP that is similar to U.S. averages.

The input values used in the first part of the calculations are the x_k values, representing the proportion of each MVSP according to U.S. averages and shown in Table K–7, and the q_k values for susceptibility to disease from bacteria, shown in Table K–8. These values are applied to the equations described above for calculating p_h ; the probability of infection for healthy adults, which can then be used to calculate p_k for $k = 1$ to 5; and the probabilities of infection for individuals in each MVSP. The results of these calculations are shown in Table K–9.

Table K–9: Example results for probability of infection for population groups.^a

Population	Probability of infection (p) from exposure to 1 CFU of <i>F. tularensis</i>
Overall population	$p = 0.061$
Healthy adult	$p_h = 0.055$
Children under 5	$p_1 = 0.073$
Adults over 65	$p_2 = 0.082$
People with diabetes	$p_3 = 0.071$
People with HIV/AIDS	$p_4 = 0.077$
Pregnant Women	$p_5 = 0.071$

^a The overall population probability was calculated directly from the literature-based dose-response model for *F. tularensis*. The healthy adult probability is applied to the portion of the overall population that does not belong to any of the five MVSP.

These results show that the given assumptions lead to an estimate for the probability of infection at 1 CFU exposure to *F. tularensis* for healthy adults to be 5.5%, and the probability for members of MVSP range from 7.1% to 8.2%. The weighted average of these probabilities over each sub-group is the original 6.1% probability assumed for the overall population. Similar calculations are applied for the probability of infection at each level of exposure relevant for the earthquake release scenarios for each pathogen and also for case fatality rates.

Results such as those in Table K–9, along with the site MVSP estimates y_k listed in Table K–7, form the basis for calculating the site-adjusted and MVSP-specific earthquake release results presented in Section K.3.5 below.

K.3 Results

K.3.1 Needlestick

The health consequences resulting from exposure to a pathogen via needlestick are dependent on several pathogen characteristics and host factors. This RA assumes that the infectious dose of the pathogen delivered via needlestick is sufficient to cause disease (see Chapter 4, Section 4.2.3.2); therefore, no probabilistic calculations for initial infections are performed in this Appendix. Further, this RA assumes that the pathogen is viable in the needle at the time of the needlestick. An important characteristic is the pathogen's ability to cause infection by this route. As with all infections, the health consequences are also dependent on the immune status and general health of the affected person (host). For this RA, for needlestick injuries involving laboratory workers, the assumption is that the laboratory worker is a healthy young adult. For needlestick events that are not promptly detected and reported, the health consequences are also based on the assumption that post-exposure prophylaxis (if available), quarantine, and supportive measures are not instituted until the laboratory worker exhibits symptoms and seeks medical attention.

Of the BSL-3 pathogens, and based on the biology of the pathogen and routes of transmission of the disease noted in natural, accidental, and laboratory settings (as described in detail in Chapter 4 and Appendix C), it is assumed that *B. anthracis*, *F. tularensis*, *Y. pestis*, RVFV, and ANDV would cause an illness similar to the natural disease if introduced into the host by the percutaneous route (i.e., needlesticks). This represents a conservative approach as the exact course and extent of disease resulting from a needlestick is not known for these pathogens. Pandemic influenza viruses have been detected in the blood (viremia), whereas seasonal influenza viruses have a less prominent viremia (Likos et al. 2007; Stramer et al. 2009). This viremia is noted to be secondary to the illness and the primary pathology involving influenza is in the respiratory tract with the specific tropism of the virus to that area. Thus, if 1918 H1N1V were to be introduced into the host via the percutaneous route, it is considered likely that viremia and some systemic illness would occur. Although it is considered unlikely that the host will develop the classical influenza disease involving the respiratory tract, this outcome cannot be ruled out. A similar situation is considered for SARS-CoV.

Of the BSL-4 pathogens, EBOV, MARV, LASV, JUNV, and TBEV-FE are considered capable of causing illness similar to the natural disease by the percutaneous route. Based on the biology and routes of transmission of NIPV, it is considered unlikely that pneumonia or encephalitis would occur as seen in the

1 natural outbreaks if the virus is transmitted to the host via the percutaneous route. However, as the course
2 and extent of disease resulting from a needlestick is not known, this also cannot be ruled out.

3
4 Table K–10 summarizes the potential health consequences in the laboratory worker and subsequent risk to
5 the public. In the setting of illness caused by needlestick, the presentation and disease course might be
6 different from that of the natural disease—especially for pathogens that are not normally known to cause
7 disease by direct introduction into the host through the skin such as 1918 H1N1V, SARS-CoV, and
8 NIPV. However, in the absence of data to suggest otherwise, this RA makes the conservative assumption
9 that the illness caused by needlestick would mimic the natural disease with respect to the course, the
10 organ systems affected, the morbidity and mortality caused, and potential for secondary transmission.

11
12 The issues of pre-existing immunity and potentially available vaccines for each pathogen are further
13 discussed in Appendix J. Full descriptions of the clinical diseases caused by the pathogens are provided in
14 Chapter 3 and Appendix C. The case fatality estimates provided here are summarized in Chapter 3,
15 Appendix C and (Mahmoud et al. 2008) and are assumed to apply to heterogeneous populations
16 containing individuals from medically vulnerable groups. The case fatality estimates are based on
17 observations from natural outbreaks and as such represent mortality from the natural disease. In the
18 setting of illness caused by needlestick, the presentation and disease course can be different from that of
19 the natural disease; thus, the case fatality estimates from natural disease outbreaks may not necessarily
20 apply. Applying these case fatality estimates to laboratory workers may be considered conservative, as it
21 is presumed that laboratory workers are healthy adults as discussed further in Appendix I. Potential risk to
22 the public from laboratory workers infected with transmissible pathogens is further discussed in Chapter 9
23 and Appendix L.

1

Table K–10. Summary of Health Consequences in Laboratory Worker from Needlestick

Pathogen	Pre-existing immunity to pathogen in laboratory worker	Resulting illness via needlestick route	Case fatality estimates from infection	Potential for secondary transmission to members of the public if initial infection is undetected and/or unreported
Biosafety Level 3 Pathogens				
<i>B. anthracis</i>	Possible, as vaccine is available	Bacteremia and sepsis with <i>B anthracis</i>	45%	No
<i>F. tularensis</i>	No	Bacteremia, sepsis and pneumonic form of tularemia	< 2%	No
<i>Y. pestis</i>	No	Bacteremia, primary septicemic plague and pneumonic plague	15%	Yes, if pneumonic plague is present
1918 H1N1V	Possible, due to cross-protection from past influenza vaccines or infections	Influenza	2.5%	Yes, if respiratory symptoms are present
SARS-CoV	No	SARS	10%	Yes, if respiratory symptoms are present
RVFV	Possible, as vaccine is available	Rift Valley fever	0.5–2%	No
ANDV	No	Viremia and Hantavirus pulmonary syndrome	50%	Yes, if respiratory symptoms are present
Biosafety Level 4 Pathogens				
EBOV	No	Ebola hemorrhagic fever	40–90%	Yes
MARV	No	Hemorrhagic fever	100%	Yes
LASV	No	Lassa fever (hemorrhagic fever)	1–2%	Yes
JUNV	No	Argentine hemorrhagic fever	< 1%	Yes
TBEV-FE	No	Encephalitis	20–40%	No
NIPV	No	Viremia, encephalitis and/or pneumonia	40–70%	Yes, if respiratory symptoms are present

The case fatality estimates provided in Table K–10 can be combined with the frequency category for a needlestick incident to estimate the frequency with which deaths would occur among laboratory workers due to infections via needlestick. The death rates are presumably most applicable to needlestick events without prompt detection and reporting, in which treatment of the infection would likely not begin until after symptoms appear, and which is likely most often the case during natural disease outbreaks from which the case fatality rate estimates were derived. The frequency of needlestick events without prompt detection and reporting was assigned to the frequency category B (0.01 to 0.0001 per year). Frequencies within the category range were multiplied with case fatality rates, with the results shown in Table K–11.

Table K–11. Frequency of mortality among laboratory workers for needlestick event without prompt detection and reporting.

Pathogen	Assumed case fatality rate	Frequency range of laboratory worker mortalities	Frequency category
BSL-3 Pathogens			
<i>B. anthracis</i>	0.45	0.0045 to 0.000045/yr ≈ 1 per 200 to 20,000 yrs	B or C
<i>F. tularensis</i>	0.02	0.0002 to 0.000002/yr ≈ 1 per 5,000 to 500,000 yrs	B or C
<i>Y. pestis</i>	0.15	0.0015 to 0.000015/yr ≈ 1 per 700 to 70,000 yrs	B or C
1918 H1N1V	0.025	0.00025 to 0.0000025/yr ≈ 1 per 4,000 to 400,000 yrs	B or C
SARS-CoV	0.1	0.001 to 0.00001/yr ≈ 1 per 1,000 to 100,000 yrs	B or C
RVFV	0.02	0.0002 to 0.000002/yr ≈ 1 per 5,000 to 500,000 yrs	B or C
ANDV	0.5	0.005 to 0.00005/yr ≈ 1 per 200 to 20,000 yrs	B or C
BSL-4 Pathogens			
EBOV	0.9	0.009 to 0.00009/yr ≈ 1 per 100 to 10,000 yrs	B
MARV	1	0.01 to 0.0001/yr ≈ 1 per 100 to 10,000 yrs	B
LASV	0.02	0.0002 to 0.000002/yr ≈ 1 per 5,000 to 500,000 yrs	B or C

Pathogen	Assumed case fatality rate	Frequency range of laboratory worker mortalities	Frequency category
JUNV	0.01	0.0001 to 0.000001/yr ≈ 1 per 10,000 to 1 million yrs	C
TBEV-FE	0.4	0.004 to 0.00004/yr ≈ 1 per 200 to 20,000 yrs	B or C
NIPV	0.7	0.007 to 0.00007/yr ≈ 1 per 100 to 10,000 yrs	B

A = 1 in 1 to 100 years; B = 1 in 100 to 10,000 years; C = 1 in 10,000 to 1 million years; D = 1 in > 1 million years

For the needlestick event *with* prompt detection and reporting, the case fatality rate estimates for some pathogens would likely be lower than those listed in the second column of Table K–1b. This is because a laboratory worker promptly reporting a potential infection would receive the best available care in a timely manner. However, for some pathogens, even the best available care provided immediately might not be effective in significantly reducing the likelihood of morbidity or mortality. Given that needlesticks with prompt detection and reporting are assumed to occur in frequency category A, it is possible that deaths due to this event would also occur in frequency category A—especially for pathogens with a very high average case fatality rate such as EBOV, MARV, and NIPV. Beyond the analysis described above, quantitative estimates were not attempted, due to a paucity of available data on the ability of prompt care to prevent death from infection with these pathogens.

K.3.2 BSL-3 Centrifuge Aerosol Release

This section is organized by pathogen. For each pathogen, the results from Chapter 4 and Appendix F detailing the range of doses estimated for each lab worker are synthesized with the dose-response information from Appendix J. Next, the results from the calculations, uncertainty analysis, and sensitivity analysis described in Sections K.2.2.3 to K.2.2.5 are provided.

K.3.2.1 *Bacillus anthracis*

This section discusses the potential for infection with *B. anthracis* among laboratory workers as a result of a centrifuge release. In Chapter 4, the estimated exposure range resulting from a centrifuge release of *B. anthracis* was 0–2 CFU for laboratory workers with full respiratory protection, and 0–200 CFU for workers with partial respiratory protection. As described in the dose-response appendix (Appendix J), there is no direct evidence that humans have become infected after inhaling doses of *B. anthracis* in either of these dose ranges. The lowest dose to which nonhuman primates have succumbed in published

experimental studies was about 200 CFU, which is also the maximum dose estimated for partial respiratory protection. However, there is also no direct evidence that infection from inhaling doses lower than 200 CFU or even 2 CFU is impossible, especially in a heterogeneous population containing individuals who have respiratory health problems or are immunocompromised. The dose-response models fit to the available data and to the expert estimates reflect the possibility that low doses result in a non-zero probability of infection.

Frequency of Initial Infections – Central Estimate

First, the calculations described in Section K.2.2.3 were conducted for base-case assumptions for each of the input values described in Section K.2.2.2. Step-by-step calculations and results under the assumed values and distributions are shown in Tables K–12, K–13, and K–14.

Table K–12. Central estimate calculations for centrifuge release of *B. anthracis*, part I

Output	Respiratory protection	Calculation
Expected probability of infection per worker (q)	Full	$ \begin{aligned} p(0) &= 0 \\ p(0.5) &= 1.3 \times 10^{-5} \\ p(1) &= 2.6 \times 10^{-5} \\ p(1.5) &= 3.9 \times 10^{-5} \\ p(2) &= 5.2 \times 10^{-5} \end{aligned} $ $q_1 = [p(0) + p(0.5) + p(1) + p(1.5) + p(2)]/5$ $q_1 = 2.6 \times 10^{-5} \approx 0.003\%$
	Partial	$ \begin{aligned} p(0) &= 0 \\ p(50) &= 1.3 \times 10^{-3} \\ p(100) &= 2.6 \times 10^{-3} \\ p(150) &= 3.9 \times 10^{-3} \\ p(200) &= 5.2 \times 10^{-3} \end{aligned} $ $q_2 = [p(0) + p(50) + p(100) + p(150) + p(200)]/5$ $q_2 = 2.6 \times 10^{-3} \approx 0.3\%$

The results in Table K–12 provide information about what the example dose-response function $p(d)$ estimates for the probability of infection across the two dose ranges. The five doses shown in each case are the five evenly spaced values across the ranges 0–2 and 0–200 CFU as described previously in the methodology sections. For workers with full respiratory protection, the function predicts up to 5.2×10^{-5} probability of infection at the maximum dose $d = 2$. The average probability of infection across the five

doses shown calculates to 2.6×10^{-5} , or approximately a 3-in-100,000 chance of infection per worker. For workers with partial respiratory protection, the function predicts up to 5.2×10^{-3} probability of infection at the maximum dose $d = 200$. The average probability of infection across the five doses shown calculates to 2.6×10^{-3} , or an approximately 3-in-1,000 chance of infection per worker. While these probabilities are small, they are potentially significant depending on the number of workers exposed and the frequency with which releases occur. These are incorporated in the next parts of the calculations.

Table K–13. Central estimate calculations for centrifuge release of *B. anthracis*, part II.

Output	Respiratory protection	Calculation
Probability of x initial infections per release (μ_x).	Full	$p_1 = 0.9975 \times q_1$ $\mu_1 = 2 \times p_1 \times (1 - p_1)$ $\mu_2 = (p_1)^2$ $\mu_1 = 5.2 \times 10^{-5} \approx 0.005\%$ $\mu_2 = 6.8 \times 10^{-10} \approx 0.00000007\%$
	Partial	$p_2 = 0.0025 \times q_2$ $\mu_1 = 2 \times p_2 \times (1 - p_2)$ $\mu_2 = (p_2)^2$ $\mu_1 = 1.3 \times 10^{-5} \approx 0.001\%$ $\mu_2 = 4.2 \times 10^{-11} \approx 0.000000004\%$
	Full or Partial	$p_T = p_1 + p_2$ $\mu_1 = 2 \times p_T \times (1 - p_T)$ $\mu_2 = (p_T)^2$ $\mu_1 = 6.5 \times 10^{-5} \approx 0.007\%$ $\mu_2 = 1.1 \times 10^{-9} \approx 0.0000001\%$

The calculations in Table K–13 above continue where the calculations from the previous table (K–12) left off, and include the central estimate assumption that there will be exactly two workers in the biocontainment area of a centrifuge release who might become infected after exposure. Calculations were conducted for the probability that one or both of the workers are infected with full respiratory protection, that one or both of the workers are infected without full respiratory protection, and that one or both of the workers are infected with either level of protection.

The probability p_1 of a particular worker both having full respiratory protection and becoming infected with that level of protection is the product of the probability of having full respiratory protection (assumed to be 0.9975) and the average probability of infection across the estimated dose range for that level of protection (q_1 , calculated in Table K–12). Next, the probability that exactly one of two workers becomes infected with full respiratory protection (μ_1) is the product of p_1 and $(1 - p_1)$, referring to the

probability that one becomes infected with respiratory protection and the other does not, and multiplied by two because there are two ways to choose one out of two people. The probability of both of two workers having full respiratory protection and becoming infected is the square of p_1 .

A similar set of calculations are shown for workers with partial respiratory protection, this time using p_2 , which is the product of the probability of a particular worker having partial respiratory protection (assumed to be 0.0025) and the average probability of infection across the estimated dose range for partial protection (q_2 , calculated in Table K–12).

The final set of calculations in Table K–13 is for the probability that one or both of the workers become infected, regardless of respiratory protection level. Here, the value p_T , which is the sum of p_1 and p_2 , is the estimated probability of a particular worker becoming infected, and this value is used in the calculation of μ_1 and μ_2 as described above.

The results in the Table K–13 show that under the central estimate input values, the probability of one or two infections occurring among workers with full respiratory protection is higher than the corresponding probabilities among workers with partial respiratory protection. Although this result may seem counterintuitive (i.e., because a worker with partial respiratory protection has a chance to inhale a much higher dose than a worker with full protection), it is outweighed by the fact that it is much less likely that a worker would have only partial protection in the first place, and the rarity of occurrence of these higher-level exposures results in the lower derived probabilities of experiencing one or two infections.

Overall, the results show that under the central estimate example input values, the probability of an infection resulting from a centrifuge release of *B. anthracis* is estimated at about 6.5×10^{-5} , which is about a 1-in-15,000 chance. This is a small chance, but not necessarily negligible depending on how often centrifuge releases might occur, which is incorporated in the next set of calculations. The central estimate results above also show that the probability of *two* workers becoming infected by a single centrifuge release is vanishingly small.

Table K–14. Central estimate calculations for centrifuge release of *B. anthracis*, part III.

Output	Respiratory protection	Calculation
Frequency of an <i>x</i> -or-more infection event ($\lambda_{\geq x}$)	Full	$\lambda_{\geq 1} = (\mu_1 + \mu_2) \times 0.02/\text{year} = 1.0 \times 10^{-6}/\text{year}$ $\lambda_{\geq 2} = \mu_2 \times 0.02/\text{year} = 1.4 \times 10^{-11}/\text{year}$ <p> $\lambda_{\geq 1} \approx \mathbf{1 \text{ in 1 million years}}$ $\lambda_{\geq 2} \approx \mathbf{1 \text{ in } > 10 \text{ million years}}$ </p>
	Partial	$\lambda_{\geq 1} = (\mu_1 + \mu_2) \times 0.02/\text{year} = 2.6 \times 10^{-7}/\text{year}$ $\lambda_{\geq 2} = \mu_2 \times 0.02/\text{year} = 8.5 \times 10^{-13}/\text{year}$ <p> $\lambda_{\geq 1} \approx \mathbf{1 \text{ in 4 million years}}$ $\lambda_{\geq 2} \approx \mathbf{1 \text{ in } > 10 \text{ million years}}$ </p>
	Full or Partial	$\lambda_{\geq 1} = (\mu_1 + \mu_2) \times 0.02/\text{year} = 1.3 \times 10^{-6}/\text{year}$ $\lambda_{\geq 2} = \mu_2 \times 0.02/\text{year} = 2.1 \times 10^{-11}/\text{year}$ <p> $\lambda_{\geq 1} \approx \mathbf{1 \text{ in 800,000 years}}$ $\lambda_{\geq 2} \approx \mathbf{1 \text{ in } > 10 \text{ million years}}$ </p>

The calculations in Table K–14 above continue where the calculations in the previous table left off. To calculate the frequency of a centrifuge release resulting in one-or-more initial infections, the values of μ_1 and μ_2 corresponding to the given level of respiratory protection (calculated in Table K–13) are summed and multiplied by the central estimate example frequency of the occurrence of centrifuge releases (0.02/year, or once per 50 years on average).

The bottom row of Table K–14 gives the estimates for the overall frequency of centrifuge releases leading to infections in laboratory workers. The estimate for the frequency of a one-or-more infection event would be placed in the C frequency category (between 1 in 10,000 years and 1 in one million years). Events leading to two-or-more initial infections would be placed in the D frequency category (less than 1 in one million years).

Frequency of Initial Infections – Uncertainty

The uncertainty procedure described in Section K.2.2.4 was applied. Uncertainty ranges for each input parameter are described in Section K.2.2.2. The results, presented in Table K–15, display how many different input combinations (of 10,000) lead to a frequency estimate in each category. These results provide a sense of the uncertainty associated with estimating the frequency of a given event occurring.

Table K–15: Uncertainty results for the frequency of centrifuge releases leading to the given number of initial infections (among workers with full or partial protection) for *B. anthracis*.^a

Dose-response estimate	Number of initial infections	A 1 in 1 to 100 yrs	B 1 in 100 to 10,000 yrs	C 1 in 10,000 to 1 million yrs	D 1 in > 1 million yrs
Literature-based	1 or more	0	20 (< 1%)	7606 (76%)	2374 (24%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
	4 or more	0	0	0	10,000 (100%)
Expert-based	1 or more	0	217 (2%)	7484 (75%)	2299 (23%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
	4 or more	0	0	0	10,000 (100%)

^a Entries are the number (and approximate percentage) of 10,000 input combinations which resulted in an estimated frequency in the given category. Because inputs are drawn randomly, exact results may differ under different sets of 10,000 input combinations, but generally agree with the given results within a percentage point.

The results in Table K–15 show that most input combinations result in an estimated frequency of at least one infection occurring from a centrifuge release within the frequency category C. A small percentage of estimates fall in the frequency category B, and the rest in the frequency category D. The distribution of estimates using the expert-based dose-response curves is similar to the distribution resulting from the literature-based curves, but with slightly more weight in the category B. From these results, it is concluded that a realistic average return period for a centrifuge release resulting in at least one *B. anthracis* infection among laboratory workers is presumed to be greater than 10,000 years.

Sensitivity Analysis

The sensitivity analysis procedure described in Section K.2.2.5 was applied. The results of the sensitivity analysis are shown in Table K–16. The output variable selected for sensitivity evaluation was the frequency of a centrifuge release leading to one or more initial infections (with full or partial respiratory protection).

Table K–16: Sensitivity results – PRCC. The effect of changing each input on the frequency of at least one initial infection (with full or partial respiratory protection)

	Distribution of number exposed	Distribution of amount of exposure	Dose-response curve	Frequency of release
Literature-based	0.74	0.75	0.75	0.95
Expert-based	0.50	0.58	0.94	0.86

Because each PRCC in Table K–16 is statistically significantly greater than zero, it can be concluded that each source of uncertainty played a significant role in contributing to the uncertainty apparent in Table K–15. For the estimates using the literature-based dose-response curve, the PRCC for the release frequency input is the highest, which means that reducing the uncertainty in estimating the frequency with which releases occur from centrifuges in BSL-3 laboratories would have the greatest effect on reducing the uncertainty in the results. For the estimates using the expert-based dose-response curve, the PRCC for the dose-response curve is the highest, which means that achieving greater certainty in appropriate dose-dependent probabilities of infection for humans with *B. anthracis* would have the greatest impact in reducing the uncertainty in those results.

K.3.2.2 *Francisella tularensis*

This section discusses the potential for infection with *F. tularensis* among laboratory workers as a result of a centrifuge release. In Chapter 4, the estimated exposure range resulting from a centrifuge release of *F. tularensis* was 0–2 CFU for laboratory workers with full respiratory protection and 0–200 CFU for workers with partial respiratory protection. As described in the dose-response appendix (Appendix J), there exist published data from studies on human volunteers who inhaled doses of *F. tularensis* measured as low as 10 CFU and became infected. There is no direct evidence of humans being infected from inhaling doses smaller than 2 CFU, though the high rate of infection observed in the range of about 10 CFU to 50 CFU suggests that infection at even lower doses might be possible—a notion that is reflected in the dose-response models derived in Appendix J. For the partial-protection 0–200 CFU dose range estimate, the human data (and the models derived from them) strongly suggest a high likelihood of infection at inhaled doses in the higher parts of the range.

Frequency of Initial Infections – Central Estimate

First, the calculations described in Section K.2.2.3 were conducted for base-case assumptions for each of the input values described in Section K.2.2.2. Step-by-step calculations and results under the assumed values and distributions are shown in Tables K–17, K–18, and K–19.

Table K–17. Central estimate calculations for centrifuge release of *F. tularensis*, part I

Output	Respiratory protection	Calculation
Expected probability of infection per worker (<i>q</i>)	Full	$ \begin{aligned} p(0) &= 0 \\ p(0.5) &= 0.031 \\ p(1) &= 0.061 \\ p(1.5) &= 0.090 \\ p(2) &= 0.12 \\ q_1 &= [p(0) + p(0.5) + p(1) + p(1.5) + p(2)]/5 \\ q_1 &= 0.060 \approx 6\% \end{aligned} $
	Partial	$ \begin{aligned} p(0) &= 0 \\ p(50) &= 0.96 \\ p(100) &= 0.998 \\ p(150) &= 0.99992 \\ p(200) &= 0.999997 \\ q_2 &= [p(0) + p(50) + p(100) + p(150) + p(200)]/5 \\ q_2 &= 0.79 \approx 80\% \end{aligned} $

Table K–18. Central estimate calculations for centrifuge release of *F. tularensis*, part II.

Output	Respiratory Protection	Calculation
Probability of x initial infections per release (μ_x).	Full	$p_1 = 0.9975 \times q_1$ $\mu_1 = 2 \times p_1 \times (1 - p_1)$ $\mu_2 = (p_1)^2$ $\mu_1 = 0.11 \approx 10\%$ $\mu_2 = 0.0036 \approx 0.4\%$
	Partial	$p_2 = 0.0025 \times q_2$ $\mu_1 = 2 \times p_2 \times (1 - p_2)$ $\mu_2 = (p_2)^2$ $\mu_1 = 0.0039 \approx 0.4\%$ $\mu_2 = 3.9 \times 10^{-6} \approx 0.0004\%$
	Full or partial	$p_T = p_1 + p_2$ $\mu_1 = 2 \times p_T \times (1 - p_T)$ $\mu_2 = (p_T)^2$ $\mu_1 = 0.12 \approx 10\%$ $\mu_2 = 0.0038 \approx 0.4\%$

The results in Table K–17 above provide information about what the example dose-response function $p(d)$ estimates for the probability of infection across the two dose ranges. For workers with full respiratory protection, the function predicts up to 0.12 probability of infection at the maximum dose $d = 2$. The average probability of infection across the five doses shown calculates to 0.060, or an approximately 1-in-20 chance of infection per worker. For workers with partial respiratory protection, the function estimates greater than 95% probability of infection at the doses $d = 50$ or higher, with near certainty of infection at the maximum estimated dose $d = 200$. The average probability of infection across the five doses shown calculates to 0.79, or roughly 80% chance of infection per worker.

The calculations in Table K–18 above continue where the calculations from the previous table left off, now including the central estimate assumption that there will be exactly two workers in the biocontainment area of a centrifuge release who might become infected after exposure. Calculations were conducted for the probability that one or both of the workers are infected with full respiratory protection, that one or both of the workers are infected without full respiratory protection, and that one or both of the workers are infected with either level of protection.

The probability (p_1) of a particular worker both having full respiratory protection and becoming infected with that level of protection is the product of the probability of having full respiratory protection

(assumed to be 0.9975) and the average probability of infection across the estimated dose range for that level of protection (q_1 , calculated in Table K–17). Next, the probability that exactly one of two workers becomes infected with full respiratory protection (μ_1) is the product of p_1 and $(1 - p_1)$, referring to the probability that one becomes infected with respiratory protection and the other does not, multiplied by two because there are two ways to choose one out of two people. The probability of both of two workers having full respiratory protection and becoming infected is the square of p_1 .

A similar set of calculations are shown for workers with partial respiratory protection, this time using p_2 , which is the product of the probability of a particular worker having partial respiratory protection (assumed to be 0.0025) and the average probability of infection across the estimated dose range for partial protection (q_2 , calculated in Table K–17).

The final set of calculations in Table K–18 is for the probability that one or both of the workers become infected, regardless of respiratory protection level. Here the value p_T , which is the sum of p_1 and p_2 , is the estimated probability of a particular worker becoming infected, and this value is used in the calculation of μ_1 and μ_2 as described above.

The results in the Table K–18 show that, under the central estimate input values, the probability of one or two infections occurring among workers with full respiratory protection is higher than the corresponding probabilities among workers with partial respiratory protection. This result may seem counterintuitive because a worker with partial respiratory protection has a chance to inhale a much higher dose than a worker with full protection. However, this is outweighed by the fact that it is much less likely that a worker would have only partial protection in the first place, and the rarity of occurrence of these higher-level exposures results in the lower derived probabilities experiencing one or two infections.

Overall, the results show that, under the central estimate example input values, the probability of one out of two workers being infected after exposure resulting from a centrifuge release of *F. tularensis* is estimated at about 0.12, which is about a 1-in-9 chance. The probability of both workers becoming infected is calculated to be 0.0038, which is roughly a 1-in-300 chance.

Table K–19. Central estimate calculations for centrifuge release of *F. tularensis*, part III.

Output	Respiratory protection	Calculation
Frequency of an <i>x</i> -or-more infection event ($\lambda_{\geq x}$)	Full	$\lambda_{\geq 1} = (\mu_1 + \mu_2) \times 0.02/\text{year} = 2.3 \times 10^{-3}/\text{year}$ $\lambda_{\geq 2} = \mu_2 \times 0.02/\text{year} = 7.2 \times 10^{-5}/\text{year}$ <p> $\lambda_{\geq 1} \approx \mathbf{1 \text{ in } 400 \text{ years}}$ $\lambda_{\geq 2} \approx \mathbf{1 \text{ in } 10,000 \text{ years}}$ </p>
	Partial	$\lambda_{\geq 1} = (\mu_1 + \mu_2) \times 0.02/\text{year} = 7.9 \times 10^{-5}/\text{year}$ $\lambda_{\geq 2} = \mu_2 \times 0.02/\text{year} = 7.8 \times 10^{-8}/\text{year}$ <p> $\lambda_{\geq 1} \approx \mathbf{1 \text{ in } 10,000 \text{ years}}$ $\lambda_{\geq 2} \approx \mathbf{1 \text{ in } 10 \text{ million years}}$ </p>
	Full or Partial	$\lambda_{\geq 1} = (\mu_1 + \mu_2) \times 0.02/\text{year} = 2.4 \times 10^{-3}/\text{year}$ $\lambda_{\geq 2} = \mu_2 \times 0.02/\text{year} = 7.7 \times 10^{-5}/\text{year}$ <p> $\lambda_{\geq 1} \approx \mathbf{1 \text{ in } 400 \text{ years}}$ $\lambda_{\geq 2} \approx \mathbf{1 \text{ in } 10,000 \text{ years}}$ </p>

The calculations in Table K–19 above continue where the calculations in the previous table left off. To calculate the frequency of a centrifuge release resulting in one-or-more initial infections, the values of μ_1 and μ_2 corresponding to the given level of respiratory protection (calculated in Table K–18) are summed and multiplied by the central estimate example frequency of the occurrence of centrifuge releases (0.02/year, or once per 50 years on average).

The bottom row of Table K–19 provides estimates for the overall frequency of centrifuge releases leading to infections in laboratory workers. The estimate for the frequency of a one-or-more infection event would be placed in the B frequency category (between 1 in 100 years and 1 in 10,000 years). The estimated frequency of events leading to two-or-more initial infections is near the boundary between the B and C frequency category.

Frequency of Initial Infections – Uncertainty

The uncertainty procedure described in Section K.2.2.4 was applied. Uncertainty ranges for each input parameter are described in Section K.2.2.2. The results, presented in Table K–20, display how many different input combinations (of 10,000) lead to a frequency estimate in each category. These results provide a sense of the uncertainty associated with estimating the frequency of a given event occurring.

Table K–20: Uncertainty results for the frequency of centrifuge releases leading to the given number of initial infections (among workers with full or partial protection) for *F. tularensis*.^a

Dose-response estimate	Number of initial infections	A < 1 per year > 1 per 100 yrs	B < 1 per 100 yrs > 1 per 10K yrs	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs
Literature-based	1 or more	1513 (15%)	8487 (85%)	0	0
	2 or more	56 (< 1%)	7036 (70%)	2908 (29%)	0
	3 or more	0	451 (5%)	7854 (79%)	1695 (17%)
	4 or more	0	2 (<0.1%)	929 (9%)	9069 (91%)
Expert-based	1 or more	348 (3%)	7557 (76%)	2095 (21%)	0
	2 or more	5 (<0.1%)	1380 (14%)	5123 (51%)	3492 (35%)
	3 or more	0	23 (< 1%)	1806 (18%)	8171 (82%)
	4 or more	0	0	32 (< 1%)	9968 (>99%)

^a Entries are the number (and approximate percentage) of 10,000 input combinations which resulted in an estimated frequency in the given category. Because inputs are drawn randomly, exact results may differ under different sets of 10,000 input combinations, but generally agree with the given results within a percentage point.

The results in Table K–20 show that most input combinations result in an estimated frequency of at least one infection occurring from a centrifuge release within the B frequency category. A percentage of estimates also fall in the A frequency category, with the estimates that use the literature-based dose-response model producing more results with average return period less than 100 years. The distribution of estimates using the expert-based dose-response curves produces more results in the lower frequency categories. The frequency of centrifuge releases resulting in multiple infections of *F. tularensis* is most often estimated to be in the B frequency category (with literature-based dose-response) or the C category (with expert-based dose-response), with some estimates falling into each extreme category as well.

Sensitivity Results

The sensitivity analysis procedure described in Section K.2.2.5 was applied. The results of the sensitivity analysis are shown in Table K–21. The output variable selected for sensitivity evaluation was the

frequency of a centrifuge release leading to one or more initial infections (with full or partial respiratory protection).

Table K–21: Sensitivity results – PRCC. The effect of changing each input on the frequency of at least one initial infection (with full or partial respiratory protection).

	Distribution of number exposed	Distribution of amount of exposure	Dose-response curve	Frequency of release
Literature-based	0.75	0.75	0.71	0.96
Expert-based	0.48	0.52	0.95	0.85

Because each PRCC in Table K–21 is statistically significantly greater than zero, it can be concluded that each source of uncertainty played a significant role in contributing to the uncertainty apparent in Table K–20. For the estimates using the literature-based dose-response curve, the PRCC for the release frequency input is the highest, which means that reducing the uncertainty in estimating the frequency with which releases occur from centrifuges in BSL-3 laboratories would have the greatest effect on reducing the uncertainty in the results. For the estimates using the expert-based dose-response curve, the PRCC for the dose-response curve is the highest, which means that achieving greater certainty in appropriate dose-dependent probabilities of infection for humans with *F. tularensis* would have the greatest impact in reducing the uncertainty in those results.

K.3.2.3 *Yersinia pestis*

This section discusses the potential for infection with *Y. pestis* among laboratory workers as a result of a centrifuge release. In Chapter 4, the estimated exposure range resulting from a centrifuge release of *Y. pestis* was 0–0.09 CFU for laboratory workers with full respiratory protection and 0–9 CFU for workers with partial respiratory protection. As described in the dose-response appendix (Appendix J), there is no direct evidence that humans have become infected after inhaling doses of *Y. pestis* in either of these dose ranges. The lowest inhalational dose to which nonhuman primates have succumbed in published experimental studies was about 580 CFU; however, through intratracheal inoculation, nonhuman primates have succumbed to doses as low as 120–270 CFU. These doses are more than a factor of 10 higher than the maximum dose estimated for workers with partial respiratory protection. However, because data from exposures to lower doses are not plentiful, the possibility remains that doses less than 9 CFU would result in a non-zero probability of infection, which is reflected in the dose-response models fit to the available data and to the expert estimates.

Frequency of Initial Infections – Central Estimate

First, the calculations described in Section K.2.2.3 were conducted for base-case assumptions for each of the input values described in Section K.2.2.2. Step-by-step calculations and results under the assumed values and distributions are shown in Tables K–22, K–23, and K–24.

Table K–22. Central estimate calculations for centrifuge release of *Y. pestis*, part I

Output	Respiratory protection	Calculation
Expected probability of infection per worker (q)	Full	$ \begin{aligned} p(0) &= 0 \\ p(0.0225) &= 1.8 \times 10^{-6} \\ p(0.045) &= 3.7 \times 10^{-6} \\ p(0.0675) &= 5.5 \times 10^{-6} \\ p(0.09) &= 7.3 \times 10^{-6} \\ q_1 &= [p(0) + p(0.0225) + p(0.045) + p(0.0675) + p(0.09)]/5 \\ q_1 &= 3.7 \times 10^{-6} \approx 0.0004\% \end{aligned} $
	Partial	$ \begin{aligned} p(0) &= 0 \\ p(2.25) &= 1.8 \times 10^{-4} \\ p(4.5) &= 3.7 \times 10^{-4} \\ p(6.75) &= 5.5 \times 10^{-4} \\ p(9) &= 7.3 \times 10^{-4} \\ q_2 &= [p(0) + p(2.25) + p(4.5) + p(6.75) + p(9)]/5 \\ q_2 &= 3.7 \times 10^{-4} \approx 0.04\% \end{aligned} $

Table K–23. Central estimate calculations for centrifuge release of *Y. pestis*, part II.

Output	Respiratory protection	Calculation
Probability of x initial infections per release (μ_x).	Full	$p_1 = 0.9975 \times q_1$ $\mu_1 = 2 \times p_1 \times (1 - p_1)$ $\mu_2 = (p_1)^2$ $\mu_1 = 7.3 \times 10^{-6} \approx 0.0007\%$ $\mu_2 = 1.3 \times 10^{-11} \approx 0.000000001\%$
	Partial	$p_2 = 0.0025 \times q_2$ $\mu_1 = 2 \times p_2 \times (1 - p_2)$ $\mu_2 = (p_2)^2$ $\mu_1 = 1.8 \times 10^{-6} \approx 0.0002\%$ $\mu_2 = 8.4 \times 10^{-13} \approx 0.00000000008\%$
	Full or partial	$p_T = p_1 + p_2$ $\mu_1 = 2 \times p_T \times (1 - p_T)$ $\mu_2 = (p_T)^2$ $\mu_1 = 9.1 \times 10^{-6} \approx 0.0009\%$ $\mu_2 = 2.1 \times 10^{-11} \approx 0.000000002\%$

The results in Table K–22 above provide information about what the example dose-response function $p(d)$ estimates for the probability of infection across the two dose ranges. For workers with full respiratory protection, the function estimates up to 7.3×10^{-6} probability of infection at the maximum dose $d = 0.09$. The average probability of infection across the five doses shown calculates to 3.7×10^{-6} , or an approximately 1-in-300,000 chance of infection per worker. For workers with partial respiratory protection, the function estimates up to 7.3×10^{-4} probability of infection at the maximum dose $d = 9$. The average probability of infection across the five doses shown calculates to 3.7×10^{-4} , or an approximately 1-in-3000 chance of infection per worker.

The calculations in Table K–23 above continue where the calculations from the previous table left off, now including the central estimate assumption that there will be exactly two workers in the biocontainment area of a centrifuge release who might become infected after exposure. Calculations were conducted for the probability that one or both of the workers are infected with full respiratory protection, that one or both of the workers are infected without full respiratory protection, and that one or both of the workers are infected with either level of protection.

The probability p_1 of a particular worker both having full respiratory protection and becoming infected with that level of protection is the product of the probability of having full respiratory protection

(assumed to be 0.9975) and the average probability of infection across the estimated dose range for that level of protection (q_1 , calculated in Table K–22). Next, the probability that exactly one of two workers becomes infected with full respiratory protection (μ_1) is the product of p_1 and $(1 - p_1)$, referring to the probability that one becomes infected with respiratory protection and the other does not, multiplied by two because there are two ways to choose one out of two people. The probability of both of two workers having full respiratory protection and becoming infected is the square of p_1 .

A similar set of calculations are shown for workers with partial respiratory protection, this time using p_2 , which is the product of the probability of a particular worker having partial respiratory protection (assumed to be 0.0025) and the average probability of infection across the estimated dose range for partial protection (q_2 , calculated in Table K–22).

The final set of calculations in Table K–23 is for the probability that one or both of the workers become infected, regardless of respiratory protection level. Here the value p_T , which is the sum of p_1 and p_2 , is the estimated probability of a particular worker becoming infected, and this value is used in the calculation of μ_1 and μ_2 as described above.

The results in the Table K–23 show that, under the central estimate input values, the probability of one or two infections occurring among workers with full respiratory protection is higher than the corresponding probabilities among workers with partial respiratory protection. While this result may seem counterintuitive (because a worker with partial respiratory protection has a chance to inhale a much higher dose than a worker with full protection), this is outweighed by the fact that it is much less likely that a worker would have only partial protection in the first place, and given the rarity of occurrence of these higher-level exposures results in the lower derived probabilities experiencing one or two infections.

Overall, the results show that, under the central estimate example input values, the probability of one out of two workers being infected after exposure resulting from a centrifuge release of *Y. pestis* is estimated at about 9.1×10^{-6} , which is about a 1-in-100,000 chance. The calculated probability of both workers becoming infected is vanishingly small.

Table K–24. Central estimate calculations for centrifuge release of *Y. pestis*, part III.

Output	Respiratory protection	Calculation
Frequency of an <i>x</i> -or-more infection event ($\lambda_{\geq x}$)	Full	$\lambda_{\geq 1} = (\mu_1 + \mu_2) \times 0.02/\text{year} = 1.5 \times 10^{-7}/\text{year}$ $\lambda_{\geq 2} = \mu_2 \times 0.02/\text{year} = 2.7 \times 10^{-13}/\text{year}$ <p> $\lambda_{\geq 1} \approx 1 \text{ in } 7 \text{ million years}$ $\lambda_{\geq 2} \approx 1 \text{ in } > 10 \text{ million years}$ </p>
	Partial	$\lambda_{\geq 1} = (\mu_1 + \mu_2) \times 0.02/\text{year} = 3.7 \times 10^{-8}/\text{year}$ $\lambda_{\geq 2} = \mu_2 \times 0.02/\text{year} = 1.7 \times 10^{-14}/\text{year}$ <p> $\lambda_{\geq 1} \approx 1 \text{ in } > 10 \text{ million years}$ $\lambda_{\geq 2} \approx 1 \text{ in } > 10 \text{ million years}$ </p>
	Full or partial	$\lambda_{\geq 1} = (\mu_1 + \mu_2) \times 0.02/\text{year} = 1.8 \times 10^{-7}/\text{year}$ $\lambda_{\geq 2} = \mu_2 \times 0.02/\text{year} = 4.2 \times 10^{-13}/\text{year}$ <p> $\lambda_{\geq 1} \approx 1 \text{ in } 5 \text{ million years}$ $\lambda_{\geq 2} \approx 1 \text{ in } > 10 \text{ million years}$ </p>

The calculations in Table K–24 above continue where the calculations in the previous table left off. To calculate the frequency of a centrifuge release resulting in one-or-more initial infections, the values of μ_1 and μ_2 corresponding to the given level of respiratory protection (calculated in Table K–23) are summed and multiplied by the central estimate example frequency of the occurrence of centrifuge releases (0.02/year, or once per 50 years on average).

The bottom row of Table K–24 provides estimates for the overall frequency of centrifuge releases leading to infections in laboratory workers. The estimate for the frequency of a one-or-more infection event would be placed in frequency category D (less than one in one million years).

Frequency of Initial Infections – Uncertainty

The uncertainty procedure described in Section K.2.2.4 was applied. Uncertainty ranges for each input parameter are described in Section K.2.2.2. The results, presented in Table K–25, display how many

different input combinations (of 10,000) lead to a frequency estimate in each category. These results provide a sense of the uncertainty associated with estimating the frequency of a given event occurring.

Table K–25: Uncertainty results for the frequency of centrifuge releases leading to the given number of initial infections (among workers with full or partial protection) for *Y. pestis*.^a

Dose-Response Estimate	Number of Initial Infections	A < 1 per year > 1 per 100 yrs	B < 1 per 100 yrs > 1 per 10K yrs	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs
Literature-based	1 or more	0	0	1,156 (12%)	8,844 (88%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
	4 or more	0	0	0	10,000 (100%)
Expert-based	1 or more	0	24 (< 1%)	3,281 (33%)	6,695 (67%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
	4 or more	0	0	0	10,000 (100%)

^a Entries are the number (and approximate percentage) of 10,000 input combinations that resulted in an estimated frequency in the given category. Because inputs are drawn randomly, exact results might differ under different sets of 10,000 input combinations, but generally agree with the given results within a percentage point.

The results in Table K–25 show that most input combinations result in an estimated frequency of at least one infection occurring from a centrifuge release within frequency category D. A percentage of estimates also fall in the C frequency category, with the estimates that use the expert-based dose-response model producing more results with average return period less than one million years, including a small percentage in the B frequency category. The frequency of centrifuge releases resulting in multiple infections of *Y. pestis* is was estimated to be in the D frequency category for 100% of the inputs.

Sensitivity Results

The sensitivity analysis procedure described in Section K.2.2.5 was applied. The results of the sensitivity analysis are shown in Table K–26. The output variable selected for sensitivity evaluation was the frequency of a centrifuge release leading to one or more initial infections (with full or partial respiratory protection).

Table K–26: Sensitivity results – PRCC. The effect of changing each input on the frequency of at least one initial infection (with full or partial respiratory protection)

	Distribution of number exposed	Distribution of amount of exposure	Dose-response curve	Frequency of release
Literature-based	0.65	0.67	0.86	0.93
Expert-based	0.46	0.55	0.97	0.84

Because each PRCC in Table K–26 is statistically significantly greater than zero, it can be concluded that each source of uncertainty played a significant role in contributing to the uncertainty apparent in Table K–25. For the estimates using the literature-based dose-response curve, the PRCC for the release frequency input is the highest, which means that reducing the uncertainty in estimating the frequency with which releases occur from centrifuges in BSL-3 laboratories would have the greatest effect on reducing the uncertainty in the results. For the estimates using the expert-based dose-response curve, the PRCC for the dose-response curve is the highest, which means that achieving greater certainty in appropriate dose-dependent probabilities of infection for humans with *Y. pestis* would have the greatest impact in reducing the uncertainty in those results.

K.3.2.4 1918 H1N1 influenza virus

This section discusses the potential for infection with 1918 H1N1V among laboratory workers as a result of a centrifuge release. In Chapter 4, the estimated exposure range resulting from a centrifuge release of 1918 H1N1V was 0–0.9 PFU for laboratory workers with full respiratory protection and 0–90 PFU for workers with partial respiratory protection. As described in the dose-response appendix (Appendix J), there is no direct evidence that humans have become infected after inhaling doses of 1918 H1N1V in either of these dose ranges. There are numerous data sets from human volunteers exposed to other strains of influenza virus, but in the vast majority of those studies, volunteers were exposed to high doses. One study reported outcomes from human volunteers exposed to low-dose aerosols of an H2N2 strain, concluding that unprotected individuals were infected by doses as low as 1 CCID₅₀. These data suggest that humans could potentially be infected by doses in the estimated exposure ranges for the centrifuge release, considering that quantities of virus are generally similar or higher in units of CCID₅₀ compared to PFU.

Frequency of Initial Infections – Central Estimate

First, the calculations described in Section K.2.2.3 were conducted for base-case assumptions for each of the input values described in Section K.2.2.2. Step-by-step calculations and results under the assumed values and distributions are shown in Tables K–27, K–28, and K–29.

Table K–27. Central estimate calculations for centrifuge release of 1918 H1N1V, part I.

Output	Respiratory protection	Calculation
Expected probability of infection per worker (q)	Full	$p(0) = 0$ $p(0.225) = 3.0 \times 10^{-4}$ $p(0.45) = 8.2 \times 10^{-4}$ $p(0.675) = 1.4 \times 10^{-3}$ $p(0.9) = 2.1 \times 10^{-3}$ $q_1 = [p(0) + p(0.225) + p(0.45) + p(0.675) + p(0.9)]/5$ $q_1 = 9.3 \times 10^{-4} \approx 0.09\%$
	Partial	$p(0) = 0$ $p(22.5) = 0.062$ $p(45) = 0.11$ $p(67.5) = 0.14$ $p(90) = 0.17$ $q_2 = [p(0) + p(2.25) + p(4.5) + p(6.75) + p(9)]/5$ $q_2 = 0.095 \approx 10\%$

The results in Table K–27 above provide information about what the example dose-response function $p(d)$ estimates for the probability of infection across the two dose ranges. For workers with full respiratory protection, the function estimates up to 0.0021 probability of infection at the maximum dose $d = 0.9$. The average probability of infection across the five doses shown calculates to 9.3×10^{-4} , or an approximately 1-in-1000 chance of infection per worker. For workers with partial respiratory protection, the function estimates up to 0.17 probability of infection at the maximum dose $d = 90$. The average probability of infection across the five doses shown calculates to 0.095, or an approximately 1-in-10 chance of infection per worker.

Table K–28. Central estimate calculations for centrifuge release of 1918 H1N1V, part II.

Output	Respiratory protection	Calculation
Probability of x initial infections per release (μ_x)	Full	$p_1 = 0.9975 \times q_1$ $\mu_1 = 2 \times p_1 \times (1 - p_1)$ $\mu_2 = (p_1)^2$ $\mu_1 = 1.9 \times 10^{-3} \approx 0.2\%$ $\mu_2 = 8.7 \times 10^{-7} \approx 0.00009\%$
	Partial	$p_2 = 0.0025 \times q_2$ $\mu_1 = 2 \times p_2 \times (1 - p_2)$ $\mu_2 = (p_2)^2$ $\mu_1 = 4.8 \times 10^{-4} \approx 0.05\%$ $\mu_2 = 5.7 \times 10^{-8} \approx 0.000006\%$
	Full or partial	$p_T = p_1 + p_2$ $\mu_1 = 2 \times p_T \times (1 - p_T)$ $\mu_2 = (p_T)^2$ $\mu_1 = 2.3 \times 10^{-3} \approx 0.2\%$ $\mu_2 = 1.4 \times 10^{-6} \approx 0.0001\%$

The calculations in Table K–28 above continue where the calculations from the previous table left off, now including the central estimate assumption that there will be exactly two workers in the biocontainment area of a centrifuge release who might become infected after exposure. Calculations were conducted for the probability that one or both of the workers are infected with full respiratory protection, that one or both of the workers are infected without full respiratory protection, and that one or both of the workers are infected with either level of protection.

The probability p_1 of a particular worker both having full respiratory protection and becoming infected with that level of protection is the product of the probability of having full respiratory protection (assumed to be 0.9975) and the average probability of infection across the estimated dose range for that level of protection (q_1 , calculated in Table K–27). Next, the probability that exactly one of two workers becomes infected with full respiratory protection (μ_1) is the product of p_1 and $(1 - p_1)$, referring to the probability that one becomes infected with respiratory protection and the other does not, multiplied by two because there are two ways to choose one out of two people. The probability of both of two workers having full respiratory protection and becoming infected is the square of p_1 .

A similar set of calculations are shown for workers with partial respiratory protection, this time using p_2 , which is the product of the probability of a particular worker having partial respiratory protection

1 (assumed to be 0.0025) and the average probability of infection across the estimated dose range for partial
2 protection (q_2 , calculated in Table K–27).

3
4 The final set of calculations in Table K–28 is for the probability that one or both of the workers become
5 infected, regardless of respiratory protection level. Here the value p_T , which is the sum of p_1 and p_2 , is the
6 estimated probability of a particular worker becoming infected, and this value is used in the calculation of
7 μ_1 and μ_2 as described above.

8
9 The results in the Table K–28 show that, under the central estimate input values, the probability of one or
10 two infections occurring among workers with full respiratory protection is higher than the corresponding
11 probabilities among workers with partial respiratory protection. This result seems counterintuitive
12 because a worker with partial respiratory protection has a chance to inhale a much higher dose than a
13 worker with full protection. However, this is outweighed by the fact that it is much less likely that a
14 worker would have only partial protection in the first place, and the rarity of occurrence of these higher-
15 level exposures results in the lower derived probabilities of seeing one or two infections.

16 Overall, the results show that, under the central estimate example input values, the probability of one out
17 of two workers being infected after exposure resulting from a centrifuge release of 1918 H1N1V is
18 estimated at about 2.3×10^{-3} , which is about a 1-in-400 chance. The calculated probability of both
19 workers becoming infected is about 1.4×10^{-6} , which is about a 1-in-700,000 chance.

Table K–29. Central estimate calculations for centrifuge release of 1918 H1N1V, part III.

Output	Respiratory protection	Calculation
Frequency of an x-or-more infection event ($\lambda_{\geq x}$)	Full	$\lambda_{\geq 1} = (\mu_1 + \mu_2) \times 0.02/\text{year} = 3.7 \times 10^{-5}/\text{year}$ $\lambda_{\geq 2} = \mu_2 \times 0.02/\text{year} = 1.7 \times 10^{-8}/\text{year}$ <p>$\lambda_{\geq 1} \approx 1$ in 30,000 years $\lambda_{\geq 2} \approx 1$ in > 10 million years</p>
	Partial	$\lambda_{\geq 1} = (\mu_1 + \mu_2) \times 0.02/\text{year} = 9.5 \times 10^{-6}/\text{year}$ $\lambda_{\geq 2} = \mu_2 \times 0.02/\text{year} = 1.1 \times 10^{-9}/\text{year}$ <p>$\lambda_{\geq 1} \approx 1$ in 100,000 years $\lambda_{\geq 2} \approx 1$ in > 10 million years</p>
	Full or Partial	$\lambda_{\geq 1} = (\mu_1 + \mu_2) \times 0.02/\text{year} = 4.7 \times 10^{-5}/\text{year}$ $\lambda_{\geq 2} = \mu_2 \times 0.02/\text{year} = 2.7 \times 10^{-8}/\text{year}$ <p>$\lambda_{\geq 1} \approx 1$ in 20,000 years $\lambda_{\geq 2} \approx \text{one}$ in > 10 million years</p>

The calculations in Table K–29 above continue where the calculations in the previous table left off. To calculate the frequency of a centrifuge release resulting in one-or-more initial infections, the values of μ_1 and μ_2 corresponding to the given level of respiratory protection (calculated in Table K–28) are summed and multiplied by the central estimate example frequency of the occurrence of centrifuge releases (0.02/year, or once per 50 years on average).

The bottom row of Table K–29 gives the estimates for the overall frequency of centrifuge releases leading to infections in laboratory workers. The estimate for the frequency of a one-or-more infection event would be placed in the C frequency category (between 1 in 10,000 years and 1 in 1 million years), and the frequency estimate for an event infecting two or more workers would be placed in the D frequency category.

Frequency of Initial Infections – Uncertainty

The uncertainty procedure described in Section K.2.2.4 was applied. Uncertainty ranges for each input parameter are described in Section K.2.2.2. The results, presented in Table K–30, display how many

different input combinations (of 10,000) lead to a frequency estimate in each category. These results provide a sense of the uncertainty associated with estimating the frequency of a given event occurring.

Table K–30: Results for the frequency of centrifuge releases leading to the given number of initial infections (among workers with full or partial protection) for 1918 H1N1V.^a

Dose-Response Estimate	Number of Initial Infections	A < 1 per year > 1 per 100 yrs	B < 1 per 100 yrs > 1 per 10K yrs	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs
Expert-based	1 or more	28 (< 1%)	3916 (39%)	4467 (45%)	1589 (16%)
	2 or more	0	21 (< 1%)	2524 (25%)	7455 (75%)
	3 or more	0	0	7 (0.1%)	9993 (99.9%)
	4 or more	0	0	0	10,000 (100%)

^a Entries are the number (and approximate percentage) of 10,000 input combinations that resulted in an estimated frequency in the given category. Because inputs are drawn randomly, exact results might differ under different sets of 10,000 input combinations, but generally agree with the given results within a percentage point.

The results in Table K–30 show that most input combinations result in an estimated frequency of at least one infection occurring from a centrifuge release within the B or C frequency categories. A small percentage of estimates also fall in the A frequency category, and about 16% fall in the D frequency category. The frequency of centrifuge releases resulting in multiple infections of 1918 H1N1V was mostly estimated to be in the D frequency category, though about a quarter of the inputs resulted in return periods of less than one million years.

Sensitivity Results

The sensitivity analysis procedure described in Section K.2.2.5 was applied. The results of the sensitivity analysis are shown in Table K–31. The output variable selected for sensitivity evaluation was the frequency of a centrifuge release leading to one or more initial infections (with full or partial respiratory protection).

Table K–31: Sensitivity results – PRCC. The effect of changing each input on the frequency of at least one initial infection (with full or partial respiratory protection).

	Distribution of number exposed	Distribution of amount of exposure	Dose-response curve	Frequency of release
Expert-based	0.40	0.43	0.97	0.76

1 Because each PRCC in Table K–31 is statistically significantly greater than zero, it can be concluded that
2 each source of uncertainty played a significant role in contributing to the uncertainty apparent in Table K–
3 30. The PRCC for the dose-response curve is the highest, which means that achieving greater certainty in
4 appropriate dose-dependent probabilities of infection for humans with 1918 H1N1V would have the
5 greatest impact in reducing the very wide uncertainty range shown in the Table K–30 results.
6

7 **K.3.2.5 SARS-associated coronavirus**

8 This section discusses the potential for infection with SARS-CoV among laboratory workers as a result of
9 a centrifuge release. In Chapter 4, the estimated exposure range resulting from a centrifuge release of
10 SARS-CoV was 0–0.09 PFU for laboratory workers with full respiratory protection and 0–9 PFU for
11 workers with partial respiratory protection. As described in the dose-response appendix (Appendix J),
12 there is no direct evidence that humans have become infected after inhaling doses of SARS-CoV in either
13 of these dose ranges. However, there are published experimental studies on viruses related to SARS-CoV
14 in which individuals have been infected by low inhalational doses, including humans becoming infected
15 by doses as low as 4 CCID₅₀, so it is possible that doses less than 9 PFU would result in a non-zero
16 probability of infection, which is reflected in the dose-response models fit to the available data and to the
17 expert estimates.
18

19 **Frequency of Initial Infections – Central Estimate**

20 First, the calculations described in Section K.2.2.3 were conducted for base-case assumptions for each of
21 the input values described in Section K.2.2.2. Step-by-step calculations and results under the assumed
22 values and distributions are shown in Tables K–32, K–33, and K–34.

Table K–32. Central estimate calculations for centrifuge release of SARS-CoV, part I.

Output	Respiratory protection	Calculation
Expected probability of infection per worker (q)	Full	$ \begin{aligned} p(0) &= 0 \\ p(0.0225) &= 5.5 \times 10^{-5} \\ p(0.045) &= 1.1 \times 10^{-4} \\ p(0.0675) &= 1.7 \times 10^{-4} \\ p(0.09) &= 2.2 \times 10^{-4} \\ q_1 &= [p(0) + p(0.0225) + p(0.045) + p(0.0675) + p(0.09)]/5 \\ q_1 &= 1.1 \times 10^{-4} \approx 0.01\% \end{aligned} $
	Partial	$ \begin{aligned} p(0) &= 0 \\ p(2.25) &= 0.0055 \\ p(4.5) &= 0.011 \\ p(6.75) &= 0.016 \\ p(9) &= 0.022 \\ q_2 &= [p(0) + p(2.25) + p(4.5) + p(6.75) + p(9)]/5 \\ q_2 &= 0.011 \approx 1\% \end{aligned} $

The results in Table K–32 above provide information about what the example dose-response function $p(d)$ estimates for the probability of infection across the two dose ranges. For workers with full respiratory protection, the function estimates up to 2.2×10^{-4} probability of infection at the maximum dose $d = 0.09$. The average probability of infection across the five doses shown calculates to 1.1×10^{-4} , or an approximately 1-in-9000 chance of infection per worker. For workers with partial respiratory protection, the function estimates up to 0.022 probability of infection at the maximum dose $d = 9$. The average probability of infection across the five doses shown calculates to 0.011, or an approximately 1-in-90 chance of infection per worker.

Table K–33. Central estimate calculations for centrifuge release of SARS-CoV, part II.

Output	Respiratory protection	Calculation
Probability of x initial infections per release (μ_x).	Full	$p_1 = 0.9975 \times q_1$ $\mu_1 = 2 \times p_1 \times (1 - p_1)$ $\mu_2 = (p_1)^2$ $\mu_1 = 2.2 \times 10^{-4} \approx 0.02\%$ $\mu_2 = 1.2 \times 10^{-8} \approx 0.000001\%$
	Partial	$p_2 = 0.0025 \times q_2$ $\mu_1 = 2 \times p_2 \times (1 - p_2)$ $\mu_2 = (p_2)^2$ $\mu_1 = 5.5 \times 10^{-5} \approx 0.005\%$ $\mu_2 = 7.5 \times 10^{-10} \approx 0.00000008\%$
	Full or partial	$p_T = p_1 + p_2$ $\mu_1 = 2 \times p_T \times (1 - p_T)$ $\mu_2 = (p_T)^2$ $\mu_1 = 2.8 \times 10^{-4} \approx 0.03\%$ $\mu_2 = 1.9 \times 10^{-8} \approx 0.000002\%$

The calculations in Table K–33 above continue where the calculations from the previous table left off, now including the central estimate assumption that there will be exactly two workers in the biocontainment area of a centrifuge release who might become infected after exposure. Calculations were conducted for the probability that one or both of the workers are infected with full respiratory protection, one or both of the workers are infected without full respiratory protection, and that one or both of the workers are infected with either level of protection.

The probability p_1 of a particular worker both having full respiratory protection and becoming infected with that level of protection is the product of the probability of having full respiratory protection (assumed to be 0.9975) and the average probability of infection across the estimated dose range for that level of protection (q_1 , calculated in Table K–32). Next, the probability that exactly one of two workers becomes infected with full respiratory protection (μ_1) is the product of p_1 and $(1 - p_1)$, referring to the probability that one becomes infected with respiratory protection and the other does not, multiplied by two because there are two ways to choose one out of two people. The probability of both of two workers having full respiratory protection and becoming infected is the square of p_1 .

A similar set of calculations are shown for workers with partial respiratory protection, this time using p_2 , which is the product of the probability of a particular worker having partial respiratory protection

1 (assumed to be 0.0025) and the average probability of infection across the estimated dose range for partial
2 protection (q_2 , calculated in Table K–32).

3
4 The final set of calculations in Table K–33 is for the probability that one or both of the workers become
5 infected, regardless of respiratory protection level. Here the value p_T , which is the sum of p_1 and p_2 , is the
6 estimated probability of a particular worker becoming infected, and this value is used in the calculation of
7 μ_1 and μ_2 as described above.

8
9 The results in the Table K–33 show that, under the central estimate input values, the probability of one or
10 two infections occurring among workers with full respiratory protection is higher than the corresponding
11 probabilities among workers with partial respiratory protection. This result seems counterintuitive
12 because a worker with partial respiratory protection has a chance to inhale a much higher dose than a
13 worker with full protection. However, this is outweighed by the fact that it is much less likely that a
14 worker would have only partial protection in the first place, and the rarity of occurrence of these higher-
15 level exposures results in the lower derived probabilities of seeing one or two infections.

16
17 Overall, the results show that under the central estimate example input values, the probability of one out
18 of two workers being infected after exposure resulting from a centrifuge release of SARS-CoV is
19 estimated at about 2.8×10^{-4} , which is approximately a 1-in-4000 chance. The calculated probability of
20 both workers becoming infected is 1.9×10^{-8} , which is less than a 1-in-10 million chance.

Table K–34. Central estimate calculations for centrifuge release of SARS-CoV, part III.

Output	Respiratory protection	Calculation
Frequency of an x-or-more infection event ($\lambda_{\geq x}$)	Full	$\lambda_{\geq 1} = (\mu_1 + \mu_2) \times 0.02/\text{year} = 4.4 \times 10^{-6}/\text{year}$ $\lambda_{\geq 2} = \mu_2 \times 0.02/\text{year} = 2.4 \times 10^{-10}/\text{year}$ <p>$\lambda_{\geq 1} \approx \text{one in 200,000 years}$ $\lambda_{\geq 2} \approx 1 \text{ in } > 10 \text{ million years}$</p>
	Partial	$\lambda_{\geq 1} = (\mu_1 + \mu_2) \times 0.02/\text{year} = 1.1 \times 10^{-6}/\text{year}$ $\lambda_{\geq 2} = \mu_2 \times 0.02/\text{year} = 1.5 \times 10^{-11}/\text{year}$ <p>$\lambda_{\geq 1} \approx 1 \text{ in 900,000 years}$ $\lambda_{\geq 2} \approx 1 \text{ in } > 10 \text{ million years}$</p>
	Full or partial	$\lambda_{\geq 1} = (\mu_1 + \mu_2) \times 0.02/\text{year} = 5.5 \times 10^{-6}/\text{year}$ $\lambda_{\geq 2} = \mu_2 \times 0.02/\text{year} = 3.8 \times 10^{-10}/\text{year}$ <p>$\lambda_{\geq 1} \approx 1 \text{ in 200,000 years}$ $\lambda_{\geq 2} \approx 1 \text{ in } > 10 \text{ million years}$</p>

The calculations in Table K–34 above continue where the calculations in the previous table left off. To calculate the frequency of a centrifuge release resulting in one-or-more initial infections, the values of μ_1 and μ_2 corresponding to the given level of respiratory protection (calculated in Table K–33) are summed and multiplied by the central estimate example frequency of the occurrence of centrifuge releases (0.02/year, or once per 50 years on average).

The bottom row of Table K–34 provides the estimates for the overall frequency of centrifuge releases leading to infections in laboratory workers. The estimate for the frequency of a one-or-more infection event would be placed in the C frequency category (between 1 in 10,000 years and 1 in 1 million years). The estimate for the frequency of a two-or-more infection event would be placed in the D frequency category.

Frequency of Initial Infections – Uncertainty

The uncertainty procedure described in Section K.2.2.4 was applied. Uncertainty ranges for each input parameter are described in Section K.2.2.2. The results, presented in Table K–35, display how many different input combinations (of 10,000) lead to a frequency estimate in each category. These results provide a sense of the uncertainty associated with estimating the frequency of a given event occurring.

Table K–35: Uncertainty results for the frequency of centrifuge releases leading to the given number of initial infections (among workers with full or partial protection) for SARS-CoV.^a

Dose-response estimate	Number of initial infections	A < 1 per year > 1 per 100 yrs	B < 1 per 100 yrs > 1 per 10K yrs	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs
Literature-based	1 or more	0	282 (3%)	9694 (97%)	24 (< 1%)
	2 or more	0	0	1 (<0.1%)	9,999 (>99.9%)
	3 or more	0	0	0	10,000 (100%)
	4 or more	0	0	0	10,000 (100%)
Expert-based	1 or more	0	28 (< 1%)	2792 (28%)	7,180 (72%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
	4 or more	0	0	0	10,000 (100%)

^a Entries are the number (and approximate percentage) of 10,000 input combinations that resulted in an estimated frequency in the given category. Because inputs are drawn randomly, exact results might differ under different sets of 10,000 input combinations, but generally agree with the given results within a percentage point.

The results in Table K–35 show that for the estimates that use the literature-based dose-response estimates, most input combinations result in an estimated frequency of at least one infection occurring from a centrifuge release within the C frequency category, while for the estimates that use the expert-based dose-response estimates, most estimates fall in the D frequency category. In both cases, a small percentage of estimates also fall in the B frequency category. The frequency of centrifuge releases resulting in multiple infections of SARS-CoV is was estimated to be D frequency except for a single input combination.

Sensitivity Results

The sensitivity analysis procedure described in Section K.2.2.5 was applied. The results of the sensitivity analysis are shown in Table K–36. The output variable selected for sensitivity evaluation was the frequency of a centrifuge release leading to one or more initial infections (with full or partial respiratory protection).

Table K–36: Sensitivity results – PRCCs and the effect of changing each input on the frequency of at least one initial infection (with full or partial respiratory protection).

	Distribution of number exposed	Distribution of amount of exposure	Dose-response curve	Frequency of release
Literature-based	0.69	0.71	0.82	0.94
Expert-based	0.40	0.50	0.93	0.78

Because each PRCC in Table K–36 is statistically significantly greater than zero, it can be concluded that each source of uncertainty played a significant role in contributing to the uncertainty apparent in Table K–35. For the estimates using the literature-based dose-response curve, the PRCC for the release frequency input is the highest, which means that reducing the uncertainty in estimating the frequency with which releases occur from centrifuges in BSL-3 laboratories would have the greatest effect on reducing the uncertainty in the results. For the estimates using the expert-based dose-response curve, the PRCC for the dose-response curve is the highest, which means that achieving greater certainty in appropriate dose-dependent probabilities of infection for humans with SARS-CoV would have the greatest impact in reducing the uncertainty in those results.

K.3.2.6 Rift Valley fever virus

This section discusses the potential for infection with RVFV among laboratory workers as a result of a centrifuge release. In Chapter 4, the estimated exposure range resulting from a centrifuge release of RVFV was 0–9 MICLD₅₀ or 0–0.9 for laboratory workers with full respiratory protection and 0–900 MICLD₅₀ or 0–90 PFU for workers with partial respiratory protection. As described in the dose-response appendix (Appendix J), there is no direct evidence that humans have become infected after inhaling doses of RVFV in either of these dose ranges. However, there are numerous published experimental studies on animal exposures to aerosols in which individuals have been infected by low inhalational doses well within the estimated ranges for the centrifuge release, so it is possible that doses in these ranges would result in a non-zero and perhaps substantial probability of infection for humans, which is reflected in the dose-response models fit to the available data and to the expert estimates.

Frequency of Initial Infections – Central Estimate

First, the calculations described in Section K.2.2.3 were conducted for base-case assumptions for each of the input values described in Section K.2.2.2. Step-by-step calculations and results under the assumed values and distributions are shown in Tables K–37, K–38, and K–39.

Table K–37. Central estimate calculations for centrifuge release of RVFV, part I

Output	Respiratory Protection	Calculation
Expected probability of infection per worker (q)	Full	$p(0) = 0$ $p(2.25) = 0.15$ $p(4.5) = 0.28$ $p(6.75) = 0.38$ $p(9) = 0.48$ $q_1 = [p(0) + p(2.25) + p(4.5) + p(6.75) + p(9)]/5$ $q_1 = 0.26 \approx 30\%$
	Partial	$p(0) = 0$ $p(225) = 0.9999999$ $p(450) \approx 1$ $p(675) \approx 1$ $p(900) \approx 1$ $q_2 = [p(0) + p(225) + p(450) + p(675) + p(900)]/5$ $q_2 = 0.80 \approx 80\%$

The results in Table K–37 above provide information about what the example dose-response function $p(d)$ estimates for the probability of infection across the two dose ranges. For workers with full respiratory protection, the function estimates up to 0.48 probability of infection at the maximum dose $d = 9$. The average probability of infection across the five doses shown calculates to 0.26, or an approximately 1-in-4 chance of infection per worker. For workers with partial respiratory protection, the function estimates close to certainty of infection at dose points $d = 225$ and greater. The average probability of infection across the five doses shown calculates to 0.80, or about a 4/5 chance of infection per worker.

Table K–38. Central estimate calculations for centrifuge release of RVFV, part II.

Output	Respiratory protection	Calculation
Probability of x initial infections per release (μ_x)	Full	$p_1 = 0.9975 \times q_1$ $\mu_1 = 2 \times p_1 \times (1 - p_1)$ $\mu_2 = (p_1)^2$ $\mu_1 = 0.38 \approx 40\%$ $\mu_2 = 0.066 \approx 7\%$
	Partial	$p_2 = 0.0025 \times q_2$ $\mu_1 = 2 \times p_2 \times (1 - p_2)$ $\mu_2 = (p_2)^2$ $\mu_1 = 4.0 \times 10^{-3} \approx 0.4\%$ $\mu_2 = 4.0 \times 10^{-6} \approx 0.0004\%$
	Full or partial	$p_T = p_1 + p_2$ $\mu_1 = 2 \times p_T \times (1 - p_T)$ $\mu_2 = (p_T)^2$ $\mu_1 = 0.38 \approx 40\%$ $\mu_2 = 0.067 \approx 7\%$

The calculations in Table K–38 above continue where the calculations from the previous table left off, now including the central estimate assumption that there will be exactly two workers in the biocontainment area of a centrifuge release who might become infected after exposure. Calculations were conducted for the probability that one or both of the workers are infected with full respiratory protection, one or both of the workers are infected without full respiratory protection, and that one or both of the workers are infected with either level of protection.

The probability p_1 of a particular worker both having full respiratory protection and becoming infected with that level of protection is the product of the probability of having full respiratory protection (assumed to be 0.9975) and the average probability of infection across the estimated dose range for that level of protection (q_1 , calculated in Table K–37). Next, the probability that exactly one of two workers becomes infected with full respiratory protection (μ_1) is the product of p_1 and $(1 - p_1)$, referring to the probability that one becomes infected with respiratory protection and the other does not, multiplied by two because there are two ways to choose one out of two people. The probability of both of two workers having full respiratory protection and becoming infected is the square of p_1 .

A similar set of calculations are shown for workers with partial respiratory protection, this time using p_2 , which is the product of the probability of a particular worker having partial respiratory protection

1 (assumed to be 0.0025) and the average probability of infection across the estimated dose range for partial
2 protection (q_2 , calculated in Table K–37).

3
4 The final set of calculations in Table K–38 is for the probability that one or both of the workers become
5 infected, regardless of respiratory protection level. Here the value p_T , which is the sum of p_1 and p_2 , is the
6 estimated probability of a particular worker becoming infected, and this value is used in the calculation of
7 μ_1 and μ_2 as described above.

8
9 The results in the Table K–38 show that, under the central estimate input values, the probability of one or
10 two infections occurring among workers with full respiratory protection is higher than the corresponding
11 probabilities among workers with partial respiratory protection. This result may seem counterintuitive
12 because a worker with partial respiratory protection has a chance to inhale a much higher dose than a
13 worker with full protection. However, this is outweighed by the fact that it is much less likely that a
14 worker would have only partial protection in the first place, as well as the rarity of occurrence of these
15 higher-level exposures results in the lower derived probabilities of seeing one or two infections.

16 Overall, the results show that under the central estimate example input values, the probability of one out
17 of two workers being infected after exposure resulting from a centrifuge release of RVFV is estimated at
18 about 40%. The calculated probability of both workers becoming infected is estimated to be about 7%.

Table K–39. Central estimate calculations for centrifuge release of RVFV, part III.

Output	Respiratory protection	Calculation
Frequency of an x-or-more infection event ($\lambda_{\geq x}$)	Full	$\lambda_{\geq 1} = (\mu_1 + \mu_2) \times 0.02/\text{year} = 8.9 \times 10^{-3}/\text{year}$ $\lambda_{\geq 2} = \mu_2 \times 0.02/\text{year} = 1.3 \times 10^{-3}/\text{year}$ <p> $\lambda_{\geq 1} \approx 1 \text{ in } 100 \text{ years}$ $\lambda_{\geq 2} \approx 1 \text{ in } 800 \text{ years}$ </p>
	Partial	$\lambda_{\geq 1} = (\mu_1 + \mu_2) \times 0.02/\text{year} = 8.0 \times 10^{-5}/\text{year}$ $\lambda_{\geq 2} = \mu_2 \times 0.02/\text{year} = 8.0 \times 10^{-8}/\text{year}$ <p> $\lambda_{\geq 1} \approx 1 \text{ in } 10,000 \text{ years}$ $\lambda_{\geq 2} \approx 1 \text{ in } 10 \text{ million years}$ </p>
	Full or partial	$\lambda_{\geq 1} = (\mu_1 + \mu_2) \times 0.02/\text{year} = 9.0 \times 10^{-3}/\text{year}$ $\lambda_{\geq 2} = \mu_2 \times 0.02/\text{year} = 1.3 \times 10^{-3}/\text{year}$ <p> $\lambda_{\geq 1} \approx 1 \text{ in } 100 \text{ years}$ $\lambda_{\geq 2} \approx 1 \text{ in } 800 \text{ years}$ </p>

The calculations in Table K–39 above continue where the calculations in the previous table left off. To calculate the frequency of a centrifuge release resulting in one-or-more initial infections, the values of μ_1 and μ_2 corresponding to the given level of respiratory protection (calculated in Table K–38) are summed and multiplied by the central estimate example frequency of the occurrence of centrifuge releases (0.02/year, or once per 50 years on average).

The bottom row of Table K–39 gives the estimates for the overall frequency of centrifuge releases leading to infections in laboratory workers. The estimate for the frequency of a one-or-more infection event is near the boundary of the A and B frequency categories. The estimate for the frequency of a two-or-more infection event would be placed in the B frequency category (between once in 100 years and once in 10,000 years).

Frequency of Initial Infections – Uncertainty

The uncertainty procedure described in Section K.2.2.4 was applied. Uncertainty ranges for each input parameter are described in Section K.2.2.2. The results, presented in Table K–40, display how many different input combinations (of 10,000) lead to a frequency estimate in each category. These results provide a sense of the uncertainty associated with estimating the frequency of a given event occurring.

Table K–40: Uncertainty results for the frequency of centrifuge releases leading to the given number of initial infections (among workers with full or partial protection) for RVFV.^a

Dose-response estimate	Number of initial infections	A < 1 per year > 1 per 100 yrs	B < 1 per 100 yrs > 1 per 10K yrs	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs
Literature-based	1 or more	5400 (54%)	4600 (46%)	0	0
	2 or more	1679 (17%)	8313 (83%)	8 (0.1%)	0
	3 or more	310 (3%)	7608 (76%)	2080 (21%)	2 (<0.1%)
	4 or more	31 (< 1%)	2517 (25%)	4068 (41%)	3384 (34%)
Expert-based	1 or more	10 (0.1%)	2222 (22%)	7361 (74%)	407 (4%)
	2 or more	0	8 (0.1%)	1091 (11%)	8901 (89%)
	3 or more	0	0	2 (<0.1%)	9998 (>99.9%)
	4 or more	0	0	0	10,000 (100%)

^a Entries are the number (and approximate percentage) of 10,000 input combinations that resulted in an estimated frequency in the given category. Because inputs are drawn randomly, exact results might differ under different sets of 10,000 input combinations, but generally agree with the given results within a percentage point.

The results in Table K–40 show that, for the estimates that use the literature-based dose-response estimates, all input combinations result in an estimated frequency of at least one infection occurring from a centrifuge release within the A or B frequency categories, while for the estimates that use the expert-based dose-response estimates, most estimates fall in the B or C category with only a small percentage in the A category. The frequency of centrifuge releases resulting in multiple infections of RVFV was estimated to be mostly B frequency category for the estimates using the literature-based dose-response and mostly in the D frequency category for the estimates using expert-based dose-response, although the uncertainty range is wide in both cases.

Sensitivity Results

The sensitivity analysis procedure described in Section K.2.2.5 was applied. The results of the sensitivity analysis are shown in Table K–41. The output variable selected for sensitivity evaluation was the

frequency of a centrifuge release leading to one or more initial infections (with full or partial respiratory protection).

Table K–41: Sensitivity Results – PRCC. The effect of changing each input on the frequency of at least one initial infection (with full or partial respiratory protection)

	Distribution of number exposed	Distribution of amount of exposure	Dose-response curve	Frequency of release
<i>Literature-based</i>	0.69	0.68	0.76	0.96
<i>Expert-based</i>	0.37	0.42	0.90	0.75

Because each PRCC in Table K–41 is statistically significantly greater than zero, it can be concluded that each source of uncertainty played a significant role in contributing to the uncertainty apparent in Table K–40. For the estimates using the literature-based dose-response curve, the PRCC for the release frequency input is the highest, which means that reducing the uncertainty in estimating the frequency with which releases occur from centrifuges in BSL-3 laboratories would have the greatest effect on reducing the uncertainty in the results. For the estimates using the expert-based dose-response curve, the PRCC for the dose-response curve is the highest, which means that achieving greater certainty in appropriate dose-dependent probabilities of infection for humans with RVFV would have the greatest impact in reducing the uncertainty in those results.

K.3.2.7 Andes virus

This section discusses the potential for infection with ANDV among laboratory workers as a result of a centrifuge release. In Chapter 4, the estimated exposure range resulting from a centrifuge release of ANDV was 0–0.009 CCID₅₀ for laboratory workers with full respiratory protection and 0–0.9 CCID₅₀ for workers with partial respiratory protection. As described in the dose-response appendix (Appendix J), there is no direct evidence that humans have become infected after inhaling doses of ANDV in either of these dose ranges. The lowest dose of ANDV that infected Syrian hamsters intranasally was about 20 PFU, which is presumed to be at least 10 times higher than the maximum estimated dose under partial respiratory protection. However, data on low dose exposures are scarce, so it is possible that doses less than 1 CCID₅₀ could result in a non-zero probability of infection, which is reflected in the dose-response models fit to the available data and to the expert estimates.

Frequency of Initial Infections – Central Estimate

First, the calculations described in Section K.2.2.3 were conducted for base-case assumptions for each of the input values described in Section K.2.2.2. Step-by-step calculations and results under the above assumed values and distributions are shown in Tables K–42, K–43, and K–44.

Table K–42. Central estimate calculations for centrifuge release of ANDV, part I.

Output	Respiratory protection	Calculation
Expected probability of infection per worker (q)	Full	$ \begin{aligned} p(0) &= 0 \\ p(0.00225) &= 2.5 \times 10^{-5} \\ p(0.0045) &= 5.0 \times 10^{-5} \\ p(0.00675) &= 7.4 \times 10^{-5} \\ p(0.009) &= 9.9 \times 10^{-5} \end{aligned} $ $q_1 = [p(0) + p(0.00225) + p(0.0045) + p(0.00675) + p(0.009)]/5$ $q_1 = 5.0 \times 10^{-5} \approx 0.005\%$
	Partial	$ \begin{aligned} p(0) &= 0 \\ p(0.225) &= 0.0025 \\ p(0.45) &= 0.0049 \\ p(0.675) &= 0.0074 \\ p(0.9) &= 0.0099 \end{aligned} $ $q_2 = [p(0) + p(0.225) + p(0.45) + p(0.675) + p(0.9)]/5$ $q_2 = 0.0049 \approx 0.5\%$

The results in Table K–42 above provide information about what the example dose-response function $p(d)$ estimates for the probability of infection across the two dose ranges. For workers with full respiratory protection, the function estimates up to 9.9×10^{-5} probability of infection at the maximum dose $d = 0.009$. The average probability of infection across the five doses shown calculates to 5.0×10^{-5} , or an approximately 1-in-20,000 chance of infection per worker. For workers with partial respiratory protection, the function estimates up to 0.0099 probability of infection at the maximum dose $d = 0.9$. The average probability of infection across the five doses shown calculates to 0.0049, or an approximately 1-in-200 chance of infection per worker.

Table K–43. Central estimate calculations for centrifuge release of ANDV, part II.

Output	Respiratory protection	Calculation
Probability of x initial infections per release (μ_x)	Full	$p_1 = 0.9975 \times q_1$ $\mu_1 = 2 \times p_1 \times (1 - p_1)$ $\mu_2 = (p_1)^2$ $\mu_1 = 9.9 \times 10^{-5} \approx 0.01\%$ $\mu_2 = 2.4 \times 10^{-9} \approx 0.0000002\%$
	Partial	$p_2 = 0.0025 \times q_2$ $\mu_1 = 2 \times p_2 \times (1 - p_2)$ $\mu_2 = (p_2)^2$ $\mu_1 = 2.5 \times 10^{-5} \approx 0.002\%$ $\mu_2 = 1.5 \times 10^{-10} \approx 0.00000002\%$
	Full or partial	$p_T = p_1 + p_2$ $\mu_1 = 2 \times p_T \times (1 - p_T)$ $\mu_2 = (p_T)^2$ $\mu_1 = 1.2 \times 10^{-4} \approx 0.01\%$ $\mu_2 = 3.8 \times 10^{-9} \approx 0.0000004\%$

The calculations in Table K–43 above continue where the calculations from the previous table left off, now including the central estimate assumption that there will be exactly two workers in the biocontainment area of a centrifuge release who might become infected after exposure. Calculations were conducted for the probability that one or both of the workers are infected with full respiratory protection, one or both of the workers are infected without full respiratory protection, and that one or both of the workers are infected with either level of protection.

The probability p_1 of a particular worker both having full respiratory protection and becoming infected with that level of protection is the product of the probability of having full respiratory protection (assumed to be 0.9975) and the average probability of infection across the estimated dose range for that level of protection (q_1 , calculated in Table K–42). Next, the probability that exactly one of two workers becomes infected with full respiratory protection (μ_1) is the product of p_1 and $(1 - p_1)$, referring to the probability that one becomes infected with respiratory protection and the other does not, multiplied by two because there are two ways to choose one out of two people. The probability of both of two workers having full respiratory protection and becoming infected is the square of p_1 .

A similar set of calculations are shown for workers with partial respiratory protection, this time using p_2 , which is the product of the probability of a particular worker having partial respiratory protection

(assumed to be 0.0025) and the average probability of infection across the estimated dose range for partial protection (q_2 , calculated in Table K-42).

The final set of calculations in Table K-43 is for the probability that one or both of the workers become infected, regardless of respiratory protection level. Here the value p_T , which is the sum of p_1 and p_2 , is the estimated probability of a particular worker becoming infected, and this value is used in the calculation of μ_1 and μ_2 as described above.

The results in the Table K-43 show that under the central estimate input values, the probability of one or two infections occurring among workers with full respiratory protection is higher than the corresponding probabilities among workers with partial respiratory protection. This result may seem counterintuitive because a worker with partial respiratory protection has a chance to inhale a much higher dose than a worker with full protection. However, this is outweighed by the fact that it is much less likely that a worker would have only partial protection in the first place, and the rarity of occurrence of these higher-level exposures results in the lower derived probabilities of experiencing one or two infections.

Overall, the results show that, under the central estimate example input values, the probability of one out of two workers being infected after exposure resulting from a centrifuge release of ANDV is estimated at about 1.2×10^{-4} , which is roughly a 1-in-8000 chance. The calculated probability of both workers becoming infected is 3.8×10^{-9} , which is vanishingly small.

Table K–44. Central estimate calculations for centrifuge release of ANDV, part III.

Output	Respiratory protection	Calculation
Frequency of an <i>x</i> -or-more infection event ($\lambda_{\geq x}$)	Full	$\lambda_{\geq 1} = (\mu_1 + \mu_2) \times 0.02/\text{year} = 2.0 \times 10^{-6}/\text{year}$ $\lambda_{\geq 2} = \mu_2 \times 0.02/\text{year} = 4.9 \times 10^{-11}/\text{year}$ <p> $\lambda_{\geq 1} \approx 1$ in 500,000 years $\lambda_{\geq 2} \approx 1$ in > 10 million years </p>
	Partial	$\lambda_{\geq 1} = (\mu_1 + \mu_2) \times 0.02/\text{year} = 4.9 \times 10^{-7}/\text{year}$ $\lambda_{\geq 2} = \mu_2 \times 0.02/\text{year} = 3.1 \times 10^{-12}/\text{year}$ <p> $\lambda_{\geq 1} \approx 1$ in 2 million years $\lambda_{\geq 2} \approx 1$ in > 10 million years </p>
	Full or partial	$\lambda_{\geq 1} = (\mu_1 + \mu_2) \times 0.02/\text{year} = 2.5 \times 10^{-6}/\text{year}$ $\lambda_{\geq 2} = \mu_2 \times 0.02/\text{year} = 7.6 \times 10^{-11}/\text{year}$ <p> $\lambda_{\geq 1} \approx 1$ in 400,000 years $\lambda_{\geq 2} \approx 1$ in > 10 million years </p>

The calculations in Table K–44 above continue where the calculations in the previous table left off. To calculate the frequency of a centrifuge release resulting in one-or-more initial infections, the values of μ_1 and μ_2 corresponding to the given level of respiratory protection (calculated in Table K–43) are summed and multiplied by the central estimate example frequency of the occurrence of centrifuge releases (0.02/year, or once per 50 years on average).

The bottom row of Table K–44 gives the estimates for the overall frequency of centrifuge releases leading to infections in laboratory workers. The estimate for the frequency of a one-or-more infection event would be placed in the C frequency category (between once in 10,000 years and once in 1 million years). The estimate for the frequency of a two-or-more infection event would be placed in the D frequency category.

Frequency of Initial Infections – Uncertainty

The uncertainty procedure described in Section K.2.2.4 was applied. Uncertainty ranges for each input parameter are described in Section K.2.2.2. The results, presented in Table K–45, display how many different input combinations (of 10,000) lead to a frequency estimate in each category. These results provide a sense of the uncertainty associated with estimating the frequency of a given event occurring.

Table K–45: Uncertainty results for the frequency of centrifuge releases leading to the given number of initial infections (among workers with full or partial protection) for ANDV.^a

Dose-response estimate	Number of initial infections	A < 1 per year > 1 per 100 yrs	B < 1 per 100 yrs > 1 per 10K yrs	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs
Literature-based	1 or more	0	92 (1%)	9,211 (92%)	697 (7%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
	4 or more	0	0	0	10,000 (100%)
Expert-based	1 or more	0	25 (< 1%)	2,332 (23%)	7,643 (76%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
	4 or more	0	0	0	10,000 (100%)

^a Entries are the number (and approximate percentage) of 10,000 input combinations that resulted in an estimated frequency in the given category. Because inputs are drawn randomly, exact results might differ under different sets of 10,000 input combinations, but generally agree with the given results within a percentage point.

The results in Table K–45 show that for the estimates that use the literature-based dose-response estimates, most input combinations result in an estimated frequency of at least one infection occurring from a centrifuge release within the C frequency category, while for the estimates that use the expert-based dose-response estimates, most estimates fall in the D frequency category. In both cases, a small percentage of estimates also fall in the B frequency category. The frequency of centrifuge releases resulting in multiple infections of ANDV was estimated to be in the D frequency category for all input combinations.

Sensitivity Results

The sensitivity analysis procedure described in Section K.2.2.5 was applied. The results of the sensitivity analysis are shown in Table K–46. The output variable selected for sensitivity evaluation was the frequency of a centrifuge release leading to one or more initial infections (with full or partial respiratory protection).

Table K–46: Sensitivity results – PRCC. The effect of changing each input on the frequency of at least one initial infection (with full or partial respiratory protection).

	Distribution of number exposed	Distribution of amount of exposure	Dose-response curve	Frequency of release
Literature-based	0.68	0.70	0.83	0.93
Expert-based	0.37	0.46	0.97	0.77

Because each PRCC in Table K–46 is statistically significantly greater than zero, it can be concluded that each source of uncertainty played a significant role in contributing to the uncertainty apparent in Table K–45. For the estimates using the literature-based dose-response curve, the PRCC for the release frequency input is the highest, which means that reducing the uncertainty in estimating the frequency with which releases occur from centrifuges in BSL-3 laboratories would have the greatest effect on reducing the uncertainty in the results. For the estimates using the expert-based dose-response curve, the PRCC for the dose-response curve is the highest, which means that achieving greater certainty in appropriate dose-dependent probabilities of infection for humans with ANDV would have the greatest impact in reducing the uncertainty in those results.

K.3.2.8 Summary of infection frequency estimates

This section summarizes the results from Sections K.3.1.1 to K.3.1.7. Table K–47 compiles the central estimate results while Table K–48 compiles the uncertainty results for all seven BSL-3 pathogens.

Table K–47. Central estimate overall calculations for BSL-3 centrifuge release (with full or partial respiratory protection).

Pathogen	Number of initial infections (x)	Probability of x or more initial infections ($\mu_{\geq x}$)	Frequency of release leading to x or more initial infections ($\lambda_{\geq x}$)
<i>B. anthracis</i>	1 or more	6.5×10^{-5}	$1.3 \times 10^{-6}/\text{year} \approx 1 \text{ in } 800,000 \text{ years}$
<i>F. tularensis</i>	1 or more	0.12	$2.4 \times 10^{-3}/\text{year} \approx 1 \text{ in } 400 \text{ years}$
	2 or more	3.8×10^{-3}	$7.7 \times 10^{-5}/\text{year} \approx 1 \text{ in } 10,000 \text{ years}$
<i>Y. pestis</i>	1 or more	9.1×10^{-6}	$1.8 \times 10^{-7}/\text{year} \approx 1 \text{ in } 5 \text{ million years}$
1918 H1N1V	1 or more	2.3×10^{-3}	$4.7 \times 10^{-5}/\text{year} \approx 1 \text{ in } 20,000 \text{ years}$

Pathogen	Number of initial infections (x)	Probability of x or more initial infections ($\mu_{\geq x}$)	Frequency of release leading to x or more initial infections ($\lambda_{\geq x}$)
SARS-CoV	1 or more	2.8×10^{-4}	$5.5 \times 10^{-6}/\text{year} \approx 1$ in 200,000 years
RVFV	1 or more	0.38	$9.0 \times 10^{-3}/\text{year} \approx 1$ in 100 years
	2 or more	0.067	$1.3 \times 10^{-3}/\text{year} \approx 1$ in 800 years
ANDV	1 or more	1.2×10^{-4}	$2.5 \times 10^{-6}/\text{year} \approx 1$ in 400,000 years

Table K-48: Summary of uncertainty results: number of 10,000 input combinations that resulted in the frequency of centrifuge releases leading to the given number of initial infections (among workers with full or partial protection) falling into each frequency category.

Pathogen	Dose-response estimate	Number of initial infections	A < 1 per year > 1 per 100 yrs	B < 1 per 100 yrs > 1 per 10K yrs	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs
<i>B. anthracis</i>	Literature-based	1 or more	0	20 (< 1%)	7,606 (76%)	2,374 (24%)
		2 or more	0	0	0	10,000 (100%)
	Expert-based	1 or more	0	217 (2%)	7,484 (75%)	2,299 (23%)

		2 or more	0	0	0	10,000 (100%)

K.3.2.9 Summary of potential health consequences

The results described above estimate a non-zero risk of a laboratory worker developing an infection after exposure to any of the BSL-3 pathogens as a result of loss of biocontainment after an event involving a centrifuge. The route of exposure considered is via inhalation. As it is assumed that the exposure from the centrifuge event is undetected and/or unreported, the health consequences are based on the assumption that post-exposure prophylaxis (if available), quarantine, and supportive measures are not instituted unless and until the laboratory worker exhibits symptoms and seeks medical attention. Table K–49 summarizes the potential health consequences in the laboratory worker and subsequent risk to the public in the event of an inhalational infection occurring in the laboratory worker.

The issues of pre-existing immunity and potentially available vaccines for each pathogen are further discussed in Appendix J. Full descriptions of the clinical diseases caused by the pathogens are provided in Chapter 4 and Appendix C. The mortality estimates provided below are also summarized in Chapter 4, Appendix C, and Mahmoud (2008), and are presumed to apply to heterogeneous populations containing individuals from medically vulnerable groups. Therefore, applying these mortality estimates to laboratory workers may be conservative, as it is presumed that laboratory workers are healthy adults as discussed further in Appendix I. Potential risks to the public from laboratory workers infected with transmissible pathogens is further discussed in Chapter 10 and Appendix L.

Table K–49. Summary of health consequences in laboratory worker from centrifuge event.^a

Pathogen	Pre-existing immunity to pathogen in laboratory worker	Resulting illness via inhalation route	Case fatality estimates from infection	Potential for secondary transmission to members of the public if initial infection is undetected and/or unreported
<i>B. anthracis</i>	Possible, as vaccine is available	Inhalational anthrax	45%	No
<i>F. tularensis</i>	No	Pneumonic form of tularemia	< 2%	No
<i>Y. pestis</i>	No	Pneumonic plague	15%	Yes
1918 H1N1V	Possible, due to cross-protection from past influenza vaccines or infections	Influenza	2.5%	Yes
SARS-CoV	No	SARS	10%	Yes
RVFV	Possible, as vaccine is available	Rift Valley fever	0.5–2%	No
ANDV	No	Hantavirus pulmonary syndrome	50%	Yes

^a Adapted from Mahmoud et al. (2008).

Finally, the case fatality rate estimates in Table K–49 were integrated into the initial infections calculations to compute estimates for the frequency of centrifuge releases leading to mortalities among laboratory workers. For *F. tularensis* and RVFV, the conservative value of 2% case fatality was applied. The results under the central estimate example inputs are shown in Table K–50.

Table K–50. Central estimate mortality results for BSL-3 centrifuge infectious aerosol release among laboratory workers (with full or partial respiratory protection).

Pathogen	Number of deaths among laboratory workers (<i>x</i>)	Probability of <i>x</i> or more deaths among laboratory workers	Frequency of release leading to <i>x</i> or more deaths among laboratory workers
<i>B. anthracis</i>	1 or more	2.9×10^{-5}	5.9×10^{-7} /year \approx 1 in 2 million years
<i>F. tularensis</i>	1 or more	2.5×10^{-3}	5.0×10^{-5} /year \approx 1 in 20,000 years
	2 or more	1.5×10^{-6}	3.1×10^{-8} /year = 1 in > 10 million years

Pathogen	Number of deaths among laboratory workers (x)	Probability of x or more deaths among laboratory workers	Frequency of release leading to x or more deaths among laboratory workers
<i>Y. pestis</i>	1 or more	1.4×10^{-6}	$2.7 \times 10^{-8}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
1918 H1N1V	1 or more	5.8×10^{-5}	$1.2 \times 10^{-6}/\text{year} \approx 1 \text{ in } 900,000 \text{ years}$
SARS-CoV	1 or more	2.8×10^{-5}	$5.5 \times 10^{-7}/\text{year} \approx 1 \text{ in } 2 \text{ million years}$
RVFV	1 or more	0.010	$2.1 \times 10^{-4}/\text{year} \approx 1 \text{ in } 5,000 \text{ years}$
	2 or more	2.7×10^{-5}	$5.3 \times 10^{-7}/\text{year} \approx 1 \text{ in } 2 \text{ million years}$
ANDV	1 or more	6.2×10^{-5}	$1.2 \times 10^{-6}/\text{year} = 1 \text{ in } 800,000 \text{ years}$

Under the central estimate inputs, centrifuge releases leading to one or more deaths among laboratory workers would be placed in the B frequency category for RVFV; the C frequency category for *F. tularensis*, 1918 H1N1V, and ANDV; and the D frequency category for *B. anthracis*, *Y. pestis*, and SARS-CoV. Centrifuge releases leading to two or more deaths among laboratory workers would be placed in the D frequency category for all pathogens.

Uncertainty results pertaining to these mortality estimates are presented in Table K-51.

Table K-51: Summary of mortality uncertainty results: percentage of 10,000 input combinations that resulted in the frequency of centrifuge releases leading to the given number of deaths (among workers with full or partial protection) falling into each frequency category.

Pathogen	Dose-response estimate	Number of deaths among laboratory workers	A < 1 per year > 1 per 100 yrs	B < 1 per 100 yrs > 1 per 10K yrs	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs
<i>B. anthracis</i>	Literature-based	1 or more	0	0	3,969 (40%)	6,031 (60%)
		2 or more	0	0	0	10,000 (100%)
	Expert-based	1 or more	0	77 (1%)	6,278 (63%)	3,645 (36%)
		2 or more	0	0	0	10,000 (100%)
<i>F. tularensis</i>	Literature-based	1 or more	0	3,353 (34%)	6,647 (66%)	0
		2 or more	0	0	407 (4%)	9,593 (96%)
		3 or more	0	0	0	10,000 (100%)
	Expert-based	1 or more	0	820 (8%)	8,121 (81%)	1,059 (11%)
		2 or more	0	0	40 (< 1%)	9,960 (> 99%)
		3 or more	0	0	0	10,000 (100%)
<i>Y. pestis</i>	Literature-based	1 or more	0	0	93 (1%)	9,907 (99%)
		2 or more	0	0	0	10,000 (100%)
	Expert-based	1 or more	0	0	754 (8%)	9,246 (92%)
		2 or more	0	0	0	10,000 (100%)
1918 H1N1V	Expert-based	1 or more	0	102 (1%)	4,780 (48%)	5,118 (51%)
		2 or more	0	0	0	10,000 (100%)
SARS-CoV	Literature-based	1 or more	0	2 (< 0.1%)	3,866 (39%)	6,132 (61%)
		2 or more	0	0	0	10,000 (100%)
	Expert-based	1 or more	0	0	537 (5%)	9,463 (95%)
		2 or more	0	0	0	10,000 (100%)
RVFV	Literature-based	1 or more	69 (1%)	9,249 (92%)	682 (7%)	0
		2 or more	0	54 (1%)	6,409 (64%)	3,537 (35%)
		3 or more	0	0	14 (0.1%)	9,986 (99.9%)
		4 or more	0	0	0	10,000 (100%)
	Expert-based	1 or more	0	34 (< 1%)	2,914 (29%)	7,052 (71%)
		2 or more	0	0	0	10,000 (100%)
ANDV	Literature-based	1 or more	0	21 (< 1%)	7,196 (72%)	2,783 (28%)
		2 or more	0	0	0	10,000 (100%)
	Expert-based	1 or more	0	10 (0.1%)	1,713 (17%)	8,277 (83%)
		2 or more	0	0	0	10,000 (100%)

B. anthracis mortality frequency is placed mostly in the D frequency category under the literature-based dose-response models and mostly in C under the expert-based models.

1 *F. tularensis* mortality frequency is placed mostly in the C category. Under the literature-based dose-
2 response models, a significant percentage (34%) placed in B frequency category, compared to only 8%
3 under the expert-based models.

4
5 *Y. pestis* mortality frequency is placed mostly in the D frequency category, with small percentages (1% or
6 8%) in the C frequency category.

7
8 1918 H1N1V mortality frequency was split close to evenly between C and in the D frequency category,
9 with a small percentage (1%) in B frequency category.

10
11 SARS-CoV mortality frequency was placed mostly in the D frequency category, with a significant
12 percentage (39%) placed in the C frequency category under the literature-based dose-response models,
13 compared to only 5% in C frequency category under the expert-based models.

14
15 RVFV mortality frequency (one or more deaths) was placed mostly in B frequency category under the
16 literature-based dose-response models and mostly in the D frequency category under the expert-based
17 models, with uncertainty ranges across three frequency categories in each case.

18
19 ANDV mortality frequency was placed mostly in the C frequency category under the literature-based
20 dose-response models and mostly in the D frequency category under the expert-based models, with small
21 percentages (< 0.3%) in B frequency category in both cases.

22 23 **K.3.3 Earthquake Beyond Design Basis Release**

24 The calculations described in Sections K.2.3.3 to K.2.3.4 were performed using the exposure estimates
25 from the (BDB Release scenario described in Chapter 4 and Appendix F. As the calculations resulted in
26 very low risk estimates for every pathogen under every population scenario, the results are displayed here
27 only in summary form. A more detailed discussion of aspects of each pathogen relevant to potential initial
28 infections in the public is provided in Section K.3.4.

Table K–52. Central estimate calculations for urban site BDB earthquake release.

Pathogen	Number of initial infections overall (x)	Probability of x or more initial infections overall ($\mu_{\geq x}$)	Frequency of release leading to x or more initial infections ($\lambda_{\geq x}$)
<i>B. anthracis</i>	1 or more	1.5×10^{-9}	$1.5 \times 10^{-14}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
<i>F. tularensis</i>	1 or more	6.1×10^{-7}	$6.1 \times 10^{-12}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
<i>Y. pestis</i>	1 or more	4.0×10^{-11}	$4.0 \times 10^{-16}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
1918 H1N1V	1 or more	6.6×10^{-20}	$6.6 \times 10^{-25}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
SARS-CoV	1 or more	1.8×10^{-8}	$1.8 \times 10^{-13}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
RVFV	1 or more	5.2×10^{-5}	$5.2 \times 10^{-10}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
ANDV	1 or more	8.0×10^{-9}	$8.0 \times 10^{-14}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
EBOV	1 or more	1.5×10^{-9}	$1.5 \times 10^{-14}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
MARV	1 or more	9.0×10^{-10}	$9.0 \times 10^{-15}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
LASV	1 or more	8.6×10^{-10}	$8.6 \times 10^{-15}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
JUNV	1 or more	1.5×10^{-10}	$1.5 \times 10^{-15}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
TBEV-FE	1 or more	5.6×10^{-52}	$5.6 \times 10^{-57}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
NIPV	1 or more	5.5×10^{-11}	$5.5 \times 10^{-16}/\text{year} = 1 \text{ in } > 10 \text{ million years}$

For the central estimate example, all pathogens are estimated to produce a low probability that one or more infections will occur among members of the public. The highest estimated probability is for RVFV (5.2×10^{-5}), which is about a 1-in-20,000 chance. Combined with the central estimate estimated frequency of the occurrence of an earthquake release (once in 100,000 years), the frequency of an earthquake BDB release resulting in one or more infections of any pathogen is estimated to be well into the D frequency category frequency category.

Table K–53: Summary of uncertainty results: number of 10,000 input combinations that resulted in the frequency of earthquake BDB release (urban site) leading to the given number of initial infections falling into each frequency category.

Pathogen	Dose-response estimate	Number of initial infections	A < 1 per year > 1 per 100 yrs	B < 1 per 100 yrs > 1 per 10K yrs	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs
<i>B. anthracis</i>	Both	1 or more	0	0	0	10,000 (100%)
<i>F. tularensis</i>	Both	1 or more	0	0	0	10,000 (100%)
<i>Y. pestis</i>	Both	1 or more	0	0	0	10,000 (100%)

These uncertainty results apply for estimates using both the literature-based and the expert-based range of dose-response estimates. Every combination of dose-response estimates and earthquake release frequency estimates results in an estimated frequency of at least one initial infection in frequency category D. This means that even the most conservative dose-response models combined with the most conservative earthquake frequency (once per 10,000 years) results in an average return period estimate greater than one million years.

Results for urban residents, suburban site, and rural site

The results in Tables K–52 and K–53 were calculated using the overall estimated urban population, which includes estimates of area residents as well as daytime students, workers, hospital patients, and passersby within a 1km radius. If the population inputs are restricted to residents only, the resulting probabilities in Table K–52 are even lower, and the same conclusions are drawn regarding the frequency category for one or more infections occurring (frequency category D).

The average, per-person exposure estimates at the suburban and rural sites are slightly higher than at the urban site (see also Chapter 4 and Appendix F), but the estimated suburban and rural populations are lower, which results in lower probabilities of at least one infection compared to the urban results in Table K–52. Therefore, the same conclusions are drawn regarding the frequency category for one or more infections occurring at the suburban and rural sites (frequency category D).

A more detailed discussion of the effects of site differences on the earthquake initial infections calculations is provided in Section K.3.4, in which site and population differences lead to placement of some results in different frequency categories under the larger exposure estimates for the MRF release quantities.

K.3.4 Earthquake Maximum Reasonably Foreseeable Release

This section is organized by pathogen. For each pathogen, the results from Chapter 4 and Appendix F detailing the MRF exposure estimates for the urban site are synthesized with the dose-response information from Appendix J. Next, the results from the calculations, uncertainty analysis, and sensitivity analysis described in Sections 2.3.3 to 2.3.5 are displayed. At the end of this section, the results for urban residents and the suburban and rural sites are summarized.

K.3.4.1 *Bacillus anthracis*

This section discusses the potential for initial infection and mortality with *B. anthracis* among members of the public after a MRF earthquake release. In Chapter 4, the estimated average exposure for an MEI, an individual located 30 m from the release point at the centerline of the simulated plume, was approximately 0.053 CFU for the urban site, and the estimates decrease steadily with distance away from the release, down to approximately 1×10^{-4} CFU at 1 km on the centerline. If it is assumed 1 CFU represents a single, potentially infectious bacterial cell, and under the assumption of Poisson-distributed

1 variability around the average dose, the MEI exposure estimate of 0.053 CFU can be interpreted to mean
2 that, for people very close to a release and in the path of the plume, the chance of inhaling one or more
3 cells of *B. anthracis* is, at most, about 5%. Further, this probability becomes significantly lower for
4 individuals located farther away.

5
6 As described in the dose-response appendix (Appendix J), there is no direct evidence that humans have
7 become infected after inhaling doses of *B. anthracis* on the order of 1 CFU. The lowest dose to which
8 nonhuman primates have succumbed in published experimental studies was about 200 CFU. However,
9 there is also no direct evidence that infection from inhaling very low doses is impossible, especially in a
10 heterogeneous population containing individuals who have respiratory health problems or are
11 immunocompromised. The dose-response models fit to the available data and to the expert estimates
12 reflect the possibility that low doses result in a non-zero probability of infection.

13
14 It is important to note that *B. anthracis* is the only pathogen examined in this RA for which there is a
15 documented historical example of a large-scale aerosol release from a biological research facility that
16 caused infections in members of the public downwind of the release point (the Sverdlovsk incident,
17 discussed in Appendix J). Certain aspects of the spatial and temporal distribution of the observed cases of
18 disease that resulted from the release were used to justify the assumed form of the literature-based dose-
19 response model described in Appendix J and applied here. However, the quantity of *B. anthracis* that was
20 released from the facility is not known and could have been much different than the stock inventory
21 estimates assumed for NEIDL. Therefore, there is a limited amount of inference that can be drawn from
22 the number of infections that occurred in Sverdlovsk to the number likely to occur in the scenarios
23 described here.

24 25 **Frequency of Initial Infections – Central Estimate**

26 The calculations described in Section K.2.3.3 were applied to the central estimate inputs described in
27 Section K.2.3.2.

Table K–54. Central estimate calculations for urban site earthquake MRF release of *B. anthracis*.

Number of initial infections/deaths (x)	Probability of x or more initial infections ($\mu_{\geq x}$) or deaths ($\delta_{\geq x}$) overall	Frequency of release leading to x or more initial infections or deaths ($\lambda_{\geq x}$)
Initial infections		
1 or more	5.3×10^{-5}	$5.3 \times 10^{-10}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
2 or more	1.4×10^{-9}	$1.4 \times 10^{-14}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
3 or more	2.5×10^{-14}	$2.5 \times 10^{-19}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
Deaths among initially infected		
1 or more	2.4×10^{-5}	$2.4 \times 10^{-10}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
2 or more	2.9×10^{-10}	$2.9 \times 10^{-15}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
3 or more	2.5×10^{-15}	$2.5 \times 10^{-20}/\text{year} = 1 \text{ in } > 10 \text{ million years}$

The results in Table K–54 show that the base-case estimate for the probability of one or more *B. anthracis* infections occurring, should a maximum earthquake release occur, is 5.3×10^{-5} , or roughly a 1-in-20,000 chance. This result, combined with the low estimated frequency of occurrence of a MRF earthquake release, leads to the frequency of occurrence of initial infections or deaths from *B. anthracis* being placed in the D frequency category.

Frequency of Initial Infections – Uncertainty

The uncertainty procedure described in Section K.2.3.4 was applied. Uncertainty ranges for each input parameter are described in Section K.2.3.2. The results, presented in Table K–55, display how many different input combinations (of 10,000) lead to a frequency estimate in each category. These results provide a sense of the uncertainty associated with estimating the frequency of a given event occurring.

Table K–55: Percentage of results for the frequency of maximum earthquake releases leading to the given number of initial infections or deaths for *B. anthracis*.

Dose-response estimate	Number of initial infections or deaths	A < 1 per yr > 1 per 100 yrs	B < 1 per 100 yrs > 1 per 10K yrs	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs
Initial infections					
Literature-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Expert-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Deaths among initially infected					
Literature-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Expert-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)

The results in Table K–55 show that all input combinations result in an estimated frequency of at least one infection occurring from an earthquake within the D frequency category. This means that even the most conservative dose-response estimates from the extremes of the either the literature-based or the expert-based models, combined with the most conservative estimate of earthquake frequency (once per 10,000 years), does not lead to an estimate of a return period less than 1 million years for the occurrence of an infection or mortality.

K.3.4.2 *Francisella tularensis*

This section discusses the potential for infection with *F. tularensis* among members of the public after an MRF earthquake release. In Chapter 4, the estimated average exposure for an MEI, an individual located 30 m from the release point at the centerline of the simulated plume, was approximately 0.0088 CFU for the urban site, and the estimates decrease steadily with distance away from the release, down to approximately 2×10^{-5} CFU at 1 km on the centerline. If it is assumed 1 CFU represents a single, potentially infectious bacterial cell, and under the assumption of Poisson-distributed variability around the average dose, the MEI exposure estimate of 0.0088 CFU can be interpreted to mean that, for people very close to a release and in the path of the plume, the chance of inhaling one or more cells of *F. tularensis* is,

at most, close to 1%, and this probability becomes significantly lower for individuals located farther away.

As described in the dose-response appendix (Appendix J), there exist published data from studies on human volunteers who inhaled doses of *F. tularensis* measured as low as 10 CFU and became infected. There is no direct evidence of humans being infected from inhaling doses on the order of 1 CFU, although the high rate of infection observed in the range of about 10 to 50 CFU suggests that infection at even lower doses might be possible, a notion that is reflected in the dose-response models derived in Appendix J.

Frequency of Initial Infections – Central estimate

The calculations described in Section K.2.3.3 were applied to the central estimate inputs described in Section K.2.3.2.

Table K–56. Central estimate calculations for urban site earthquake MRF release of *F. tularensis*.

Number of initial infections/deaths (x)	Probability of x or more initial infections ($\mu_{\geq x}$) or deaths ($\delta_{\geq x}$) overall	Frequency of release leading to x or more initial infections or deaths ($\lambda_{\geq x}$)
Initial infections		
1 or more	0.021	$2.1 \times 10^{-7}/\text{year} \approx 1$ in 5 million years
2 or more	2.3×10^{-4}	$2.3 \times 10^{-9}/\text{year} = 1$ in > 10 million years
3 or more	1.6×10^{-6}	$1.6 \times 10^{-11}/\text{year} = 1$ in > 10 million years
Deaths among initially infected		
1 or more	4.3×10^{-4}	$4.3 \times 10^{-9}/\text{year} = 1$ in > 10 million years
2 or more	9.2×10^{-8}	$9.2 \times 10^{-13}/\text{year} = 1$ in > 10 million years
3 or more	1.3×10^{-11}	$1.3 \times 10^{-16}/\text{year} = 1$ in > 10 million years

The results in Table K–56 show that the base-case estimate for the probability of one or more *F. tularensis* infections occurring, should an MRF earthquake release occur, is 0.021, or roughly a 1-in-10 chance. This result, combined with the central estimate estimated frequency of occurrence of an MRF

earthquake release, leads to the frequency of occurrence of one or more initial infections with *F. tularensis* being approximately once in five million years, which is in the D frequency category. A one-or-more death event would also be placed in the D frequency category.

Frequency of Initial Infections – Uncertainty

The uncertainty procedure described in Section K.2.3.4 was applied. Uncertainty ranges for each input parameter are described in Section K.2.3.2. The results, presented in Table K–57, display how many different input combinations (of 10,000) lead to a frequency estimate in each category. These results provide a sense of the uncertainty associated with estimating the frequency of a given event occurring.

Table K–57: Percentage of results for the frequency of maximum earthquake releases leading to the given number of initial infections for *F. tularensis*.

Dose-response estimate	Number of initial infections or deaths	A < 1 per year > 1 per 100 yrs	B < 1 per 100 yrs > 1 per 10K yrs	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs
Initial infections					
Literature-based	1 or more	0	0	1,760 (18%)	8,240 (82%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Expert-based	1 or more	0	0	196 (2%)	9,804 (98%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Deaths among initially infected					
Literature-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Expert-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)

The results in Table K–57 show that some input combinations result in an estimated frequency of at least one infection occurring from an earthquake within the C frequency category and others in the D frequency category. About 18% of the results using the literature-based dose-response estimates are placed in the C category, compared to only about 2% for results using the expert-based dose-response estimates. All results for the frequency of multiple infections and for mortalities are placed in the D frequency category.

K.3.4.3 *Yersinia pestis*

This section discusses the potential for infection with *Y. pestis* among members of the public after an MRF earthquake release. In Chapter 4, the estimated average exposure for an MEI, an individual located 30 m from the release point at the centerline of the simulated plume, was approximately 0.00044 CFU for the urban site, and the estimates decrease steadily with distance away from the release, down to approximately 1×10^{-6} CFU at 1 km on the centerline. If it is assumed 1 CFU represents a single, potentially infectious bacterial cell, and under the assumption of Poisson-distributed variability around the average dose, the MEI exposure estimate of 0.00044 CFU can be interpreted to mean that, for people very close to a release and in the path of the plume, the chance of inhaling one or more cells of *Y. pestis* is, at most, about 0.04% (about a one in 2000 chance), and this probability becomes significantly lower for individuals located farther away.

In the rare case of an individual potentially inhaling one cell of *Y. pestis*, the evidence described in the dose-response appendix (Appendix J) suggests low infectivity, as the lowest dose to which nonhuman primates succumbed to exposure in published data sets was in the range of 120–270 organisms, and several monkeys withstood exposure to both lower and higher doses. However, there is no direct evidence that infections resulting from very low inhaled doses are impossible, a notion that is reflected in the dose-response models derived in Appendix J, which generally estimate low but non-zero probabilities of infection at a dose of one organism.

Frequency of Initial Infections – Central Estimate

The calculations described in Section K.2.3.3 were applied to the central estimate inputs described in Section K.2.3.2.

Table K–58. Central estimate calculations for urban site earthquake MRF release of *Y. pestis*.

Number of initial infections/deaths (x)	Probability of x or more initial infections ($\mu_{\geq x}$) or deaths ($\delta_{\geq x}$) overall	Frequency of release leading to x or more initial infections or deaths ($\lambda_{\geq x}$)
Initial infections		
1 or more	1.4×10^{-6}	$1.4 \times 10^{-11}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
2 or more	9.5×10^{-13}	$9.5 \times 10^{-18}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
Deaths among initially infected		
1 or more	2.1×10^{-7}	$2.1 \times 10^{-12}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
2 or more	2.1×10^{-14}	$2.1 \times 10^{-19}/\text{year} = 1 \text{ in } > 10 \text{ million years}$

The results in Table K–58 show that the base-case estimate for the probability of one or more *Y. pestis* infections occurring, should an MRF earthquake release occur, is 4.8×10^{-5} , or roughly a 1-in-200,000 chance. This result, combined with the central estimate estimated frequency of occurrence of an MRF earthquake release, leads to the frequency of occurrence of one or more initial infections or deaths from *Y. pestis* being placed in the D frequency category.

Frequency of Initial Infections – Uncertainty

The uncertainty procedure described in Section K.2.3.4 was applied. Uncertainty ranges for each input parameter are described in Section K.2.3.2. The results, presented in Table K–59, display how many different input combinations (of 10,000) lead to a frequency estimate in each category. These results provide a sense of the uncertainty associated with estimating the frequency of a given event occurring.

Table K–59: Percentage of results for the frequency of maximum earthquake releases leading to the given number of initial infections for *Y. pestis*.

Dose-response estimate	Number of initial infections or deaths	A < 1 per year > 1 per 100 yrs	B < 1 per 100 yrs > 1 per 10K yrs	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs
Initial infections					
Literature-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Expert-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Deaths among initially infected					
Literature-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Expert-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)

The results in Table K–59 show that all input combinations for *Y. pestis* result in an estimated frequency of at least one infection or mortality occurring from an earthquake MRF release within the D frequency category.

K.3.4.4 1918 H1N1 influenza virus

This section discusses the potential for infection with 1918 H1N1V among members of the public after an MRF earthquake release. In Chapter 4, the estimated average exposure for an MEI, an individual located 30 m from the release point at the centerline of the simulated plume, was approximately 0.066 PFU for the urban site, and the estimates decrease steadily with distance away from the release, down to approximately 1×10^{-4} PFU at 1 km on the centerline. If it is assumed 1 PFU represents a single, potentially infectious unit, and under the assumption of Poisson-distributed variability around the average dose, the MEI exposure estimate of 0.066 PFU can be interpreted to mean that, for people very close to a release and in the path of the plume, the chance of inhaling one or more potentially infectious units of 1918 H1N1V is, at most, about 7%, and this probability becomes significantly lower for individuals located farther away.

As described in the dose-response appendix (Appendix J), there is no direct evidence that humans have become infected after inhaling doses of 1918 H1N1V on the order of 1 PFU. There are numerous data sets from human volunteers exposed to other strains of influenza virus, but in the vast majority of these studies, volunteers were exposed to high doses. One study reported outcomes from human volunteers exposed to low-dose aerosols of an H2N2 strain, concluding that unprotected individuals were infected by doses as low as 1 CCID₅₀. These data suggest that humans could potentially be infected by very low doses of influenza virus, considering that quantities of virus are generally similar or higher in units of CCID₅₀ compared to PFU. No literature-based dose-response estimate was derived for 1918 H1N1V. The expert-based dose-response range includes models that estimate greater than 1% probability of infection at an average inhaled dose of 1 PFU.

Frequency of Initial Infections – Central Estimate

The calculations described in Section K.2.3.3 were applied to the central estimate inputs described in Section K.2.3.2.

Table K–60. Central estimate calculations for urban site earthquake MRF release of 1918 H1N1V.

Number of initial infections/deaths (x)	Probability of x or more initial infections ($\mu_{\geq x}$) or deaths ($\delta_{\geq x}$) overall	Frequency of release leading to x or more initial infections or deaths ($\lambda_{\geq x}$)
Initial infections		
1 or more	4.5×10^{-4}	$4.5 \times 10^{-9}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
2 or more	1.0×10^{-7}	$1.0 \times 10^{-12}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
3 or more	1.6×10^{-11}	$1.6 \times 10^{-16}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
Deaths among initially infected		
1 or more	1.1×10^{-5}	$1.1 \times 10^{-10}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
2 or more	6.5×10^{-11}	$6.5 \times 10^{-16}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
3 or more	8.8×10^{-17}	$8.8 \times 10^{-22}/\text{year} = 1 \text{ in } > 10 \text{ million years}$

The results in Table K–60 show that the base-case estimate for the probability of one or more 1918 H1N1V infections occurring, should an MRF earthquake release occur, is 4.5×10^{-4} , or roughly a 1-in-

2000 chance. This result, combined with the central estimate estimated frequency of occurrence of an MRF earthquake release, leads to the frequency of occurrence of one or more initial infections or deaths from 1918 H1N1V being placed in the D frequency category.

Frequency of Initial Infections – Uncertainty

The uncertainty procedure described in Section K.2.3.4 was applied. Uncertainty ranges for each input parameter are described in Section K.2.3.2. The results, presented in Table K–61, display how many different input combinations (of 10,000) lead to a frequency estimate in each category. These results provide a sense of the uncertainty associated with estimating the frequency of a given event occurring.

Table K–61: Percentage of results for the frequency of maximum earthquake releases leading to the given number of initial infections for 1918 H1N1V.

Dose-response estimate	Number of initial infections or deaths	A < 1 per year > 1 per 100 yrs	B < 1 per 100 yrs > 1 per 10K yrs	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs
Initial infections					
Expert-based	1 or more	0	0	755 (8%)	9,245 (92%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Deaths among initially infected					
Expert-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)

The results in Table K–61 show that most input combinations result in an estimated frequency of at least one infection occurring from an earthquake MRF release within the D frequency category. About 8% of the estimates fall in the C frequency category. All results for the frequency of multiple infections and mortalities fall in the D frequency category.

K.3.4.5 SARS-associated coronavirus

This section discusses the potential for infection with SARS-CoV among members of the public after an MRF earthquake release. In Chapter 4, the estimated average exposure for an MEI, an individual located 30 m from the release point at the centerline of the simulated plume, was approximately 0.0066 PFU for the urban site, and the estimates decrease steadily with distance away from the release, down to approximately 1×10^{-5} PFU at 1 km on the centerline. If it is assumed 1 PFU represents a single, potentially infectious unit, and under the assumption of Poisson-distributed variability around the average

dose, the MEI exposure estimate of 0.0066 PFU can be interpreted to mean that, for people very close to a release and in the path of the plume, the chance of inhaling one or more potentially infectious units of SARS-CoV is less than 1%, and this probability becomes significantly lower for individuals located farther away.

As described in the dose-response appendix (Appendix J), there is no direct evidence that humans have become infected after inhaling doses of SARS-CoV on the order of 1 PFU. However, there are published experimental studies on viruses related to SARS-CoV in which individuals have been infected by low inhalational doses, including humans becoming infected by doses as low as 4 CCID₅₀, so it is possible that very low doses would result in a non-zero probability of infection, which is reflected in the dose-response models fit to the available data and to the expert estimates.

Frequency of Initial Infections – Central Estimate

The calculations described in Section K.2.3.3 were applied to the central estimate inputs described in Section K.2.3.2.

Table K–62. Central estimate calculations for urban site earthquake MRF release of SARS-CoV.

Number of initial infections/deaths (x)	Probability of x or more initial infections ($\mu_{\geq x}$) or deaths ($\delta_{\geq x}$) overall	Frequency of release leading to x or more initial infections or deaths ($\lambda_{\geq x}$)
Initial infections		
1 or more	6.3×10^{-4}	$6.3 \times 10^{-9}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
2 or more	2.0×10^{-7}	$2.0 \times 10^{-12}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
3 or more	4.1×10^{-11}	$4.1 \times 10^{-16}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
Deaths among initially infected		
1 or more	6.3×10^{-5}	$6.3 \times 10^{-10}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
2 or more	2.0×10^{-9}	$2.0 \times 10^{-14}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
3 or more	4.1×10^{-14}	$4.1 \times 10^{-19}/\text{year} = 1 \text{ in } > 10 \text{ million years}$

The results in Table K–63 show that the base-case estimate for the probability of one or more SARS-CoV infections occurring, should an MRF earthquake release occur, is 6.3×10^{-4} , or roughly a 1-in-2,000 chance. This result, combined with the central estimate estimated frequency of occurrence of an MRF earthquake release, leads to the frequency of occurrence of one or more initial infections or deaths from SARS-CoV being placed in the D frequency category.

Frequency of Initial Infections – Uncertainty

The uncertainty procedure described in Section K.2.3.4 was applied. Uncertainty ranges for each input parameter are described in Section K.2.3.2. The results, presented in Table K–64, display how many different input combinations (of 10,000) lead to a frequency estimate in each category. These results provide a sense of the uncertainty associated with estimating the frequency of a given event occurring.

Table K–64: Percentage of results for the frequency of maximum earthquake releases leading to the given number of initial infections for SARS-CoV.

Dose-response estimate	Number of initial infections or deaths	A < 1 per year > 1 per 100 yrs	B < 1 per 100 yrs > 1 per 10K yrs	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs
Initial infections					
Literature-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Expert-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Deaths among initially infected					
Literature-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Expert-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)

The results in Table K–64 show that all input combinations result in an estimated frequency of at least one infection or mortality from SARS-CoV occurring from an earthquake MRF release within the D frequency category.

K.3.4.6 Rift Valley fever virus

This section discusses the potential for infection with RVFV among members of the public after an MRF earthquake release. In Chapter 4, the estimated average exposure for an MEI, an individual located 30 m from the release point at the centerline of the simulated plume, was approximately 0.66 MICLD₅₀ (0.066 PFU) for the urban site. Further, the estimates decrease steadily with distance away from the release, down to approximately 1×10^{-3} MICLD₅₀ (1×10^{-4} PFU) at 1 km on the centerline.

As described in the dose-response appendix (Appendix J), there is no direct evidence that humans have become infected after inhaling low doses of RVFV. However, there are numerous published experimental studies on animal exposures to aerosols in which individuals have been infected by low inhalational doses near or less than the above estimated MEI exposure. Therefore, it is possible that doses in these ranges would result in a non-zero and potentially substantial probability of infection for humans, which is especially reflected in the literature-based dose-response models fit to the available data.

Frequency of Initial Infections – Central Estimate

The calculations described in Section K.2.3.3 were applied to the central estimate inputs described in Section K.2.3.2.

Table K–65. Central estimate calculations for urban site earthquake MRF release of RVFV.

Number of initial infections/deaths (x)	Probability of x or more initial infections ($\mu_{\geq x}$) or deaths ($\delta_{\geq x}$) overall	Frequency of release leading to x or more initial infections or deaths ($\lambda_{\geq x}$)
Initial infections		
1 or more	0.84	$8.4 \times 10^{-6}/\text{year} \approx 1 \text{ in } 100,000 \text{ years}$
2 or more	0.54	$5.4 \times 10^{-6}/\text{year} \approx 1 \text{ in } 200,000 \text{ years}$
3 or more	0.27	$4.6 \times 10^{-6}/\text{year} \approx 1 \text{ in } 400,000 \text{ years}$
4 or more	0.11	$1.1 \times 10^{-6}/\text{year} \approx 1 \text{ in } 900,000 \text{ years}$
5 or more	0.038	$3.8 \times 10^{-7}/\text{year} \approx 1 \text{ in } 3 \text{ million years}$
Deaths among initially infected		
1 or more	0.036	$3.6 \times 10^{-7}/\text{year} \approx 1 \text{ in } 3 \text{ million years}$
2 or more	6.4×10^{-4}	$6.4 \times 10^{-9}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
3 or more	7.8×10^{-6}	$7.8 \times 10^{-11}/\text{year} = 1 \text{ in } > 10 \text{ million years}$

The results in Table K–65 show that, should an MRF earthquake release occur, the base-case estimates state that there is about a 84% chance that 1 or more initial infections would occur within 1 km of the Boston site. This results in an estimated return period for a 1 or more infection event of just above 100,000 years, which was the assumed central estimate return period of the occurrence of the earthquake release itself. A 4-or-more infection event has an estimated return period of 900,000 years, which is also within the C frequency category, though a 5-or-more infection event would be placed in the D frequency category. The above results also reveal that the median number of infections expected under the central estimate inputs would be about two. Note that the annular ring-specific calculations for RVFV revealed an approximately 2% probability that at least one infection would occur in the annular ring farthest from the release source (between 900 and 1000 m); thus, including population at distances farther than 1 km would slightly increase the probabilities in Table K–65.

The estimated probability for one or more deaths from RVFV occurring after an MRF earthquake release is 0.036, or about a 1-in-30 chance. A one-or-more death event has an estimated return period of about 3 million years, which falls in the D frequency category.

Frequency of Initial Infections – Uncertainty

The uncertainty procedure described in Section K.2.3.4 was applied. Uncertainty ranges for each input parameter are described in Section K.2.3.2. The results, presented in Table K–66, display how many different input combinations (of 10,000) lead to a frequency estimate in each category. These results provide a sense of the uncertainty associated with estimating the frequency of a given event occurring. As described in the RVFV section of Appendix J, the exposures in units of MICLD₅₀ are applied to the literature-based dose-response estimates, and the exposures in units of PFU are applied to the expert-based dose-response estimates.

Table K–66: Percentage of results for the frequency of maximum earthquake releases leading to the given number of initial infections for RVFV.

Dose-response estimate	Number of initial infections or deaths	A < 1 per year > 1 per 100 yrs	B < 1 per 100 yrs > 1 per 10K yrs	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs
Initial infections					
Literature-based	1 or more	0	0	9,638 (96%)	362 (4%)
	2 or more	0	0	8,743 (87%)	1,257 (13%)
	3 or more	0	0	7,430 (74%)	2,570 (26%)
	4 or more	0	0	5,668 (57%)	4,332 (43%)
	5 or more	0	0	3,700 (37%)	6,300 (63%)
	10 or more	0	0	182 (2%)	9,818 (98%)
Expert-based	1 or more	0	0	355 (4%)	9,645 (96%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Deaths among initially infected					
Literature-based	1 or more	0	0	3,039 (30%)	6,961 (70%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Expert-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)

For estimates using the literature-based range of dose-response estimates, the results in Table K–66 show that about 87% of input combinations result in an estimated frequency of at least one infection occurring

from an earthquake MRF release within the C frequency category. The majority of results also fall in the C category for 2-, 3-, and 4-or-more infection events. The extreme $\approx 2\%$ of inputs result in 10-or-more infection events being placed in the C frequency category, with the rest falling in D frequency category. Overall, the median number of expected initial infections across all parameter combinations using the literature-based dose-response estimates was approximately two, and 95% of the estimates fell within the range 1–6 expected initial infections. For this set of results, about 30% of the estimates for frequency of one or more deaths fell in the C frequency category.

The estimates that use the expert-based dose-response models provide a different outcome, with only about 4% of the estimates resulting in a frequency of a 1-or-more infection release in the C category, and 100% in the D frequency category for a 1-or-more death release. The lower risk expert estimates may be more relevant if it is true that humans are significantly less susceptible to low-dose infection with RVFV than are the animals that formed the basis for the literature-based dose-response estimates.

K.3.4.7 Andes virus

This section discusses the potential for infection with ANDV among members of the public after an MRF earthquake release. In Chapter 4, the estimated average exposure for an MEI, an individual located 30 m from the release point at the centerline of the simulated plume, was approximately 6.6×10^{-4} CCID₅₀ for the urban site. The estimates decrease steadily with distance away from the release, down to approximately 1×10^{-6} CCID₅₀ at 1 km on the centerline.

As described in the dose-response appendix (Appendix J), there is no direct evidence that humans have become infected after inhaling low doses of ANDV. The lowest dose of ANDV that infected Syrian hamsters intra-nasally was about 20 PFU, which is presumed to be at least 30,000 times higher than the estimated MEI exposure scenario described above (i.e., the exposure estimates would likely be lower in PFU). However, data on low dose exposures are scarce, so it is possible that doses less than 1 CCID₅₀ could result in a low but non-zero probability of infection. This is reflected in the dose-response models fit to the available data and to the expert estimates.

Frequency of Initial Infections – Central Estimate

The calculations described in Section K.2.3.3 were applied to the central estimate inputs described in Section K.2.3.2.

Table K–67. Central estimate calculations for urban site earthquake MRF release of ANDV.

Number of initial infections/deaths (x)	Probability of x or more initial infections ($\mu_{\geq x}$) or deaths ($\delta_{\geq x}$) overall	Frequency of release leading to x or more initial infections or deaths ($\lambda_{\geq x}$)
Initial infections		
1 or more	2.8×10^{-4}	$2.8 \times 10^{-9}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
2 or more	3.9×10^{-8}	$3.9 \times 10^{-13}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
3 or more	3.7×10^{-12}	$3.7 \times 10^{-16}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
Deaths among initially infected		
1 or more	1.4×10^{-4}	$1.4 \times 10^{-9}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
2 or more	9.8×10^{-9}	$9.8 \times 10^{-14}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
3 or more	4.6×10^{-13}	$4.6 \times 10^{-18}/\text{year} = 1 \text{ in } > 110 \text{ million years}$

The results in Table K–67 show that the base-case estimate for the probability of one or more ANDV infections occurring, should an MRF earthquake release occur, is 2.8×10^{-4} , or roughly a 1-in-4,000 chance. This result, combined with the central estimate estimated frequency of occurrence of an MRF earthquake release, leads to the frequency of occurrence of one or more initial infections or deaths from ANDV and falls in the D frequency category.

Frequency of Initial Infections – Uncertainty

The uncertainty procedure described in Section K.2.3.4 was applied. Uncertainty ranges for each input parameter are described in Section K.2.3.2. The results, presented in Table K–68, display how many different input combinations (of 10,000) lead to a frequency estimate in each category. These results provide a sense of the uncertainty associated with estimating the frequency of a given event occurring.

Table K–68: Percentage of results for the frequency of maximum earthquake releases leading to the given number of initial infections for ANDV.

Dose-response estimate	Number of initial infections or deaths	A < 1 per year > 1 per 100 yrs	B < 1 per 100 yrs > 1 per 10K yrs	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs
Initial infections					
Literature-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Expert-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Deaths among initially infected					
Literature-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Expert-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)

The results in Table K–68 show that all input combinations result in an estimated frequency of at least one infection or death from ANDV occurring from an earthquake MRF release within the D frequency category.

K.3.4.8 Ebola virus

This section discusses the potential for infection with EBOV among members of the public after an MRF earthquake release. In Chapter 4, the estimated average exposure at the urban site for an MEI, an individual located 30 m from the release point at the centerline of the simulated plume, was approximately 0.033 CCID₅₀, which is equivalent to approximately 0.0027 PFU according to the units conversion factor cited in Appendix J. These estimates decrease steadily with distance away from the release, down to approximately 8×10^{-5} CCID₅₀ or 7×10^{-6} PFU at 1 km on the centerline. If it is assumed 1 PFU represents a single, potentially infectious unit, and under the assumption of Poisson-distributed variability around the average dose, the MEI exposure estimate of 0.0027 PFU can be interpreted to mean that for people very close to a release and in the path of the plume, the chance of inhaling one or more potentially infectious units of EBOV is, at most, about 0.3%. This probability becomes significantly lower for individuals located farther away.

As described in the dose-response appendix (Appendix J), there is no direct evidence that humans have become infected after inhaling low doses of EBOV on the order of 1 PFU. Among nonhuman primates in laboratory studies, a 100% infection rate has been observed for monkeys inhaling as low as 20 PFU. Infections were also observed for monkeys inhaling as low as 3.5 MICLD₅₀, which as discussed in Appendix J, was shown to be equivalent to approximately 1 PFU. Given these data, it is possible that individuals inhaling doses of EBOV amounting to about 1 PFU could become infected, and this is reflected in the dose-response models fit to the available data and to the expert estimates.

Frequency of Initial Infections – Central Estimate

The calculations described in Section K.2.3.3 were applied to the central estimate inputs described in Section K.2.3.2.

Table K–69. Central estimate calculations for urban site earthquake MRF release of EBOV.

Number of initial infections/deaths (x)	Probability of x or more initial infections ($\mu_{\geq x}$) or deaths ($\delta_{\geq x}$) overall	Frequency of release leading to x or more initial infections or deaths ($\lambda_{\geq x}$)
Initial infections		
1 or more	0.017	$1.7 \times 10^{-7}/\text{year} \approx 1 \text{ in } 6 \text{ million years}$
2 or more	1.5×10^{-4}	$1.5 \times 10^{-9}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
3 or more	8.3×10^{-7}	$8.3 \times 10^{-12}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
Deaths among initially infected		
1 or more	0.015	$1.5 \times 10^{-7}/\text{year} \approx 1 \text{ in } 7 \text{ million years}$
2 or more	1.2×10^{-4}	$1.2 \times 10^{-9}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
3 or more	6.1×10^{-7}	$6.1 \times 10^{-12}/\text{year} = 1 \text{ in } > 10 \text{ million years}$

The results in Table K–69 show that the base-case estimate for the probability of one or more EBOV infections occurring, should an MRF earthquake release occur, is 0.017, or roughly a 1-in-60 chance. This result, combined with the central estimate estimated frequency of occurrence of an MRF earthquake release, leads to the frequency of occurrence of one or more initial infections with EBOV being estimated at approximately once in 6 million years. This is in the D frequency category. The results for the

probability and frequency of deaths among those initially infected are similar because of the high case fatality rate of EBOV.

Frequency of Initial Infections – Uncertainty

The uncertainty procedure described in Section K.2.3.4 was applied. Uncertainty ranges for each input parameter are described in Section K.2.3.2. The results, presented in Table K–70, display how many different input combinations (of 10,000) lead to a frequency estimate in each category. These results provide a sense of the uncertainty associated with estimating the frequency of a given event occurring.

Table K–70: Percentage of results for the frequency of maximum earthquake releases leading to the given number of initial infections for EBOV.

Dose-response estimate	Number of initial infections or deaths	A < 1 per year > 1 per 100 yrs	B < 1 per 100 yrs > 1 per 10K yrs	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs
Initial infections					
Literature-based	1 or more	0	0	1,333 (13%)	8,667 (87%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Expert-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Deaths among initially infected					
Literature-based	1 or more	0	0	1,098 (11%)	8,902 (89%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Expert-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)

For estimates using the literature-based range of dose-response estimates, the results in Table K–70 show that the majority of input combinations result in an estimated frequency of at least one infection or death occurring from an earthquake MRF release within the D frequency category. However, about 13% of results for infections and 11% for deaths fall in the C frequency category.

The estimates that use the expert-based dose-response models produced no results for the frequency of a 1-or-more infection release in the C frequency category. The lower risk expert estimates may be more relevant if it is true that humans are significantly less susceptible to low-dose infection with EBOV than are the nonhuman primates that formed the basis for the literature-based dose-response estimates.

K.3.4.9 Marburg virus

This section discusses the potential for infection with MARV among members of the public after an MRF earthquake release. In Chapter 4, the estimated average exposure at the urban site for an MEI, an individual located 30 m from the release point at the centerline of the simulated plume, was approximately 0.0066 CCID₅₀. This is equivalent to approximately 5.5×10^{-4} PFU according to the units conversion factor cited in Appendix J, and the estimates decrease steadily with distance away from the release, down to approximately 1×10^{-5} CCID₅₀ or 1×10^{-6} PFU at 1 km on the centerline. If it is assumed 1 PFU represents a single, potentially infectious unit, and under the assumption of Poisson-distributed variability around the average dose, the MEI exposure estimate of 5.5×10^{-4} PFU can be interpreted to mean that for people very close to a release and in the path of the plume, the chance of inhaling one or more potentially infectious units of MARV is, at most, about 0.05% (1-in-2,000 chance). Again, this probability becomes significantly lower for individuals located farther away.

As described in the dose-response appendix (Appendix J), there is no direct evidence that humans have become infected after inhaling low doses of MARV on the order of 1 PFU. Among nonhuman primates in laboratory studies, inhaled doses as low as 2 PFU and possibly lower have caused infection. Given these data, it is possible that individuals inhaling doses of MARV amounting to about 1 PFU could become infected, and this is reflected in the dose-response models fit to the available data and to the expert estimates.

Frequency of Initial Infections – Central Estimate

The calculations described in Section K.2.3.3 were applied to the central estimate inputs described in Section K.2.3.2.

Table K–71. Central estimate calculations for urban site earthquake MRF release of MARV.

Number of initial infections/deaths (x)	Probability of x or more initial infections ($\mu_{\geq x}$) or deaths ($\delta_{\geq x}$) overall	Frequency of release leading to x or more initial infections or deaths ($\lambda_{\geq x}$)
Initial infections		
1 or more	0.0034	$3.4 \times 10^{-8}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
2 or more	5.9×10^{-6}	$5.9 \times 10^{-11}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
3 or more	6.7×10^{-9}	$6.7 \times 10^{-14}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
Deaths among initially infected		
1 or more	0.0034	$3.4 \times 10^{-8}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
2 or more	5.9×10^{-6}	$5.9 \times 10^{-11}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
3 or more	6.7×10^{-9}	$6.7 \times 10^{-14}/\text{year} = 1 \text{ in } > 10 \text{ million years}$

The results in Table K–71 show that the base-case estimate for the probability of one or more MARV infections occurring, should an MRF earthquake release occur, is 0.0034, or roughly a 1-in-300 chance. This result, combined with the central estimate estimated frequency of occurrence of an MRF earthquake release, leads to the frequency of occurrence of one or more initial infections or deaths from MARV being placed in the D frequency category.

Frequency of Initial Infections – Uncertainty

The uncertainty procedure described in Section K.2.3.4 was applied. Uncertainty ranges for each input parameter are described in Section K.2.3.2. The results, presented in Table K–72, display how many different input combinations (of 10,000) lead to a frequency estimate in each category. These results provide a sense of the uncertainty associated with estimating the frequency of a given event occurring.

Table K–72: Percentage of results for the frequency of maximum earthquake releases leading to the given number of initial infections for MARV.

Dose-response estimate	Number of initial infections or deaths	A < 1 per year > 1 per 100 yrs	B < 1 per 100 yrs > 1 per 10K yrs	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs
Initial infections					
Literature-based	1 or more	0	0	4 (< 0.1%)	9,996 (> 99.9%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Expert-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Deaths among initially infected					
Literature-based	1 or more	0	0	4 (< 0.1%)	9,996 (> 99.9%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Expert-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)

For estimates using the literature-based range of dose-response estimates, the results in Table K–72 show that only 4 of 10,000 input combinations result in an estimated frequency of at least one infection or death occurring from an MRF release earthquake within the C frequency category. The estimates that use the expert-based dose-response models result in none of the estimates resulting in a frequency of a 1-or-more infection release in the C category.

K.3.4.10 Lassa virus

This section discusses the potential for infection with LASV among members of the public after an MRF earthquake release. In Chapter 4, the estimated average exposure at the urban site for an MEI, an individual located 30 m from the release point at the centerline of the simulated plume, was approximately 0.0066 PFU. These estimates decrease steadily with distance away from the release, down to approximately 1×10^{-5} PFU at 1 km on the centerline. If it is assumed 1 PFU represents a single, potentially infectious unit, and under the assumption of Poisson-distributed variability around the average dose, the MEI exposure estimate of 0.0066 PFU can be interpreted to mean that for people very close to a release and in the path of the plume, the chance of inhaling one or more potentially infectious units of LASV is less than 1%. Further, this probability becomes significantly lower for individuals located farther away.

As described in the dose-response appendix (Appendix J), there is no direct evidence that humans have become infected after inhaling low doses of LASV on the order of 1 PFU. In laboratory experiments, guinea pigs have become infected after inhaling doses as low as 5 PFU. Given these limited data, the possibility that individuals inhaling doses of LASV amounting to about 1 PFU could become infected cannot be ruled out. This is reflected in the dose-response models fit to the available data and to the expert estimates.

Frequency of Initial Infections – Central Estimate

The calculations described in Section K.2.3.3 were applied to the central estimate inputs described in Section K.2.3.2.

Table K–73. Central estimate calculations for urban site earthquake MRF release of LASV.

Number of initial infections/deaths (x)	Probability of x or more initial infections ($\mu_{\geq x}$) or deaths ($\delta_{\geq x}$) overall	Frequency of release leading to x or more initial infections or deaths ($\lambda_{\geq x}$)
Initial infections		
1 or more	0.010	$1.0 \times 10^{-7}/\text{year} \approx 1$ in 10 million years
2 or more	5.0×10^{-5}	$5.0 \times 10^{-10}/\text{year} = 1$ in > 10 million years
3 or more	1.7×10^{-7}	$1.7 \times 10^{-12}/\text{year} = 1$ in > 10 million years
Deaths among initially infected		
1 or more	2.0×10^{-4}	$2.0 \times 10^{-9}/\text{year} = 1$ in > 10 million years
2 or more	2.0×10^{-8}	$5.0 \times 10^{-13}/\text{year} = 1$ in > 10 million years
3 or more	1.3×10^{-12}	$1.7 \times 10^{-17}/\text{year} = 1$ in > 10 million years

The results in Table K–73 show that the base-case estimate for the probability of one or more LASV infections occurring, should an MRF earthquake release occur, is 0.010—or roughly a 1-in-100 chance. This result, combined with the central estimate estimated frequency of occurrence of an MRF earthquake release, leads to the frequency of occurrence of one or more initial infections with LASV being estimated at approximately once in 10 million years. This falls in the D frequency category. The frequency of one or more deaths from LASV would also be placed in the category D.

Frequency of Initial Infections – Uncertainty

The uncertainty procedure described in Section K.2.3.4 was applied. Uncertainty ranges for each input parameter are described in Section K.2.3.2. The results, presented in Table K–74, display how many different input combinations (of 10,000) lead to a frequency estimate in each category. These results provide a sense of the uncertainty associated with estimating the frequency of a given event occurring.

Table K–74: Percentage of results for the frequency of maximum earthquake releases leading to the given number of initial infections for LASV.

Dose-response estimate	Number of initial infections or deaths	A < 1 per year > 1 per 100 yrs	B < 1 per 100 yrs > 1 per 10K yrs	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs
Initial infections					
Literature-based	1 or more	0	0	382 (4%)	9,618 (96%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Expert-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Deaths among initially infected					
Literature-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Expert-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)

The results in Table K–74 show that all input combinations result in an estimated frequency of at least one infection or death from LASV occurring from an earthquake MRF release within the D frequency category, except for about 4% of the estimates for infection that use the literature-based dose-response models.

K.3.4.11 Junin virus

This section discusses the potential for infection with JUNV among members of the public after an MRF earthquake release. In Chapter 4, the estimated average exposure for an MEI, an individual located 30m from the release point at the centerline of the simulated plume, was approximately 0.0066 PFU for the urban site. The estimates decrease steadily with distance away from the release, down to approximately 1×10^{-5} PFU at 1 km on the centerline. If it is assumed 1 PFU represents a single, potentially infectious unit, and under the assumption of Poisson-distributed variability around the average dose, the MEI exposure estimate of 0.0066 PFU can be interpreted to mean that for people very close to a release and in

the path of the plume, the chance of inhaling one or more potentially infectious units of JUNV is less than 1%. This probability becomes significantly lower for individuals located farther away.

As described in the dose-response appendix (Appendix J), there is no direct evidence that humans have become infected after inhaling doses of JUNV on the order of 1 PFU. Laboratory nonhuman primates have been infected by doses as low as 32 PFU, and the possibility that even lower doses might also be infective cannot be ruled out in the absence of further data. No literature-based dose-response estimate was derived for JUNV. The expert-based dose-response range includes models that estimate small but non-zero probabilities of infection at an average inhaled dose of 1PFU.

Frequency of Initial Infections – Central Estimate

The calculations described in Section K.2.3.3 were applied to the central estimate inputs described in Section K.2.3.2.

Table K–75. Central estimate calculations for urban site earthquake MRF release of JUNV.

Number of initial infections/deaths (x)	Probability of x or more initial infections ($\mu_{\geq x}$) or deaths ($\delta_{\geq x}$) overall	Frequency of release leading to x or more initial infections or deaths ($\lambda_{\geq x}$)
Initial infections		
1 or more	0.0018	$1.8 \times 10^{-8}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
2 or more	1.6×10^{-6}	$1.6 \times 10^{-11}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
3 or more	9.2×10^{-10}	$9.2 \times 10^{-13}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
Deaths among initially infected		
1 or more	1.8×10^{-5}	$1.8 \times 10^{-10}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
2 or more	1.6×10^{-10}	$1.6 \times 10^{-15}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
3 or more	7.5×10^{-16}	$9.2 \times 10^{-21}/\text{year} = 1 \text{ in } > 10 \text{ million years}$

The results in Table K–75 show that the base-case estimate for the probability of one or more JUNV infections occurring, should an MRF earthquake release occur, is 0.0018, or roughly a 1-in-600 chance. This result, combined with the central estimate estimated frequency of occurrence of an MRF earthquake

release, leads to the frequency of occurrence of one or more initial infections or deaths from JUNV being placed in the D frequency category.

Frequency of Initial Infections – Uncertainty

The uncertainty procedure described in Section K.2.3.4 was applied. Uncertainty ranges for each input parameter are described in Section K.2.3.2. The results, presented in Table K–76, display how many different input combinations (of 10,000) lead to a frequency estimate in each category. These results provide a sense of the uncertainty associated with estimating the frequency of a given event occurring.

Table K–76: Percentage of results for the frequency of maximum earthquake releases leading to the given number of initial infections for JUNV.

Dose-response estimate	Number of initial infections or deaths	A < 1 per year > 1 per 100 yrs	B < 1 per 100 yrs > 1 per 10K yrs	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs
Initial infections					
Expert-based	1 or more	0	0	58 (1%)	9,942 (99%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Deaths among initially infected					
Expert-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)

The results in Table K–76 show that all input combinations result in an estimated frequency of at least one infection or death occurring from an earthquake MRF release within the D frequency category, except for about 1% of the estimates for infection that fall in the C frequency category. All results for the frequency of the occurrence of multiple infections and for mortalities fall in the D frequency category.

K.3.4.12 Tick-borne encephalitis virus, Far Eastern subtype

This section discusses the potential for infection with TBEV-FE among members of the public after an MRF earthquake release. In Chapter 4, the estimated average exposure for an MEI, an individual located 30 m from the release point at the centerline of the simulated plume, was approximately 0.066 MID₅₀ for the urban site, and the estimates decrease steadily with distance away from the release, down to approximately 1×10^{-4} MID₅₀ at 1 km on the centerline. As stated and explained in Appendix J, it is conservatively assumed that exposure estimates in units of MID₅₀ can be applied to dose-response estimates that are in units of PFU for TBEV-FE. If it is assumed 1 PFU represents a single, potentially infectious unit, and under the assumption of Poisson-distributed variability around the average dose, an

MEI exposure estimate of 0.066 PFU can be interpreted to mean that, for people very close to a release and in the path of the plume, the chance of inhaling one or more potentially infectious units of TBEV-FE is, at most, about 7%, and this probability becomes significantly lower for individuals located farther away.

As described in the dose-response appendix (Appendix J), there is no direct evidence that humans have become infected after inhaling doses of TBEV-FE on the order of 1 PFU. No low-dose inhalational animal data were found in the literature, so no literature-based dose-response estimate was derived for TBEV-FE. The expert-based dose-response range includes models that estimate small but non-zero probabilities of infection at an average inhaled dose of 1PFU.

Frequency of Initial Infections – Central Estimate

The calculations described in Section K.2.3.3 were applied to the central estimate inputs described in Section K.2.3.2.

Table K–77. Central estimate calculations for urban site earthquake MRF release of TBEV-FE.

Number of initial infections/deaths (x)	Probability of x or more initial infections ($\mu_{\geq x}$) or deaths ($\delta_{\geq x}$) overall	Frequency of release leading to x or more initial infections or deaths ($\lambda_{\geq x}$)
Initial infections		
1 or more	2.5×10^{-5}	$2.5 \times 10^{-10}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
2 or more	3.0×10^{-10}	$3.0 \times 10^{-15}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
3 or more	2.5×10^{-15}	$2.5 \times 10^{-20}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
Deaths among initially infected		
1 or more	9.8×10^{-6}	$9.8 \times 10^{-11}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
2 or more	4.8×10^{-11}	$4.8 \times 10^{-16}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
3 or more	2.6×10^{-16}	$2.6 \times 10^{-21}/\text{year} = 1 \text{ in } > 10 \text{ million years}$

The results in Table K–77 show that the base-case estimate for the probability of one or more TBEV-FE infections occurring, should an MRF earthquake release occur, is 2.5×10^{-5} , or roughly a 1-in-40,000

chance. This result, combined with the central estimate estimated frequency of occurrence of an MRF earthquake release, leads to the frequency of occurrence of one or more initial infections or deaths from TBEV-FE being placed in the D frequency category.

Frequency of Initial Infections – Uncertainty

The uncertainty procedure described in Section K.2.3.4 was applied. Uncertainty ranges for each input parameter are described in Section K.2.3.2. The results, presented in Table K–78, display how many different input combinations (of 10,000) lead to a frequency estimate in each category. These results provide a sense of the uncertainty associated with estimating the frequency of a given event occurring.

Table K–78: Percentage of results for the frequency of maximum earthquake releases leading to the given number of initial infections for TBEV-FE.

Dose-response estimate	Number of initial infections or deaths	A < 1 per year > 1 per 100 yrs	B < 1 per 100 yrs > 1 per 10K yrs	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs
Initial infections					
Expert-based	1 or more	0	0	412 (4%)	9,588 (96%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Deaths among initially infected					
Expert-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)

The results in Table K–78 show that all input combinations result in an estimated frequency of at least one infection occurring from an earthquake within the D frequency category, except for about 4% of the estimates that fall in the C frequency category. All results for the frequency of the occurrence of multiple infections and for mortalities fell in the D frequency category.

K.3.4.13 Nipah virus

This section discusses the potential for infection with NIPV among members of the public after an MRF earthquake release. In Chapter 4, the estimated average exposure for an MEI, an individual located 30 m from the release point at the centerline of the simulated plume, was approximately 0.013 CCID₅₀ or PFU for the urban site, and the estimates decrease steadily with distance away from the release, down to approximately 3×10^{-5} CCID₅₀ or PFU at 1 km on the centerline.

As described in the dose-response appendix (Appendix J), there is no direct evidence that humans have become infected after inhaling low doses of NIPV. The lowest dose of NIPV that infected ferrets by the oral-nasal route of exposure was about 500 CCID₅₀. Because low-dose exposure data are scarce, it is possible that much lower doses could result in a low but non-zero probability of infection. This is reflected in the dose-response models fit to the available data and to the expert estimates.

Frequency of Initial Infections – Central Estimate

The calculations described in Section K.2.3.3 were applied to the central estimate inputs described in Section K.2.3.2.

Table K–79. Central estimate calculations for urban site earthquake MRF release of NIPV.

Number of initial infections/deaths (x)	Probability of x or more initial infections ($\mu_{\geq x}$) or deaths ($\delta_{\geq x}$) overall	Frequency of release leading to x or more initial infections or deaths ($\lambda_{\geq x}$)
Initial infections		
1 or more	6.5×10^{-4}	$6.5 \times 10^{-9}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
2 or more	2.1×10^{-7}	$2.1 \times 10^{-12}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
3 or more	4.5×10^{-11}	$4.5 \times 10^{-16}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
Deaths among initially infected		
1 or more	4.5×10^{-4}	$4.5 \times 10^{-9}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
2 or more	1.0×10^{-7}	$1.1 \times 10^{-12}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
3 or more	1.5×10^{-11}	$1.5 \times 10^{-16}/\text{year} = 1 \text{ in } > 10 \text{ million years}$

The results in Table K–79 show that the base-case estimate for the probability of one or more NIPV infections occurring, should an MRF earthquake release occur, is 6.5×10^{-4} , or roughly a 1-in-2,000 chance. This result, combined with the central estimate estimated frequency of occurrence of an MRF earthquake release, leads to the frequency of occurrence of one or more initial infections or deaths from NIPV being placed in the D frequency category.

Frequency of Initial Infections – Uncertainty

The uncertainty procedure described in Section K.2.3.4 was applied. Uncertainty ranges for each input parameter are described in Section K.2.3.2. The results, presented in Table K–80, display how many different input combinations (of 10,000) lead to a frequency estimate in each category. These results provide a sense of the uncertainty associated with estimating the frequency of a given event occurring.

Table K–80: Percentage of results for the frequency of maximum earthquake releases leading to the given number of initial infections for NIPV.

Dose-response estimate	Number of initial infections or deaths	A < 1 per year > 1 per 100 yrs	B < 1 per 100 yrs > 1 per 10K yrs	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs
Initial infections					
Literature-based	1 or more	0	0	31 (< 1%)	9,969 (> 99%)
	2 or more	0	0	12 (< 1%)	9,988 (> 99%)
	3 or more	0	0	0	10,000 (100%)
Expert-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)
Deaths among initially infected					
Literature-based	1 or more	0	0	27 (< 1%)	9,973 (> 99%)
	2 or more	0	0	6 (< 0.1%)	9,994 (> 99.9%)
	3 or more	0	0	0	10,000 (100%)
Expert-based	1 or more	0	0	0	10,000 (100%)
	2 or more	0	0	0	10,000 (100%)
	3 or more	0	0	0	10,000 (100%)

The results in Table K–80 show that all input combinations result in an estimated frequency of at least one infection occurring from an earthquake MRF release within the D frequency category, except for a small percentage (< 1%) of the results from the estimates that use the literature-based dose-response estimates, which fall in the C frequency category. The results for the frequency of mortalities are similar.

K.3.4.14 Results summary – urban site

This section summarizes the results from Sections K.3.4.1–K.3.4.13. The base-case example results are shown in Tables K–81 and K–82, while the uncertainty results are shown in Tables K–83 and K–84.

Table K–81. Central estimate initial infection and mortality results for urban MRF earthquake release, BSL-3 pathogens.

Pathogen	Number of initial infections/deaths (x)	Probability of x or more initial infections ($\mu_{\geq x}$) or deaths ($\delta_{\geq x}$) overall	Frequency of release leading to x or more initial infections or deaths ($\lambda_{\geq x}$)
Initial infections			
<i>B. anthracis</i>	1 or more	5.3×10^{-5}	$5.3 \times 10^{-10}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
<i>F. tularensis</i>	1 or more	2.1×10^{-2}	$2.1 \times 10^{-7}/\text{year} \approx 1 \text{ in } 5 \text{ million years}$

K.3.4.15 Results summary – urban residents

The results summarized in the previous section were calculated using the overall estimated urban population including estimates of area residents as well as daytime students, workers, hospital patients, and passersby in a 1km radius. Another set of results was calculated for population inputs restricted to estimates of the resident population only. The base-case example results are shown in Tables K–85 and K–86, while the uncertainty results are shown in Tables K–87 and K–88.

Table K-85. Central estimate initial infection and mortality results among urban residents for MRF earthquake release, BSL-3 pathogens.

Pathogen	Number of initial infections/deaths (x)	Probability of x or more initial infections ($\mu_{\geq x}$) or deaths ($\delta_{\geq x}$) overall	Frequency of release leading to x or more initial infections or deaths ($\lambda_{\geq x}$)
Initial infections			
<i>B. anthracis</i>	1 or more	8.7×10^{-6}	$2.4 \times 10^{-10}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
<i>F. tularensis</i>	1 or more	3.5×10^{-3}	$9.7 \times 10^{-8}/\text{year} \approx 1 \text{ in } 10 \text{ million years}$
<i>Y. pestis</i>	1 or more	2.3×10^{-7}	$6.3 \times 10^{-12}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
1918 H1N1V	1 or more	2.1×10^{-6}	$3.1 \times 10^{-9}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
SARS-CoV	1 or more	1.0×10^{-4}	$9.5 \times 10^{-9}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
RVFV	1 or more	0.26	$2.6 \times 10^{-6}/\text{year} \approx 1 \text{ in } 400,000 \text{ years}$
	2 or more	0.037	$3.7 \times 10^{-7}/\text{year} \approx 1 \text{ in } 3 \text{ million years}$
ANDV	1 or more	4.6×10^{-5}	$4.6 \times 10^{-10}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
Deaths among initially infected			
<i>B. anthracis</i>	1 or more	3.9×10^{-6}	$3.9 \times 10^{-11}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
<i>F. tularensis</i>	1 or more	7.0×10^{-5}	$7.0 \times 10^{-10}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
<i>Y. pestis</i>	1 or more	3.4×10^{-8}	$3.4 \times 10^{-13}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
1918 H1N1V	1 or more	5.2×10^{-8}	$5.2 \times 10^{-13}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
SARS-CoV	1 or more	1.0×10^{-5}	$1.0 \times 10^{-10}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
RVFV	1 or more	6.0×10^{-3}	$6.0 \times 10^{-8}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
ANDV	1 or more	2.3×10^{-5}	$2.3 \times 10^{-10}/\text{year} = 1 \text{ in } > 10 \text{ million years}$

Under the base-case inputs, an earthquake MRF release resulting in one or more infections among urban residents would be placed in the D frequency category for every BSL-3 pathogen except for RVFV. It is estimated that one or more RVFV infections among residents would occur with about 26% probability

given a MRF release. A MRF release resulting in multiple RFVF infections among residents would be placed in the D frequency category.

Table K–86. Central estimate initial infection and mortality results among urban residents for MRF earthquake release, BSL-4 pathogens.

Pathogen	Number of initial infections/deaths (x)	Probability of x or more initial infections ($\mu_{\geq x}$) or deaths ($\delta_{\geq x}$) overall	Frequency of release leading to x or more initial infections or deaths ($\lambda_{\geq x}$)
Initial infections			
EBOV	1 or more	2.8×10^{-3}	$2.8 \times 10^{-8}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
MARV	1 or more	5.6×10^{-4}	$5.6 \times 10^{-9}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
LASV	1 or more	1.6×10^{-3}	$1.6 \times 10^{-8}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
JUNV	1 or more	2.9×10^{-4}	$2.9 \times 10^{-9}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
TBEV-FE	1 or more	4.8×10^{-9}	$4.8 \times 10^{-14}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
NIPV	1 or more	1.1×10^{-4}	$1.1 \times 10^{-9}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
Deaths among initially infected			
EBOV	1 or more	2.5×10^{-3}	$2.5 \times 10^{-8}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
MARV	1 or more	5.6×10^{-4}	$5.6 \times 10^{-9}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
LASV	1 or more	3.3×10^{-5}	$3.3 \times 10^{-10}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
JUNV	1 or more	2.9×10^{-6}	$2.9 \times 10^{-11}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
TBEV-FE	1 or more	1.9×10^{-9}	$1.9 \times 10^{-14}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
NIPV	1 or more	7.4×10^{-5}	$7.4 \times 10^{-10}/\text{year} = 1 \text{ in } > 10 \text{ million years}$

Under the base-case inputs, an earthquake MRF release resulting in one or more infections among urban residents would be placed in the D frequency category for every BSL-4 pathogen. The highest estimated probabilities are for EBOV and LASV, for which it is estimated that one or more infections among residents would occur with about 0.2% or 0.3% probability given a MRF release. Combined with the central estimate estimated frequency of the earthquake release (once per 100,000 years), these

probabilities result in an estimated return period for releases leading to infection among residents greater than ten million years.

Table K–87: Summary of uncertainty results for BSL-3 pathogens (MRF release, urban residents).

Pathogen	Dose-response estimate	Number of initial infections	A < 1 per year > 1 per 100 yrs	B < 1 per 100 yrs > 1 per 10K yrs	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs

1918 H1N1V	Expert	1 or more	0	0	0	10,000 (100%)
SARS-CoV	Both	1 or more	0	0	0	10,000 (100%)
RVFV	Literature	1 or more	0	0	94 (1%)	9,906 (99%)
	Expert	1 or more	0	0	0	10,000 (100%)
ANDV	Both	1 or more	0	0	0	10,000 (100%)

The uncertainty analysis reveals that, except for RVFV under the literature-based dose-response estimates, the majority of input combinations place the frequency of one or more infections with BSL-3 pathogens among urban residents in the D frequency category. The extreme 2.43% of input combinations for *F. tularensis* using the literature-based models fell in the C frequency category, while 10.61% of 1918 H1N1V inputs fell in the C frequency category. For RVFV, the median number of infections among urban residents expected across all input combinations using the literature based model was about 3, with 95% of estimates falling between about 1 and 9 infections. However, the expert-based dose-response models lead to D frequency category for even one RVFV infection among urban residents.

Table K–88: Summary of uncertainty results for BSL-4 pathogens (MRF release, urban residents).

Pathogen	Dose-response estimate	Number of initial infections	A < 1 per year > 1 per 100 yrs	B < 1 per 100 yrs > 1 per 10K yrs	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs
Initial infections						
EBOV	Literature	1 or more	0	0	2 (< 0.1%)	9,998 (> 99.9%)
	Expert	1 or more	0	0	0	10,000 (100%)
MARV	Both	1 or more	0	0	0	10,000 (100%)
LASV	Both	1 or more	0	0	0	10,000 (100%)
JUNV	Expert	1 or more	0	0	0	10,000 (100%)
TBEV-FE	Expert	1 or more	0	0	0	10,000 (100%)
NIPV	Literature	1 or more	0	0	14 (0.1%)	9,986 (99.9%)
	Expert	1 or more	0	0	0	100%
Deaths among initially infected						
EBOV	Both	1 or more	0	0	0	10,000 (100%)
MARV	Both	1 or more	0	0	0	10,000 (100%)
LASV	Both	1 or more	0	0	0	10,000 (100%)
JUNV	Expert	1 or more	0	0	0	10,000 (100%)
TBEV-FE	Expert	1 or more	0	0	0	10,000 (100%)
NIPV	Literature	1 or more	0	0	10 (0.1%)	9,990 (99.9%)
	Expert	1 or more	0	0	0	10,000 (100%)

The uncertainty analysis reveals that the majority of input combinations place the frequency of one or more infections or deaths with BSL-4 pathogens among urban residents in the D frequency category. Very few input combinations (0.1% or less) for EBOV and NIPV using the literature-based model fell in the C frequency category.

K.3.4.16 Results summary – suburban site

Another set of results was calculated for exposure and population inputs from estimates based on characteristic of the suburban site (see Chapter 4 and Appendix F). The base-case example results are shown in Tables K–89 and K–90, while the uncertainty results are shown in Table K–91.

Table K–89. Central estimate initial infection and mortality results at suburban site for MRF earthquake release, BSL-3 pathogens.

Pathogen	Number of initial infections/deaths (x)	Probability of x or more initial infections ($\mu_{\geq x}$) or deaths ($\delta_{\geq x}$) overall	Frequency of release leading to x or more initial infections or deaths ($\lambda_{\geq x}$)
Initial infections			
<i>B. anthracis</i>	1 or more	1.1×10^{-6}	$1.1 \times 10^{-11}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
<i>F. tularensis</i>	1 or more	4.6×10^{-4}	$4.6 \times 10^{-9}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
<i>Y. pestis</i>	1 or more	3.0×10^{-8}	$3.0 \times 10^{-13}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
1918 H1N1V	1 or more	1.6×10^{-7}	$1.6 \times 10^{-12}/\text{year} = 1 \text{ in } > 10 \text{ million years}$

JUNV	1 or more	3.8×10^{-5}	$3.8 \times 10^{-10}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
TBEV-FE	1 or more	2.6×10^{-6}	$2.6 \times 10^{-11}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
NIPV	1 or more	1.4×10^{-5}	$1.4 \times 10^{-10}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
Deaths among initially infected			
EBOV	1 or more	3.3×10^{-4}	$3.3 \times 10^{-9}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
MARV	1 or more	7.4×10^{-5}	$7.4 \times 10^{-10}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
LASV	1 or more	4.3×10^{-6}	$4.3 \times 10^{-11}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
JUNV	1 or more	3.8×10^{-7}	$3.8 \times 10^{-12}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
TBEV-FE	1 or more	1.0×10^{-6}	$1.0 \times 10^{-11}/\text{year} = 1 \text{ in } > 10 \text{ million years}$
NIPV	1 or more	9.7×10^{-6}	$9.7 \times 10^{-11}/\text{year} = 1 \text{ in } > 10 \text{ million years}$

For the central estimate example, all pathogens are estimated to produce a low probability that one or more infections occur among members of the public at the suburban site. The highest estimated probability is for RVFV (3.8×10^{-2}), which is about a 1-in-30 chance. Combined with the central estimate estimated frequency of the occurrence of an earthquake release (once in 100,000 years), the frequency of an earthquake MRF release resulting in one or more infections of any pathogen at the suburban site is estimated to be in the D frequency category.

Table K-91: Summary of uncertainty results for initial infections and deaths (MRF release, suburban site).

Pathogen	Dose-response estimates	Number of initial infections	A < 1 per year > 1 per 100 yrs	B < 1 per 100 yrs > 1 per 10K yrs	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs

The uncertainty results in the rows labeled *Both* apply for estimates using both the literature-based and the expert-based range of dose-response estimates. Every combination of dose-response estimates and earthquake release frequency estimates results in an estimated frequency of at least one initial infection at the suburban site in frequency category D, except for about 32% of the estimates using the literature-based dose-response models for RVFV.

K.3.4.17 Results summary – rural site

Another set of results was calculated for exposure and population inputs from estimates based on characteristic of the suburban site (see Chapter 4 and Appendix F). The base-case example results are shown in Tables K–92 and K–93, while the uncertainty results are shown in Table K–94.

Table K–92. Central estimate initial infection and mortality at rural site for MRF earthquake release, BSL-3 pathogens.

Pathogen	Number of initial infections / deaths (x)	Probability of x or more initial infections ($\mu_{\geq x}$) or deaths ($\delta_{\geq x}$) overall	Frequency of release leading to x or more initial infections or deaths ($\lambda_{\geq x}$)
Initial infections			
<i>B. anthracis</i>	1 or more	5.8×10^{-7}	$5.8 \times 10^{-12}/\text{year} = 1 \text{ in } > 10 \text{ million years}$

For the central estimate example, all pathogens are estimated to produce a low probability that one or more infections occur at the rural site. The highest estimated probability is for RVFV (1.9×10^{-2}), which is about a 1-in-50 chance. Combined with the central estimate estimated frequency of the occurrence of an earthquake release (once in 100,000 years), the frequency of an earthquake MRF release resulting in one or more infections or deaths from any pathogen at the rural site is estimated to fall in the D frequency category.

Table K-94: Summary of uncertainty results for initial infections and deaths (MRF release, rural site).

Pathogen	Dose-response estimates	Number of initial infections	A < 1 per year > 1 per 100 yrs	B < 1 per 100 yrs > 1 per 10K yrs	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs

The uncertainty results in the rows labeled *Both* apply for estimates using both the literature-based and the expert-based range of dose-response estimates. Every combination of dose-response estimates and earthquake release frequency estimates results in an estimated frequency of at least one initial infection at the rural site in frequency category D, except for about 17% of the estimates using the literature-based dose-response models for RVFV.

K.3.5 Medically Vulnerable Sub Populations

In this section, results from calculations described in Section K.2.4 are presented. The results are shown only for the three pathogens that produced the highest estimated probabilities of infection and death under the earthquake MRF release scenario as described in Section K.3.4. These three pathogens also represent the highest estimated infection and death probabilities among bacteria (*F. tularensis*), BSL-3 viruses (RVFV), and BSL-4 viruses (EBOV). Results from these three pathogens are sufficient to demonstrate the estimated influence of the MVSP profile at the three sites in comparison to U.S. average rates of MVSP.

K.3.5.1 Earthquake MRF release overall results adjusted for MVSP

In this section, the earthquake MRF release results presented in Section K.3.4, for which dose-response and case fatality estimates assumed to be applicable to a general U.S. population were used, are compared to adjusted results that apply site-specific MVSP data and estimates for increased susceptibility of MVSP (described in Section K.2.4).

Table K-95. Central estimate results for earthquake MRF release.

Pathogen	Adjusted results using local site MVSP estimates		Baseline results from Section K.3.4	
	Probability of 1 or more initial infections or deaths	Return period of release leading to 1 or more initial infections or deaths	Probability of 1 or more initial infections or deaths	Return period of release leading to 1 or more initial infections or deaths
URBAN SITE: initial infections				
<i>F. tularensis</i>	2.1×10^{-2}	≈ 4.7 million years	2.1×10^{-2}	≈ 4.7 million years
RVFV	0.84	$\approx 120,000$ years	0.84	$\approx 120,000$ years
EBOV	1.7×10^{-2}	≈ 5.9 million years	1.7×10^{-2}	≈ 5.9 million years
URBAN SITE: deaths among initially infected				
<i>F. tularensis</i>	4.3×10^{-4}	> 10 million years	4.3×10^{-4}	> 10 million years
RVFV	3.6×10^{-2}	≈ 2.8 million years	3.6×10^{-2}	≈ 2.8 million years
EBOV	1.5×10^{-2}	≈ 6.5 million years	1.5×10^{-2}	≈ 6.5 million years
SUBURBAN SITE: initial infections				
<i>F. tularensis</i>	4.5×10^{-4}	> 10 million years	4.6×10^{-4}	> 10 million years
RVFV	3.7×10^{-2}	≈ 2.7 million years	3.8×10^{-2}	≈ 2.6 million years
EBOV	3.6×10^{-4}	> 10 million years	3.7×10^{-4}	> 10 million years
SUBURBAN SITE: deaths among initially infected				
<i>F. tularensis</i>	8.9×10^{-6}	> 10 million years	9.3×10^{-6}	> 10 million years

Pathogen	Adjusted results using local site MVSP estimates		Baseline results from Section K.3.4	
	Probability of 1 or more initial infections or deaths	Return period of release leading to 1 or more initial infections or deaths	Probability of 1 or more initial infections or deaths	Return period of release leading to 1 or more initial infections or deaths
RVFV	7.5×10^{-4}	> 10 million years	7.8×10^{-4}	> 10 million years
EBOV	3.3×10^{-4}	> 10 million years	3.3×10^{-4}	> 10 million years
RURAL SITE: initial infections				
<i>F. tularensis</i>	2.4×10^{-4}	> 10 million years	2.3×10^{-4}	> 10 million years
RVFV	2.0×10^{-2}	≈ 5.0 million years	1.9×10^{-2}	≈ 5.1 million years
EBOV	1.9×10^{-4}	> 10 million years	1.9×10^{-4}	> 10 million years
RURAL SITE: deaths among initially infected				
<i>F. tularensis</i>	5.0×10^{-6}	> 10 million years	4.7×10^{-6}	> 10 million years
RVFV	4.2×10^{-4}	> 10 million years	3.9×10^{-4}	> 10 million years
EBOV	1.8×10^{-4}	> 10 million years	1.7×10^{-4}	> 10 million years

For the urban site, adjusting the overall results according to local proportions of MVSP does not change the estimates (to two significant Tables) for probability and frequency of at least one infection or death. This result can be explained by the observation that, while the estimated proportions of people with diabetes and HIV/AIDS are higher at the urban site than the U.S. averages, the estimated proportions of children under five and adults over 65 are lower.

For the suburban site, the estimated probabilities of at least one infection or death are slightly lower after adjusting for the local proportions of MVSP. The largest contributor to this small difference is the estimated suburban site proportion of adults over 65 years of age, which is just over half the U.S. average proportion. However, these new results do not change the assigned frequency category for the occurrence of a MRF release resulting in one or more infections or deaths at the suburban site (D frequency category).

For the rural site, the estimated probabilities of at least one infection or death are slightly higher after adjusting for the local proportions of MVSP. The largest contributor to this small difference is the estimated rural site proportion of adults over 65, which is appreciably higher than U.S. average proportion. These results do not change the assigned frequency category for the occurrence of a MRF release resulting in one or more infections or deaths at the rural site (D frequency category).

1 It is noted that the local site MVSP adjustments for the probability of deaths has a smaller effect on the
2 estimates for EBOV than for *F. tularensis* and RVFV. This can be explained by the fact that the estimated
3 EBOV case fatality rate is already quite high, even for healthy adults, so there is little room for increase
4 when the estimates of MVSP-specific case fatality rates are calculated.

5
6 Because the inputs for susceptibility of MVSP relative to healthy adults shown in Table K–8 are not
7 based on data, it is possible that they significantly underestimate the true differences in susceptibility.
8 However, the results shown in Table K–95 exhibit very low sensitivity to those inputs. For example, even
9 if the relative susceptibility values in Table K–8 are multiplied by a factor of 100, the results do not
10 change appreciably, and all estimated return periods correspond to the same frequency categories.

Table K–96. Uncertainty results for earthquake MRF release (frequency categories for release leading to one or more initial infections or deaths).

K.3.5.2 Earthquake MRF release results for each MVSP

This section contains results for estimated probabilities and frequencies of initial infections and deaths among members of each individual MVSP at each site. Each set of results is compared to what the results would be if the population at each site was the same estimated size but with MVSP in line with overall U.S. proportions.

Children under 5

Table K-97. Central estimate results for earthquake MRF release among children under 5.

Pathogen	Results using local site MVSP estimates		Results using U.S. average MVSP estimates	
	Probability of 1 or more initial infections or deaths	Return period of release leading to 1 or more initial infections or deaths	Probability of 1 or more initial infections or deaths	Return period of release leading to 1 or more initial infections or deaths
URBAN SITE: initial infections				
<i>F. tularensis</i>	1.5×10^{-3}	> 10 million years	1.8×10^{-3}	> 10 million years
RVFV	0.12	≈ 830,000 years	0.14	≈ 720,000 years
EBOV	1.2×10^{-3}	> 10 million years	1.4×10^{-4}	> 10 million years
URBAN SITE: deaths among initially infected				
<i>F. tularensis</i>	3.3×10^{-5}	> 10 million years	3.9×10^{-5}	> 10 million years
RVFV	2.8×10^{-3}	> 10 million years	3.3×10^{-3}	> 10 million years
EBOV	1.1×10^{-3}	> 10 million years	1.3×10^{-4}	> 10 million years
SUBURBAN SITE: initial infections				
<i>F. tularensis</i>	3.0×10^{-5}	> 10 million years	3.8×10^{-5}	> 10 million years
RVFV	2.6×10^{-3}	> 10 million years	3.2×10^{-3}	> 10 million years
EBOV	2.4×10^{-5}	> 10 million years	3.1×10^{-5}	> 10 million years
SUBURBAN SITE: deaths among initially infected				
<i>F. tularensis</i>	6.7×10^{-7}	> 10 million years	8.4×10^{-7}	> 10 million years
RVFV	5.6×10^{-5}	> 10 million years	7.0×10^{-5}	> 10 million years
EBOV	2.3×10^{-5}	> 10 million years	2.8×10^{-5}	> 10 million years
RURAL SITE: initial infections				
<i>F. tularensis</i>	1.6×10^{-5}	> 10 million years	1.9×10^{-5}	> 10 million years
RVFV	1.4×10^{-3}	> 10 million years	1.6×10^{-3}	> 10 million years
EBOV	1.3×10^{-5}	> 10 million years	1.6×10^{-5}	> 10 million years
RURAL SITE: deaths among initially infected				
<i>F. tularensis</i>	3.6×10^{-7}	> 10 million years	4.2×10^{-7}	> 10 million years
RVFV	3.0×10^{-5}	> 10 million years	3.6×10^{-5}	> 10 million years
EBOV	1.2×10^{-5}	> 10 million years	1.4×10^{-5}	> 10 million years

1 The results in the left columns of this table are the central estimate estimated probability and return period
2 for initial infection and mortality among children under 5 years of age at each site after an earthquake
3 MRF release. The calculations of these values incorporated the estimated proportion of children under
4 five present at each site and increased vulnerability of children under five to disease and death. At each
5 site, the estimated return periods would be placed in the D frequency category, except for at least one
6 initial infection with RVFV at the urban site that would be placed in the C frequency category.

7
8 The results in the right columns are displayed for comparison purposes—they are the equivalent estimates
9 for a site with the same population size but with a typical U.S. rate of children under five. There are some
10 small differences across each row, but all of the return periods still fall in the same frequency category
11 across each row. The direction of the small differences in each row reflect the fact that all three sites were
12 estimated to have a smaller-than-average proportion of children under five.

Table K–98. Uncertainty results for earthquake MRF release among children under 5 (frequency categories for release leading to one or more initial infections or deaths).

Pathogen	Results using local site MVSP estimates		Results using U.S. average MVSP estimates	
	C < 1 per 10K yrs >1 per 1M yrs	D < 1 per 1M yrs	C < 1 per 10K yrs >1 per 1M yrs	D < 1 per 1M yrs

<i>F. tularensis</i>	0	10,000 (100%)	0	10,000 (100%)
RVFV	5,643 (56%)	4,357 (44%)	5,974 (60%)	4,026 (40%)
EBOV	0	10,000 (100%)	0	10,000 (100%)
URBAN SITE: deaths among initially infected				
<i>F. tularensis</i>	0	10,000 (100%)	0	10,000 (100%)
RVFV	0	10,000 (100%)	12 (0.1%)	9,988 (99.9%)
EBOV	0	10,000 (100%)	0	10,000 (100%)
SUBURBAN SITE: initial infections				
<i>F. tularensis</i>	0	10,000 (100%)	0	10,000 (100%)
RVFV	0	10,000 (100%)	6 (0.1%)	9,994 (99.9%)
EBOV	0	10,000 (100%)	0	10,000 (100%)
SUBURBAN SITE: deaths among initially infected				
<i>F. tularensis</i>	0	10,000 (100%)	0	10,000 (100%)
RVFV	0	10,000 (100%)	0	10,000 (100%)
EBOV	0	10,000 (100%)	0	10,000 (100%)
RURAL SITE: initial infections				
<i>F. tularensis</i>	0	10,000 (100%)	0	10,000 (100%)
RVFV	0	10,000 (100%)	0	10,000 (100%)
EBOV	0	10,000 (100%)	0	10,000 (100%)
RURAL SITE: deaths among initially infected				
<i>F. tularensis</i>	0	10,000 (100%)	0	10,000 (100%)
RVFV	0	10,000 (100%)	0	10,000 (100%)
EBOV	0	10,000 (100%)	0	10,000 (100%)

The uncertainty analysis reveals that about 56% of input combinations result in the estimated frequency of one or more infections with RVFV among children under five at the urban site in the C frequency category. All other results are D frequency category. If the U.S. proportion of children under five were

applicable to the urban site population, the percentage of results in the C frequency category would increase slightly.

Adults over 65

Table K–99. Central estimate results for earthquake MRF release among adults over 65.

Pathogen	Results using local site MVSP estimates		Results using U.S. average MVSP estimates	
	Probability of 1 or more initial infections or deaths	Return period of release leading to 1 or more initial infections or deaths	Probability of 1 or more initial infections or deaths	Return period of release leading to 1 or more initial infections or deaths

SUBURBAN SITE: deaths among initially infected				
<i>F. tularensis</i>	1.4×10^{-6}	> 10 million years	2.2×10^{-6}	> 10 million years
RVFV	1.2×10^{-4}	> 10 million years	1.8×10^{-4}	> 10 million years
EBOV	4.0×10^{-5}	> 10 million years	6.1×10^{-5}	> 10 million years
RURAL SITE: initial infections				
<i>F. tularensis</i>	6.9×10^{-5}	> 10 million years	4.0×10^{-5}	> 10 million years
RVFV	5.7×10^{-3}	> 10 million years	3.3×10^{-3}	> 10 million years
EBOV	5.5×10^{-5}	> 10 million years	3.2×10^{-5}	> 10 million years
RURAL SITE: deaths among initially infected				
<i>F. tularensis</i>	1.9×10^{-6}	> 10 million years	1.1×10^{-6}	> 10 million years
RVFV	1.6×10^{-4}	> 10 million years	9.1×10^{-5}	> 10 million years
EBOV	5.3×10^{-5}	> 10 million years	3.1×10^{-5}	> 10 million years

The results in the left columns of this table are the central estimate estimated probability and return period for initial infection and mortality among adults over 65 years of age at each site after an earthquake MRF release. The calculations of these values incorporated the estimated proportion of adults over 65 present at each site and increased vulnerability of adults over 65 to disease and death. At each site, the estimated return periods would be placed in the D frequency category, except for infections at the urban site, for which the estimated return period is in the C frequency category.

The results in the right columns are displayed for comparison purposes – they are the equivalent estimates for a site with the same population size but with a typical U.S. proportion of adults over 65. Although there are some small differences across each row, all of the return periods fall in the same frequency category across each row. The direction of the small differences in each row reflects the fact that the urban and suburban sites were estimated to have a smaller-than-average proportion of adults over 65 and the rural site a higher-than-average proportion.

Table K–100. Uncertainty results for earthquake MRF release among adults over 65 (frequency categories for release leading to one or more initial infections or deaths).

RURAL SITE: deaths among initially infected				
<i>F. tularensis</i>	0	10,000 (100%)	0	10,000 (100%)
RVFV	0	10,000 (100%)	0	10,000 (100%)
EBOV	0	10,000 (100%)	0	10,000 (100%)

The uncertainty analysis reveals that about 73% of input combinations result in the estimated frequency of one or more infections with RVFV among adults over 65 at the urban site in the C frequency category. All other results are in the D frequency category, except for small (less than 5%) portions of results RVFV deaths at the urban site, EBOV infections at the urban site, and RVFV infections at the suburban and rural sites. If the U.S. proportion of adults over 65 were applicable to each population, the percentage of results in the C frequency category are not appreciably different.

People with diabetes

Table K–101. Central estimate results for earthquake MRF release among people with diabetes.

Pathogen	Results using local site MVSP estimates		Results using U.S. average MVSP estimates	
	Probability of 1 or more initial infections or deaths	Return period of release leading to 1 or more initial infections or deaths	Probability of 1 or more initial infections or deaths	Return period of release leading to 1 or more initial infections or deaths
URBAN SITE: initial infections				
<i>F. tularensis</i>	2.1×10^{-3}	> 10 million years	1.4×10^{-3}	> 10 million years
RVFV	0.16	≈ 640,000 years	0.11	≈ 910,000 years

<i>F. tularensis</i>	9.6×10^{-7}	> 10 million years	7.0×10^{-7}	> 10 million years
RVFV	7.8×10^{-5}	> 10 million years	5.7×10^{-5}	> 10 million years
EBOV	3.0×10^{-5}	> 10 million years	2.2×10^{-5}	> 10 million years
RURAL SITE: initial infections				
<i>F. tularensis</i>	1.8×10^{-5}	> 10 million years	1.6×10^{-5}	> 10 million years
RVFV	1.5×10^{-3}	> 10 million years	1.3×10^{-3}	> 10 million years
EBOV	1.4×10^{-5}	> 10 million years	1.2×10^{-5}	> 10 million years
RURAL SITE: deaths among initially infected				
<i>F. tularensis</i>	4.1×10^{-7}	> 10 million years	3.6×10^{-7}	> 10 million years
RVFV	3.3×10^{-5}	> 10 million years	2.9×10^{-5}	> 10 million years
EBOV	1.3×10^{-5}	> 10 million years	1.1×10^{-5}	> 10 million years

The results in the left columns of this table are the central estimate estimated probability and return period for initial infection and mortality among people with diabetes at each site after an earthquake MRF release. The calculations of these values incorporated the estimated proportion of people with diabetes present at each site and increased vulnerability of people with diabetes to disease and death. At each site, the estimated return periods would be placed in the D frequency category except for initial infections with RVFV at the urban site, which places it in the C frequency category.

The results in the right columns are displayed for comparison purposes. They are the equivalent estimates for a site with the same population size but with a typical U.S. proportion of people with diabetes. While there are some small differences across each row, all of the return periods fall in the same frequency category across each. The directions of the small differences in each row reflect the fact that all three sites were estimated to have a higher-than-average proportion of people with diabetes.

Table K–102. Uncertainty results for earthquake MRF release among people with diabetes (frequency categories for release leading to one or more initial infections or deaths).

Pathogen	Results using local site MVSP estimates		Results using U.S. average MVSP estimates	
	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs
URBAN SITE: initial infections				
<i>F. tularensis</i>	0	10,000 (100%)	0	10,000 (100%)
RVFV	6211 (62%)	3,789 (38%)	5431 (54%)	4569 (46%)
EBOV	0	10,000 (100%)	0	10,000 (100%)
URBAN SITE: deaths among initially infected				
<i>F. tularensis</i>	0	10,000 (100%)	0	10,000 (100%)
RVFV	22 (0.2%)	9,978 (99.8%)	0	10,000 (100%)
EBOV	0	10,000 (100%)	0	10,000 (100%)
SUBURBAN SITE: initial infections				
<i>F. tularensis</i>	0	10,000 (100%)	0	10,000 (100%)
RVFV	14 (0.1%)	9,986 (99.9%)	0	10,000 (100%)
EBOV	0	10,000 (100%)	0	10,000 (100%)
SUBURBAN SITE: deaths among initially infected				
<i>F. tularensis</i>	0	10,000 (100%)	0	10,000 (100%)
RVFV	0	10,000 (100%)	0	10,000 (100%)
EBOV	0	10,000 (100%)	0	10,000 (100%)
RURAL SITE: initial infections				
<i>F. tularensis</i>	0	10,000 (100%)	0	10,000 (100%)
RVFV	0	10,000 (100%)	0	10,000 (100%)
EBOV	0	10,000 (100%)	0	10,000 (100%)
RURAL SITE: deaths among initially infected				
<i>F. tularensis</i>	0	10,000 (100%)	0	10,000 (100%)
RVFV	0	10,000 (100%)	0	10,000 (100%)
EBOV	0	10,000 (100%)	0	10,000 (100%)

The uncertainty analysis reveals that about 62% of input combinations result in the estimated frequency of one or more infections with RVFV among people with diabetes at the urban site in the C frequency category, while all other results are in the D frequency category, except for a small (< 1%) portion of results for RVFV deaths at the urban site and RVFV infections at the suburban site. If the U.S. proportion

of people with diabetes were applicable to the urban site population, the percentage of results in the C frequency category would drop to 54%.

People with HIV/AIDS

Table K–103. Central estimate results for earthquake MRF release among people with HIV/AIDS.

Pathogen	Results using local site MVSP estimates		Results using U.S. average MVSP estimates	
	Probability of 1 or more initial infections or deaths	Return period of release leading to 1 or more initial infections or deaths	Probability of 1 or more initial infections or deaths	Return period of release leading to 1 or more initial infections or deaths

RURAL SITE: deaths among initially infected				
<i>F. tularensis</i>	6.0×10^{-8}	> 10 million years	6.0×10^{-8}	> 10 million years
RVFV	5.8×10^{-6}	> 10 million years	5.8×10^{-6}	> 10 million years
EBOV	2.3×10^{-6}	> 10 million years	2.3×10^{-6}	> 10 million years

The results in the left columns of this table are the central estimate estimated probability and return period for initial infection and mortality among pregnant women at each site after an earthquake MRF release.

The calculation of these values incorporated the estimated proportion of pregnant women present at each site and their increased vulnerability to disease and death. At each site, the estimated return periods would be placed in the D frequency category.

The results in the right columns are displayed for comparison purposes. They are the equivalent estimates for a site with the same population size but with a typical U.S. proportion of pregnant women. There are no differences across any of the rows, because the proportion of pregnant women at each site and in the U.S. overall was estimated to be the same (1% of the population).

Table K-106. Uncertainty results for earthquake MRF release among pregnant women (frequency categories for release leading to one or more initial infections or deaths).

Pathogen	Results using local site MVSP estimates		Results using U.S. average MVSP estimates	
	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs	C < 1 per 10K yrs > 1 per 1M yrs	D < 1 per 1M yrs
URBAN SITE: initial infections				
<i>F. tularensis</i>	0	10,000 (100%)	0	10,000 (100%)
RVFV	2,186 (22%)	7,814 (78%)	2,186 (22%)	7,814 (78%)
EBOV	0	10,000 (100%)	0	10,000 (100%)
URBAN SITE: deaths among initially infected				
<i>F. tularensis</i>	0	10,000 (100%)	0	10,000 (100%)
RVFV	0	10,000 (100%)	0	10,000 (100%)
EBOV	0	10,000 (100%)	0	10,000 (100%)
SUBURBAN SITE: initial infections				
<i>F. tularensis</i>	0	10,000 (100%)	0	10,000 (100%)
RVFV	0	10,000 (100%)	0	10,000 (100%)
EBOV	0	10,000 (100%)	0	10,000 (100%)
SUBURBAN SITE: deaths among initially infected				
<i>F. tularensis</i>	0	10,000 (100%)	0	10,000 (100%)
RVFV	0	10,000 (100%)	0	10,000 (100%)
EBOV	0	10,000 (100%)	0	10,000 (100%)
RURAL SITE: initial infections				
<i>F. tularensis</i>	0	10,000 (100%)	0	10,000 (100%)
RVFV	0	10,000 (100%)	0	10,000 (100%)
EBOV	0	10,000 (100%)	0	10,000 (100%)
RURAL SITE: deaths among initially infected				
<i>F. tularensis</i>	0	10,000 (100%)	0	10,000 (100%)
RVFV	0	10,000 (100%)	0	10,000 (100%)
EBOV	0	10,000 (100%)	0	10,000 (100%)

The uncertainty analysis reveals that about 22% of input combinations result in the estimated frequency of one or more infections with RVFV among pregnant women at the urban site in the C frequency category, while all other results are in the D frequency category. The U.S. proportion of pregnant women was estimated to be the same as that of the urban site, so the results in the right-hand columns are the same.

1 Because the inputs for susceptibility of MVSP relative to healthy adults shown in Table K–6 are not
2 based on data, it is possible that they significantly underestimate the true differences in susceptibility. The
3 numerical results in Tables K–97 to K–106 are sensitive to these inputs. The largest change in the results
4 for a particular MVSP would occur if the relative susceptibility of that MVSP is increased and the relative
5 susceptibility of all other MVSP remains the same, in which case the particular MVSP would be
6 disproportionately affected relative to not only healthy adults, but also to the other MVSP. If the relative
7 sensitivities for all MVSP are increased at the same time, then the estimated risk to each MVSP would
8 still increase, but to a much lesser extent. In all cases, however, the results regarding the risk estimates to
9 each local population as compared to what those results would be in a population with typical U.S.
10 proportions of MVSP would not change substantially. Therefore, the relative differences across each row
11 of Tables K–97 to K–106 are not sensitive to potential inaccuracies of the estimated susceptibility
12 differences of the MVSP.

9. Secondary Transmission

9.1 Introduction

Chapter 8 addressed the questions related to the potential consequences of events leading to loss of biocontainment. The results of those analyses were an estimate of the likelihood of developing initial infections in those who were directly exposed to the pathogens and how often those initial infections would be expected to occur. This chapter follows those analyses by addressing the question: what would happen if an individual with an undetected or unreported initial infection interacts with members of the community? What would be the likelihood of *secondary transmissions* occurring in members of the community the initially infected individual came into contact with? How often would infections and deaths from those secondary transmissions be expected to occur?

Secondary transmission analyses for this RA consist of qualitative and quantitative estimates of potential infection and health effects in those exposed to a pathogen because of contact with an individual already infected as a result of one of the events from the event sequence analyses. In this RA, the term *secondary transmission* refers to the transfer of pathogenic organisms from an initially infected person to another person, causing the establishment of infection in the second person, and any and all subsequent generations of transmission. Secondary transmission is distinguished from initial infection, which describes an infection caused by exposure to pathogens released directly from a NEIDL-associated event.

Under scenarios in which a laboratory worker is infected (e.g., via needlestick or centrifuge aerosol release), the worker could become contagious and transmit infection to other individuals, who could in turn transmit to others, and a chain of transmission could continue through any number of generations. Under such a scenario, the infection of the original laboratory worker is considered an initial infection, while all subsequent infections result from secondary transmission. The potential for secondary transmission increases when the exposure is undetected by the laboratory worker or if protocol in reporting or responding to a known mishap occurring in the laboratory is not followed. In those cases, the exposed worker could develop infection and become contagious while outside the laboratory among members of the public.

A member of the public who becomes infected as a result of an initial infection (e.g., via an earthquake release) or a secondary transmission may also transmit infection to others. Infected members of the public might or might not know or suspect that they have been exposed, and if symptoms develop they might not recognize the source of their disease. In assessing the possibility of extended outbreaks in the public,

1 lessons can be learned from outbreaks that have occurred in the past regardless of whether they originated
2 from loss of containment at a biological laboratory.

3 4 **9.2 Methodology**

5 For each pathogen, the potential for secondary transmission is discussed qualitatively. For four of the
6 pathogens that can be transmitted directly from one person to another—*Yersinia pestis* (*Y. pestis*) causing
7 pneumonic plague, 1918 H1N1 influenza virus (1918 H1N1V), SARS-associated coronavirus (SARS-
8 CoV), and Ebola virus (EBOV)—quantitative analyses were performed through the use of mathematical
9 modeling and statistical procedures. Those analyses involved the following:

- 10 • Description of the quantity, quality, and relevance of data from past natural outbreaks involving
11 the pathogen
- 12 • Assessment of the likelihood for given numbers of secondary transmissions occurring in the
13 community under the scenarios specific to this RA using branching process modeling methods
14 (Lloyd-Smith 2005)
- 15 • Characteristics of the pathogen as derived from published studies of past outbreaks in terms of
16 average reproductive numbers, timing of disease progression and death rates
- 17 • Consideration of public health measures that were put into place during past outbreaks of the
18 pathogens to control the outbreaks and the estimated effects of those measures
- 19 • For each pathogen, three event sequences were considered for estimating secondary transmission;
20 those were needlestick, centrifuge release, and MRF earthquake release
- 21 • Assessment of the uncertainty associated with the likelihood of transmission because of lack of
22 knowledge of the pathogen's characteristics
- 23 • Assessment of the variability in transmissions exhibited by observations of past outbreaks
- 24 • Discussion of the implications of uncertainty and variability on the assessment of the risk of
25 secondary transmission
- 26 • Analyses specific to the three NEIDL sites including differences in populations at the three sites,
27 contact-rate estimates for the local populations, differences in the proportions of medically
28 vulnerable subpopulations in the communities at the three sites and the effect of commuting of
29 workers on the spread of infection in the community

30
31 Details of the methods are provided in Appendix L.
32

9.3 Results

Assessments of the transmission potential for all 13 pathogens are presented here. In addition, the results from quantitative analyses of four of the pathogens (*Y. pestis*, 1918 H1N1V, SARS-CoV, and EBOV) are presented. The quantitative results presented here focus on estimates of how often an undetected or unreported needlestick infection leading to public infections and fatalities would occur. The needlestick event is chosen because it resulted in more frequent initial infections estimates with those four pathogens compared to the centrifuge and earthquake release events.

An initial infection after a needlestick event without prompt detection and reporting was estimated to occur in frequency category B (between once per 100 years and once per 10,000 years) (Appendix K). Values from throughout this range of estimates are multiplied by the estimated likelihood of secondary transmissions occurring in the community (derived from simulations detailed in Appendix L) to arrive at estimates of how often needlestick events leading to outbreaks of different sizes would be expected to occur. Results are displayed for both total numbers of infections and fatalities and for those that occur among Boston city residents. The portion of infections occurring among residents and non-residents are derived from estimates for rates of workers commuting, as detailed in Appendix L.

9.3.1 *Bacillus anthracis*

Bacillus anthracis (*B. anthracis*) causes inhalational, gastrointestinal or cutaneous forms of anthrax. There is no evidence of secondary transmission of inhalational and gastrointestinal anthrax. There are rare reports of person-to-person transmission of cutaneous anthrax. There are reports of humans acting as vectors in physically carrying spores on hands or inanimate items such as clothing to close contacts resulting in infection in the close contact (WHO 2008). The most recent example of this is the cutaneous anthrax that developed in a 7-month old infant who most likely came into contact with *B. anthracis* spores while being held by co-workers of his mother at her workplace in New York City that was contaminated with spores during the 2001 intentional release (Freedman, Afonja et al. 2002). As the person-to-person transmission of cutaneous anthrax is rare, secondary transmission modeling of spread of infection in the community after loss of biocontainment was not performed for *B. anthracis*.

9.3.2 *Francisella tularensis*

Francisella tularensis (*F. tularensis*) is the causative pathogen of tularemia, which is a disease of animals that also affects humans. *F. tularensis* can infect humans through the skin, mucous membranes, gastrointestinal tract, and lungs (Dennis, Inglesby et al. 2001; Ellis, Oyston et al. 2002). There are no reports of direct person-to-person transmission of *F. tularensis*, even from the pneumonic form of

1 tularemia. There is one published report that suggests that bacteria are aerosolized from patients and in
2 animal models of pneumonic tularemia and this could potentially cause secondary human infections
3 (Jones, Nicas et al. 2005); those conclusions have not been validated by other authors or experts. Because
4 there is no known direct person-to-person transmission of *F. tularensis*, secondary transmission modeling
5 of spread of infection in the community after loss of biocontainment was not performed for this pathogen.
6

7 **9.3.3 *Yersinia pestis***

8 *Y. pestis* causes plague and is transmissible from person to person, particularly in pneumonic form, as
9 described in Chapter 3. Some detailed studies exist in the literature on epidemiological parameters and
10 quantitative transmission modeling of pneumonic plague outbreaks that have occurred. Therefore, *Y.*
11 *pestis* was selected for detailed quantitative modeling of potential secondary transmission, for purposes of
12 assessing the risk posed to members of the public under the release scenarios analyzed in this RA. A
13 detailed review of the published literature on *Y. pestis* with a focus on mathematical models of the spread
14 of pneumonic plague was performed to evaluate available estimates of the reproductive numbers for
15 pneumonic plague, the average generation time between one infection and the next and case fatality rate
16 (CFR), as described in Appendix L.
17

18 As shown in Table 9–1, one or more public infections with *Y. pestis* following a needlestick event would
19 be expected to occur between once in 510 years and once in 18,000 years, which places this sequence of
20 events in frequency category B or C. An outbreak with 10 or more total public infections would be
21 expected to occur between once in 1,500 years to once in 740,000 years. An outbreak of greater than 100
22 total public infections is estimated to occur less than once in 130,000 years (frequency category C or D).
23 Outbreaks are unlikely to grow that large under the assumption that control measures would be highly
24 effective in preventing transmission, a notion that is supported by data from several pneumonic plague
25 outbreaks occurring in the 20th century, in which none exceeded 50 total cases, and standard control
26 measures were usually highly effective once hospitals and communities became aware of an outbreak
27 (Appendix L).
28

29 One or more total fatalities in the public following a needlestick would be expected to occur between
30 once in 560 years and once in 38,000 years (category B or C), while 100 or more deaths under this
31 scenario is entirely within frequency category D. Among Boston city residents, frequency estimates are
32 somewhat smaller than the total estimates because some portion of infections during an outbreak would
33 likely occur outside the city. The results show that 10 or more infections might occur with a frequency in
34 categories B, C, or D, while 100 or more infections occurring among residents would be extremely

unlikely, occurring with an average frequency less than once in 1.8 million years, entirely within category D.

Table 9–1. *Y. pestis* results—frequency of public infections and fatalities from an undetected/unreported needlestick (urban site)

Consequence		Frequency range	
		Total	Among Boston city residents
Number of public infections	1 or more	1 in 510 to 18,000 years	1 in 850 to 32,000 years
	10 or more	1 in 1,500 to 740,000 years	1 in 4,600 to 3.5 million years
	100 or more	1 in 130,000 to > 10 million years	1 in 1.8 million to > 10 million years
Number of public fatalities	1 or more	1 in 560 to 38,000 years	1 in 970 to 86,000 years
	10 or more	1 in 6,500 to > 10 million years	1 in 21,000 to > 10 million years
	100 or more	1 in 5.8 million to > 10 million years	1 in > 10 million years

9.3.4 1918 H1N1 Influenza Virus

1918 H1N1V was transmitted person-person worldwide during the 1918 influenza pandemic, as described in Chapter 3. Numerous studies exist in the literature on epidemiological parameters and quantitative transmission modeling of the 1918 pandemic in addition to other influenza pandemics, including the most recent pandemic in 2009, which was also caused by an H1N1 influenza virus (2009 H1N1V). Therefore, 1918 H1N1V was selected for detailed quantitative modeling of potential secondary transmission, for purposes of assessing the risk posed to members of the public under the release scenarios analyzed in this RA. A detailed review of the published literature on this pathogen with a focus on mathematical models of the spread of pandemic influenza was performed to evaluate available estimates of the reproductive numbers, the average generation time between one infection and the next, effects of public health control measures, and CFR, as described in Appendix L.

As shown in Table 9–2, one or more transmissions of 1918 H1N1V following a needlestick event would be expected to occur with an average frequency between once in 550 years and once in 16,000 years, which places this sequence of events in frequency category B or C. An outbreak of 1918 H1N1V in the community with 10 or more secondary transmissions following a needlestick would be expected to occur between once in 980 years to once in 43,000 years. The estimated chances of larger outbreaks (100 or more, 1,000 or more, and so on) are subject to wide uncertainty ranges. Some assumptions lead to estimating that an outbreak reaching 100 cases would be extremely infrequent (less than once in 10 million years), while other assumptions lead to estimating that a sustained, widespread outbreak could

occur with average frequency up to once in 23,000 years. Under most assumptions (more than 90 percent), such extreme, unchecked outbreaks starting from a single initially infected case would be considered unlikely (frequency category D, or less than once in 1 million years); however, their possibility is supported by the occurrence of worldwide influenza pandemics in the past.

Table 9–2. 1918 H1N1V results—frequency of public infections and fatalities from an undetected/unreported needlestick (urban site)

Consequence		Frequency range	
		Total	Among Boston city residents
Number of public infections	1 or more	1 in 550 to 16,000 years	1 in 900 to 26,000 years
	10 or more	1 in 980 to 43,000 years	1 in 1,800 to 140,000 years
	100 or more	1 in 1,400 to > 10 million years	1 in 3,900 to > 10 million years
	1,000 or more	1 in 4,300 to > 10 million years	1 in 15,000 to > 10 million years
	10,000 or more	1 in 8,300 to > 10 million years	1 in 350,000 to > 10 million years
	100,000 or more	1 in 23,000 to > 10 million years	1 in > 10 million years
Number of public fatalities	1 or more	1 in 1,100 to 70,000 years	1 in 2,300 to 170,000 years
	10 or more	1 in 2,700 to > 10 million years	1 in 10,000 to > 10 million years
	100 or more	1 in 5,800 to > 10 million years	1 in 50,000 to > 10 million years
	1,000 or more	1 in 23,000 to > 10 million years	1 in > 10 million years

9.3.5 SARS-Associated Coronavirus

SARS-CoV is transmissible person-to-person, as observed in many locations during the 2003 outbreak described in Chapter 3. Numerous studies on epidemiological parameters and quantitative transmission modeling of SARS-CoV exist in the literature. Therefore, SARS-CoV was selected for detailed quantitative modeling of potential secondary transmission, for purposes of assessing the risk posed to members of the public under the release scenarios analyzed in this RA. A detailed review of the published literature on this pathogen with a focus on mathematical models of the spread of SARS was performed to evaluate available estimates of the reproductive numbers, the average generation time between one infection and the next, effects of public health control measures, and CFR.

As shown in Table 9–3, one or more transmissions of SARS-CoV following a needlestick event would be expected to occur between once in 760 years and once in 27,000 years, which places this sequence of events in the frequency category B or C. An outbreak of SARS-CoV with 100 or more public infections would be expected to occur between once in 2,500 years and once in 440,000 years. An outbreak of

greater than 1,000 public infections is potentially very unlikely under certain assumptions (less than once in 10 million years), while other under assumptions, a sustained, widespread outbreak could occur in frequency category C, up to once in 260,000 years. Those extreme, higher risk results depend on the assumption that control measures attempting to curb transmission would not be effective at ending an outbreak that becomes large. That scenario is not supported by past experience, given that the entire worldwide outbreak of SARS in 2002–2003 resulted in about 8,000 infections and 800 deaths. For the analysis in this RA, extreme outcomes on par with those numbers or higher were observed only if it was assumed that control measures would remain relatively ineffective for a long period. If control measure effectiveness was on par with what was observed in most locations in 2003, those extreme consequences were found to be much less likely.

Table 9–3. SARS-CoV results—frequency of public infections and fatalities from an undetected/unreported needlestick (urban site)

Consequence		Frequency range	
		Total	Among Boston city residents
Number of public infections	1 or more	1 in 760 to 27,000 years	1 in 1,000 to 37,000 years
	10 or more	1 in 1,100 to 59,000 years	1 in 1,800 to 120,000 years
	100 or more	1 in 2,500 to 440,000 years	1 in 5,600 to 3.2 million years
	1,000 or more	1 in 23,000 to > 10 million years	1 in 160,000 to > 10 million years
	10,000 or more	1 in 67,000 to > 10 million years	1 in > 10 million years
	100,000 or more	1 in 260,000 to > 10 million years	1 in > 10 million years
Number of public fatalities	1 or more	1 in 1,000 to 47,000 years	1 in 1,600 to 80,000 years
	10 or more	1 in 2,500 to 350,000 years	1 in 5,300 to 1.9 million years
	100 or more	1 in 23,000 to > 10 million years	1 in 170,000 to > 10 million years
	1,000 or more	1 in 67,000 to > 10 million years	1 in > 10 million years
	10,000 or more	1 in 260,000 to > 10 million years	1 in > 10 million years

9.3.6 Rift Valley Fever Virus

Rift Valley fever virus (RVFV) is an RNA virus in the larger family of viral hemorrhagic fevers and causes Rift Valley fever. There is no direct person-to-person transmission of RVFV; transmission to humans is via arthropod vectors or by contact with infected animal products. Cattle, sheep, and goats serve as the primary amplifier of the virus. Upon developing adequate viremia (virus in the blood), humans could also serve as a virus reservoir for mosquitoes.

1 There is a limited literature on disease transmission models of RVFV involving animals, arthropod
2 vectors and human hosts. Several models have addressed other complex variables such as climate
3 conditions and livestock in the prediction and transmission of RVFV in endemic areas (Clements, Pfeiffer
4 et al. 2006; Favier, Chalvet-Monfray et al. 2006; Anyamba, Chretien et al. 2009; Metras, Collins et al.
5 2011; Mpeshe, Haario et al. 2011). The applicability of those published models and epidemiologic,
6 climate and livestock data to conditions in the United States, specifically to NEIDL sites under study in
7 the RA is unknown. Furthermore, data on ruminants and mosquito vectors are not uniformly available in
8 a format suitable for use in secondary transmission modeling. For these reasons, secondary transmission
9 modeling of spread of infection in the community following a loss of biocontainment was not performed
10 for RVFV.

11
12 The needlestick, centrifuge release, and earthquake release scenarios involving RVFV were considered
13 and the subsequent potential for secondary transmission of RVFV in the community via arthropod vectors
14 and infected animal products were qualitatively analyzed.

15
16 An initial infection after a needlestick event without prompt detection and reporting was estimated to
17 occur in frequency category B (between once per 100 years and once per 10,000 years). An initial
18 infection with RVFV following a centrifuge release event was estimated, under a higher risk set of dose-
19 response assumptions, to occur in frequency categories A or B (between about once per 10 years and once
20 per 300 years). An initial infection occurring in a member of the public after exposure to RVFV released
21 during an earthquake event was estimated to occur in frequency category C (between about once per
22 10,000 years and once per 1 million years) (Appendix K).

23
24 If a laboratory worker or a member of the public develops Rift Valley fever from any of the above events,
25 there is no possibility of directly transmitting the virus to the workers' close social contacts. However,
26 secondary transmission could occur from an initially infected laboratory worker or member of the public
27 developing sufficiently high viremia and then being bitten by a mosquito vector belonging to a permissive
28 species. The mosquito could act as a biological vector and transmit the virus to another human while
29 taking its next blood meal. That scenario is possible but considered unlikely because (1) the primary
30 amplifiers of RVFV are ruminants; (2) it is rare for humans to serve as a virus reservoir; and (3) very few
31 permissive species of mosquitoes are native to the area.

32
33 Similarly, it is possible but unlikely that an initially infected laboratory worker or member of the public
34 would transmit infection via mosquito to ruminants; therefore, it is considered unlikely that secondary

transmission to other humans would occur via infected ruminants. This scenario is distinct from the issue of establishment of RVFV in the environment after a release, which is discussed in Chapter 7.

9.3.7 Andes Virus

Andes virus (ANDV) is a New World hantavirus that causes a severe cardiopulmonary syndrome (HPS). A unique feature of ANDV is that direct person-to-person transmissions of ANDV have been reported. There are reports of HPS in close contacts with genetic evidence of person-to-person transmission, from earlier outbreaks in the 1990s to more recent cases. In such circumstances, transmission generally occurred in close family contacts who exchanged bodily fluids, with evidence of ANDV RNA found in saliva of patients (Enria, Padula et al. 1996; Padula, Edelstein et al. 1998; Martinez, Bellomo et al. 2005; Castillo, Nicklas et al. 2007; Lazaro, Cantoni et al. 2007). A recent study that prospectively studied 476 household contacts of 76 index patients with HPS in Chile found 16 contacts developed confirmed HPS (3.4 percent) (Ferres, Vial et al. 2007). A third of all the cases occurred in family clusters. Person-to-person transmission was definite in only three household contacts and probable in another nine. Sexual contacts were at the highest risk for HPS in this study.

In other reports from Argentina, 16 cases of HPS were suspected to be from person-to-person transmission, though contact or exposure to rodents could not be completely ruled out for a majority of those patients (Wells, Sosa Estani et al. 1997; Cantoni, Padula et al. 2001). There did not appear to be any hospital- or health care-associated person-to-person transmission in one outbreak in Chile (Castillo, Villagra et al. 2004). Other reports have described cases in health care workers (Lopez, Padula et al. 1996; Wells, Sosa Estani et al. 1997; Toro, Vega et al. 1998; Mertz, Hjelle et al. 2006).

In summary, direct person-to-person transmission of ANDV has been documented; although the extent of the transmission is limited to close family and possibly health care contacts and has not resulted in large outbreaks of HPS. There are limited studies available to provide epidemiologic data for detailed secondary-transmission modeling and no published mathematical models for this pathogen. A reproductive number of 0.7 has been estimated for ANDV, which would indicate that a sustained outbreak is unlikely for ANDV (Lloyd-Smith, Schreiber et al. 2005). For those reasons, secondary-transmission modeling of spread of infection in the community following a loss of biocontainment was not performed for this pathogen.

9.3.8 Ebola Virus

EBOV is transmissible person-to-person, as observed during several outbreaks that have occurred in Africa (Legrand 2006). The EBOV transmission estimates are based on information from outbreaks that occurred in Africa. As discussed further in Appendix L, the setting and population in which those outbreaks occurred are in many ways quite different than the United States, and some have suggested that the extent of transmission seen in Africa can be explained by local cultural practices that amplified transmission. However, others have concluded that the locally specific practices accounted for only a small portion of transmission and that many transmissions occurred within families and the community (see Appendix L for references). Given the lack of evidence to suggest otherwise, it was assumed that transmission estimates derived from the Africa outbreaks would be applicable to a potential outbreak in the United States.

Several studies on epidemiological parameters and quantitative transmission modeling of EBOV exist in the literature. Therefore, EBOV was selected for detailed quantitative modeling of potential secondary transmission, for purposes of assessing the risk posed to members of the public under the release scenarios analyzed in this RA. A detailed review of the published literature on this pathogen with a focus on mathematical models of the spread of EBOV was performed to evaluate available estimates of the reproductive numbers, the average generation time between one infection and the next, effects of public health control measures, and CFR, as described in Appendix L.

As shown in Table 9–4, one or more transmissions of EBOV following a needlestick event would be expected to occur between once in 550 years and once in 18,000 years, which places this sequence of events in frequency category B or C. An outbreak of EBOV with 10 or more public infections would be expected to occur between once in 1,900 years and once in 76,000 years. An outbreak of 100 or more public infections is considered much less likely than smaller outbreaks, with the estimated frequency falling to the range once in 110,000 years to less than once in 10 million years. Those results are supported by observations from at least 14 outbreaks that occurred in Africa since 1976, which ranged from a total of 12–425 infections per outbreak. Most (9 of 14) of those documented outbreaks involved fewer than 100 cases, and it is presumed that more outbreaks limited to a small number of cases have occurred and gone undocumented. The reason that EBOV outbreaks larger than 100 cases are rarer and more than 1,000 cases have not occurred is that standard, hospital-level control measures were effective once put in place.

Table 9–4. EBOV results—frequency of public infections and fatalities from an undetected/unreported needlestick (urban site)

Consequence		Frequency range	
		Total	Among Boston city residents
Number of public infections	1 or more	1 in 550 to 18,000 years	1 in 920 to 29,000 years
	10 or more	1 in 1,900 to 76,000 years	1 in 5,000 to 250,000 years
	100 or more	1 in 110,000 to > 10 million years	1 in 2.9 million to > 10 million years
Number of public fatalities	1 or more	1 in 610 to 20,000 years	1 in 1,100 to 36,000 years
	10 or more	1 in 3,100 to 240,000 years	1 in 11,000 to 1.0 million years
	100 or more	1 in 420,000 to > 10 million years	1 in 8.9 million to > 10 million years

9.3.9 Marburg Virus

Marburg virus (MARV) is a member of a group of hemorrhagic fever viruses and is closely related to EBOV. Direct person-to-person transmission of MARV from index cases to family and community contacts has been described in the 1967 outbreak and the two large outbreaks in Africa. Secondary transmission is associated with close contact with the ill patient or their bodily fluids, mainly blood (Bausch, Nichol et al. 2006; Feldmann 2006; Towner, Khristova et al. 2006). Other body fluids from infected humans (feces, vomitus, urine, saliva, and respiratory secretions) with high virus concentrations, especially when the fluids contain blood, have also been implicated in transmission.

Secondary transmission modeling of the spread of infection in the community following loss of biocontainment has been performed for the closely related EBOV. The results of the modeling are broadly applicable to MARV; for those reasons, secondary transmission modeling of spread of infection in the community following a loss of biocontainment was not performed for this pathogen.

9.3.10 Lassa Virus

Lassa virus (LASV) is the causative pathogens of Lassa fever, which is a viral hemorrhagic fever. Direct person-to-person transmission of LASV occurs, especially in hospital settings. Person-to-person transmission is associated with direct contact with the blood or other bodily fluids containing virus particles of infected individuals. Airborne transmission has also been postulated to occur. Contact with objects contaminated with virus, such as medical equipment (reused needles), is also associated with transmission in health care settings (Centers for Disease Control 2011). The viruses are generally not known to be spread through casual contact, including skin-to-skin contact without exchange of bodily fluids (Ogbu, Ajuluchukwu et al. 2007). Thus, the risk of direct person-to-person transmission is low and

involves close contact with infected body fluids. Furthermore, there are limited published mathematical models of such transmission. For those reasons, secondary transmission modeling of spread of infection in the community following loss of biocontainment was not performed for this pathogen.

9.3.11 Junín Virus

Junín virus (JUNV) is the causative pathogen of Argentine hemorrhagic fever. As with other hemorrhagic fever viruses in the family Arenaviridae (Lassa fever virus and the New World arenaviruses), there is potential for direct person-to-person transmission of JUNV, postulated to occur via close contact with infectious blood and body fluids (Borio, Inglesby et al. 2002). Note that there have been no reports of person-to-person transmission of JUNV from patients to health care workers, despite the several hundred patients with hemorrhages cared for each year in Argentina (Charrel and de Lamballerie 2003). Thus, the risk of direct person-to-person transmission of JUNV is considered low, and secondary transmission modeling of spread of infection in the community following loss of biocontainment was not performed for this pathogen.

9.3.12 Tick-borne Encephalitis Virus, Far Eastern Subtype

Tick-borne encephalitis virus, Far Eastern subtype (TBEV-FE) was formerly known as Russian spring-summer encephalitis. This virus is one member of the tick-borne encephalitis virus complex. TBEV-FE is one of the causative pathogens of tick-borne encephalitis (TBE) (Lindquist and Vapalahti 2008). The virus is transmitted to humans through the bite of an infected tick. Because there is no direct-to-person transmission of TBEV-FE, secondary transmission modeling of spread of infection in the community following loss of biocontainment was not performed for this pathogen.

9.3.13 Nipah Virus

Nipah virus (NIPV) is an emerging pathogen that was first described in 1998 from an outbreak of encephalitis in Malaysia and Singapore (1999). The mode of transmission of NIPV has changed between the Malaysian/Singapore outbreaks and those in Bangladesh/India. In the Malaysian/Singapore outbreaks, it is postulated that the virus was transmitted from bats (natural reservoir) to pigs, causing an outbreak in pigs, which subsequently led to an outbreak in humans in close contact with the pigs (abattoir workers and pig farmers). In Bangladesh, the transmission from bats to humans appears to be ongoing and via at least three different routes (Luby, Rahman et al. 2006; Luby, Hossain et al. 2009). The most frequent mode is food-borne through ingestion of Nipah-virus-contaminated date palm sap which is a staple food source in that region. A second mode of transmission appears to be via domestic animals that feed on

contaminated fruits or date palm sap that have been licked or partially eaten by fruit bats infected with NIPV. There do not appear to be any arthropod vectors in the transmission of NIPV.

Evidence from epidemiologic investigations of outbreaks in Bangladesh and India indicates that NIPV can be transmitted directly from person to person. That has occurred in patients with respiratory illness. Close physical contact with a known NIPV patient who later died was found to be the strongest risk factor for direct person-to-person transmission (Gurley, Montgomery et al. 2007). NIPV has been found in respiratory secretions of infected patients (Chua, Lam et al. 2001). Though direct transmissions have occurred and are known to be responsible for many of the Bangladeshi outbreaks, the risk of direct transmission appears to be low and requires close contact that might be culture- and region-specific (to Bangladesh) (Luby, Hossain et al. 2009). Given the limitations of conducting field investigations in rural areas of developing countries, the study (Luby, Hossain et al. 2009) estimated that only a few individuals transmitted to others and the generations of transmissions rarely exceeded two. The overall number of secondary cases resulting from an infected person was expected to be less than 0.5, indicating that it was unlikely that any one chain of transmission would result in a large outbreak.

In summary, there is a possibility of person-to-person transmission of NIPV via respiratory secretions; however the risk is low and requires close contact that could be culture- and region-specific (Luby, Hossain et al. 2009). Moreover, there are limited studies available to provide epidemiologic data for detailed secondary transmission modeling and no published mathematical models for this pathogen. For those reasons, secondary transmission modeling of spread of infection in the community following loss of biocontainment was not performed for this pathogen.

9.3.14 Site Differences

This section describes and compares results from simulations based on details specific to the suburban and rural sites. The following differences in assumptions as compared to those for the urban site are applied.

Local population size—The estimates provided in the results sections above used a local population estimate of 1 million individuals, which is representative of the daytime population in the city of Boston. The suburban and rural site simulations were run using local populations of 12,000 (approximate population of Tyngsborough, Massachusetts) and 8,000 (approximate combined population of Hancock and Peterborough, New Hampshire). Those changes have an effect only on larger outbreaks in which the

1 infected portion of the local population might become substantial enough to appreciably decrease the
2 portion of the local population that remains susceptible.

3
4 Effect of commuting—The suburban and rural site simulations incorporate commuting estimates specific
5 to those areas, as described in Appendix L. It is noted that chains of transmission occurring among non-
6 locals (who neither work nor live in the local area) are not subject to the local population constraint noted
7 above. I.e., non-locals have contacts among a wider pool of susceptible individuals than just the local
8 area, so that an extreme outbreak could potentially exceed the local population size of the area in which
9 the outbreak started.

10
11 Contact rate differences—A procedure described in Appendix L was applied to adjust estimates for
12 transmission at the suburban and rural sites, on the basis of information that suggests that residents in
13 those areas contact fewer people daily, compared to urban residents (about 15 percent fewer at the
14 suburban site and about 50 percent fewer at the rural site). The adjusted values are applied only to
15 infected individuals in the simulation if they are classified as local residents. Otherwise, the adjusted
16 contact rates are not applicable, and the estimates used for the urban site are applied.

17
18 Effectiveness of control measures—It is possible that differences between the sites would lead to different
19 expectations for the timing and effectiveness of control measures. However, no convincing evidence was
20 found to justify concrete assumptions about site differences in this regard, as explained in the following
21 points.

- 22 • Any evaluation of the current facilities, resources, personnel, and outbreak preparedness at the
23 suburban and rural sites might not be relevant if the NEIDL was actually located there.
24 Presumably, the presence of NEIDL in the area would bring new medical resources to the area
25 and potentially enhance the preparedness of the local area hospitals.
- 26 • Even if it could be concluded that there are differences in overall preparedness of hospitals at
27 different sites, there are important factors contributing to the timing and effectiveness of control
28 measures that are beyond the control of health officials. For example, (1) decisions made by
29 infected individuals in the pre-control phase of an outbreak, such as whether to seek medical
30 attention, could contribute to delays; (2) the human factor, i.e., errors made by individual health
31 care workers could contribute to delays and decrease control effectiveness; and (3) variation in
32 the biology infectious cases, for example, unusually contagious patients, could hinder control
33 efforts. Those examples could occur at any hospital, which supports the notion that the full range
34 of possible delays and control effectiveness could be relevant at any site.

- There is no guarantee that medical facilities closest to the NEIDL would be the ones primarily affected by an outbreak. Given the high rates of commuting observed at the three sites, an outbreak could easily spread outside the local area in the early stages, making it difficult to predict which area or hospital would begin seeing the first cases. For example, in the case of an outbreak started by an infected laboratory worker, the initial cases could be family members or individuals near the worker's home, which might or might not be close to the NEIDL.

Summary of Site Difference Results

Comparisons of results for the suburban and rural sites to the urban site results are summarized here and presented in detail in Appendix L.

For total numbers of infections and fatalities, the estimated likelihoods for a given consequence are generally slightly smaller at the suburban and rural sites as compared to the urban site, but the uncertainty ranges largely overlap, so that no statistically significant difference can be concluded. The reason that the overall results from the suburban and rural sites are so similar to the urban site results is that there is a high estimated rate of commuting to and from the towns at those sites, so that a significant portion of transmissions occur among nonresidents and are not subject to local population constraints or to the estimates for decreased contact rates that were based on residents only.

The effects of the site difference assumptions are more apparent when comparing the results for local residents. There tends to be a lower estimated chance of each consequence among local residents at the suburban and rural sites compared to the urban site because of commuting and contact rate differences, although uncertainty ranges overlap in most cases. The differences suggest that a more substantial portion of the risk from an undetected/unreported laboratory worker infection at the suburban and rural sites would be borne by nonresidents, particularly areas with a strong connection with the local area via commuting.

9.3.15 Medically Vulnerable Subpopulations

A procedure for incorporating information about medically vulnerable subpopulations (MVSP), described in Appendix L, was applied to SARS-CoV outbreak simulations at the three sites. MVSP, as considered in this RA, include children under 5 years of age, adults over 65 years of age, people with diabetes, people with HIV/AIDS, and pregnant women. The following factors contributing to secondary transmission estimates were included.

- Estimates for the proportion of each MVSP within the local population at each site—These estimates were based on data from the three sites (see Appendix I) and affect the likelihood that a secondary transmission would occur to a member of a specific MVSP.
- Estimates of increased susceptibility to infection, given exposure, for each MVSP—These estimates were based on expert opinion and serve to increase the likelihood that transmissions would occur to members of MVSP, compared to what would be estimated using just their proportion in the population.
- Estimates of increased CFR for each MVSP—These estimates were based on expert opinion unless data were available and serve to increase the estimated numbers of fatalities among MVSP, compared to what would be estimated under the assumption of a constant CFR across all groups.

Overall, it was determined that the MVSP profiles at the three sites potentially contribute a small effect on site differences for overall risk to the population, but that the differences are not substantial in light of the overall uncertainty and in comparison to the site differences with respect to other factors discussed above, such as differential contact rates.

In addition, estimates of the risk specific to each individual MVSP at each site were obtained. For each MVSP, the estimated likelihood of infections and fatalities occurring in that group were not substantially different across the sites, and also would not be substantially different if local MVSP profiles were in line with average U.S. proportions. See Appendix L for details.

Some limitations of this part of the analysis are as follows. First, the expert estimates of increased susceptibility to disease and mortality were based on belonging to each MVSP individually; in reality, it is possible that individuals may have multiple concomitant medical vulnerabilities such as being both elderly and diabetic, or both HIV-positive and pregnant. The susceptibility in these situations is potentially increased due to compounding effects of the individual conditions. Published data about the effects of each combination of vulnerabilities on susceptibility are scarce, and as such the simplified approach for this analysis was to assess each medical vulnerability separately. Second, because most of the estimates for susceptibility of MVSP relative to healthy adults are based on expert opinion and not on data, it is possible that they significantly underestimate the true differences in susceptibility. However, as detailed in Appendix L, the conclusions summarized above regarding comparisons across sites and to U.S. averages would not be significantly affected by assuming higher susceptibilities of each MVSP.

L. Health Effects – Secondary Transmission

L.1 Introduction

Secondary transmission analyses for this risk assessment (RA) consist of qualitative and quantitative estimates of potential infection and health effects in those exposed to a pathogen because of contact with an individual already infected as a result of one of the events from the event sequence analyses. In this RA, the term “secondary transmission” refers to the transfer of pathogenic organisms from an initially infected person to another person, causing the establishment of infection in the second person, as well as any and all subsequent generations of transmission. Secondary transmission is distinguished from initial infection, which describes an infection caused by exposure to pathogens released directly from a NEIDL-associated event.

Under scenarios in which a laboratory worker is infected (e.g., via needlestick or centrifuge aerosol release), the worker may become contagious and transmit infection to other individuals, who may in turn transmit to others, and a chain of transmission could continue through any number of generations. Under this scenario, the infection of the original laboratory worker is considered an initial infection, while all subsequent infections result from secondary transmission. The potential for secondary transmission increases when the exposure is undetected by the laboratory worker or if protocol in reporting or responding to a known mishap occurring in the laboratory is not followed. In these cases, the exposed worker may develop infection and become contagious while outside the laboratory among members of the public.

A member of the public who becomes infected as a result of an initial infection (e.g., via an earthquake release) or a secondary transmission may also transmit infection to others. Infected members of the public may or may not know or suspect that they have been exposed, and if symptoms develop they may not recognize the source of their disease. In assessing the possibility of extended outbreaks in the public, lessons can be learned from outbreaks that have occurred in the past regardless of whether or not they originated from loss of containment at a biological laboratory.

L.2 Methodology

The assessment of secondary transmission potential for each pathogen is based on observations from past outbreaks that have occurred among humans. Most historical outbreaks did not occur as a result of a release from a laboratory. Most of the documented cases of infections occurring from a large-scale laboratory release or among laboratory workers who subsequently interacted with contacts occurred with

1 pathogens that are very rarely or not at all transmissible from person to person. The cases of laboratory-
2 related initial infections with transmissible pathogens are too few to draw meaningful conclusions about
3 the likelihood of transmissions under such a scenario in general. Therefore, for purposes of this RA, it is
4 assumed that information from previous outbreaks are applicable to the initial infection scenarios
5 analyzed, regardless of whether those historical outbreaks occurred as a result of a laboratory release.

6
7 It is possible that specific circumstances surrounding a laboratory release would make information from
8 “natural” outbreaks less relevant. For example, laboratory workers developing disease symptoms would
9 presumably be more likely than an average person to link their symptoms to pathogens they had been
10 working with and take necessary precautions to avoid potential spread to others. However, there is no
11 guarantee that such precautions would be followed. In addition, some of the pathogens studied at the lab
12 cause disease in humans that are initially difficult to distinguish from the symptoms of common diseases,
13 so the worker may not initially realize the source of the infection and not take the necessary precautions to
14 avoid transmission to others. Furthermore, for some pathogens it is possible that transmission from the
15 laboratory workers could occur simultaneously with or even before symptoms develop, so that laboratory
16 workers could transmit to others before they themselves are aware or confirm that they are infected.

17
18 When evaluating the potential for secondary transmission, it is important to assess the likelihood that a
19 particular infected person will transmit infection to a given number of others. Data from previous
20 infections and outbreaks can shed light on this question, especially when adequate contact tracing is
21 performed, in which public health officials track each infected case and how many others were infected
22 by each case. However, such data are sparse for many pathogens, and the data that do exist may be
23 unreliable because there is often difficulty in determining who infected whom after the fact. As an
24 alternative, researchers often attempt to estimate the reproductive number, the *average* number of
25 transmissions from each primary case, by indirect means using more easily measureable data from
26 outbreaks and translating those data into a reproductive number through the use of mathematical
27 formulas.

28
29 Even when outbreak data are relatively rich and reproductive numbers are well established, there is still
30 uncertainty in any attempt to predict the number of transmissions that will occur from *a particular*
31 individual, because there is normally high variation from case to case. For example, studies of SARS-
32 associated coronavirus (SARS-CoV) outbreaks consistently place the basic reproductive number in the
33 range 2–4. This means that there is relatively high certainty that, early in an outbreak involving several
34 individuals, the *average* number of transmissions per individual would be in that range. However, in

examining the number of transmissions that actually occurred from particular individuals during SARS-CoV outbreaks, one finds that most individuals did not transmit infection to 2–4 others. In fact, most infected individuals did not transmit to anyone, while some individuals transmitted to far greater than four others. Understanding this high variation between cases is important in assessing the risk posed by a single infected individual entering a public community. The variation is partially caused by case-to-case differences in characteristics of the infection or of the human host and partially caused by chance events that determine whether or not transmission occurs. Two factors that contribute to determining how many transmissions occur in a particular case are a) the infected person's social contact rate and b) the likelihood that transmission occurs from each contact.

a) **Social contact rate**

The number of social contacts of an infectious person during the infectious period determines how many transmissions can potentially occur. A social contact refers to any person-to-person interaction that might result in a transmission of pathogens. A social contact may or may not involve direct physical contact between individuals. Normally a social contact with potential for transmission involves two people being in the vicinity of one another at the same time (in the same room, vehicle, or outdoor area). However, transmission can also occur between people in different rooms (for example, through a ventilation duct) or through touching the same contaminated object, or fomite, at different times.

Assessing social contact rates (number of social contacts per day) of infectious people is important for comparing the likelihood of transmission from different individuals or from people living and/or working in different areas (e.g., urban vs. suburban vs. rural). These rates are difficult to measure with certainty because of the complicated nature of social interactions and the high variation in contact rates from person to person. Furthermore, the studies that do attempt to measure contact rates tend to assess typical rates of contact in people's daily lives. However, a person with disease symptoms may behave atypically resulting in an abnormal contact rate.

Further assessments of attempts to quantify rates of social contact are discussed in later sections of this appendix.

b) **Transmissions occurring from different types of contacts**

It is important to note that not all contacts result in the same probability of transmission. Here, characteristics of the pathogen are important. Some pathogens can be transmitted through almost

any type of contact (although shorter duration contacts may result in lower probability of transmission). Others are only transmissible through physical or extended contact typical of what would occur between family members or close friends or colleagues. Still others are only transmissible through the most intimate of contacts involving the exchange of bodily fluids. Several other pathogens require a vector, such as a biting insect, for transmission to occur from person-to-person. Pathogen-specific discussion of these issues is important in comparing the likelihood of transmission across different individuals and different locations.

The issues described above are discussed on a pathogen-by-pathogen basis in Section L.3. For each pathogen, the discussion involves the following items.

- Description of the quantity, quality, and relevance of data from transmissions occurring in past outbreaks involving the pathogen.
- Assessment of the likelihood for given numbers of transmissions occurring under the scenarios specific to this RA.
- Assessment of the uncertainty associated with the likelihood of transmission due to lack of knowledge of the pathogen's characteristics.
- Assessment of the variability in transmissions exhibited by observations of past outbreaks.
- Discussion of the implications of uncertainty and variability on the assessment of transmission risk.

The above points are discussed qualitatively for each pathogen. For some of the more highly transmissible pathogens, quantitative analysis is performed through the use of mathematical modeling and statistical procedures. Quantitative analysis allows one to express assumptions in a precise manner, to accurately assess the implications of those assumptions, and to sort out the relative importance of input values, uncertainties, and variabilities, which can interact in complicated ways that are difficult to understand through non-quantitative techniques.

L.2.1 Branching Process Modeling

Pathogens for which quantitative analysis of secondary transmission is performed are analyzed using branching process models. Branching process models are stochastic mathematical models for populations of individuals in which each individual in one generation produces some number of additional individuals in the next generation. In epidemiology, branching process models have been used, dating back to Reed

1 and Frost in the 1920's (Abbey 1952), to simulate the transmission of infection from person to person in a
2 population.

3
4 When the number of infected individuals in a population is small (for example, one infected lab worker
5 entering the community), elements of chance can play an important role in determining the ultimate size
6 of a potential outbreak. Even for highly contagious diseases, there is the possibility that one infected
7 individual does not transmit to anyone because the individual has an atypically low rate of contact with
8 others, or simply because of random luck. On the other hand, one individual could transmit to many
9 others and start a large outbreak that extends to many generations of transmission. The branching process
10 modeling framework is useful for capturing the range of possibilities that could occur, starting from one
11 or a few initially infected individuals.

12
13 A recent study (Lloyd-Smith 2005) attempted to quantify the variation in the number of possible
14 transmissions from each infected individual under the branching process modeling framework, using
15 contact-tracing data from real human outbreaks of infectious diseases. We start the description of our
16 branching process model with the basic parameters and variables used in this study.

- 17
18 • R_0 is the basic reproductive number, a constant parameter for the population-wide average
19 number of secondary transmissions per infected individual in a fully susceptible population.
20 • ν is the individual reproductive number, a random variable describing the expected number of
21 secondary transmissions from any particular infected individual. Values of ν are randomly drawn
22 for each infected individual from a continuous probability distribution that has mean R_0 .
23 • Z is the number of transmissions, a random integer variable used in simulations to represent the
24 actual number of transmission from each infected individual. Values of Z are randomly drawn for
25 each infected individual from a discrete probability distribution that has mean ν .

26
27 The randomization of ν encompasses heterogeneity in a population, i.e., the ways in which individuals
28 differ from one another with regard to transmission (different number of contacts, different rate of
29 shedding pathogens, different behavioral tendencies, etc.). Then, randomization of Z represents the
30 element of chance, or how the actual number of transmissions may differ from what is expected for each
31 individual.

32
33 Note that the parameter R_0 , according to the definition, is only technically valid when there is exactly one
34 infected individual in a population where everyone else is susceptible. When multiple individuals are

infected, there's a chance that one or more contacts of any one of the infected individuals will already be infected, so that the expected number of transmissions would be less than if every contact were guaranteed to be susceptible. However, this effect is likely to be small in the early stages of a small outbreak within a large population, so for simplicity we assume that ν has a mean of R_0 for each individual in early generations of small simulated outbreaks. For extended outbreaks and when simulating the effect of public health intervention, this assumption is relaxed as described in later sections.

In a branching process simulation, random values for ν and Z are generated for each initially infected individual to determine the number of transmissions by each individual to the next generation. A sample simulation of a small outbreak is presented to illustrate the basic process, as follows. The simulation was seeded by one initially infected individual, R_0 was set to 1.8, each ν was drawn randomly from the exponential distribution (with mean R_0) and each Z was drawn randomly from the Poisson distribution (with mean ν). Note that both the exponential and Poisson distributions are one-parameter distributions, so that each distribution is fully defined when the mean is specified. Table L–1 displays the results for one simulation under these specifications.

Table L–1: Example simulation of secondary transmission

Infected ID	Infected by	ν value	Z value
A	(initial)	3.1	2
B	A	0.57	0
C	A	5.1	4
D	C	0.022	0
E	C	0.76	1
F	C	0.068	1
G	C	0.22	0
H	E	0.32	0
I	F	0.15	0

The simulated outbreak consisted of nine total infections over the course of four generations (the first generation consisting of individual A), before the outbreak extinguished when generation four (individuals H and I) did not transmit to anyone else. The fact that the outbreak extinguished relatively quickly was random luck; other simulations run under the same assumptions resulted in large outbreaks in which dozens of individuals had been infected after just a few generations.

L.2.2 Timing of Disease Progression

The sample simulation in the previous section generated results based on generations of transmission, but the timing of transmission events was not modeled. Timing of transmissions is important in estimating the speed of possible outbreaks, particularly in relation to the timing of intervention measures put in place to curb transmission, once public health officials become aware that an outbreak is occurring. The following values are used to simulate disease progression for infected individuals.

- t_I is the incubation period, or the time between exposure to pathogens and the development of symptoms.
- t_G is the generation time (also called serial interval), or the time between the onset of symptoms of a primary case and the onset of symptoms of a secondary case caused by transmission from the primary case.

The incubation period and the generation time are treated as random variables, with a distribution derived from data for each pathogen. See the sections on modeling each pathogen for details. The incubation period is only simulated for the initially infected individual(s), for whom the time of exposure is fixed at the time of the initiating incident. For secondarily infected individuals, the incubation period is included within the generation time, because the generation time incorporates both the timing of the transmission and the period before the secondary case develops symptoms.

There are several advantages to using the generation time in simulations, rather than explicitly modeling the infectious period and the timing of transmission events. When data on the generation time is available from real outbreaks, it is relatively reliable in that the development of symptoms are observable events, whereas the timing of a transmission event is generally not observable and may be highly uncertain if the primary and secondary individuals had contact over several days. Also, the generation time includes information on the average and variation of the timing of transmission events during the primary individual's infectious period, including the possibility that an individual may transmit before becoming symptomatic (which could explain observations of very low generation times). If the incubation period, infectious period and timing of transmission events are all modeled explicitly, then one has to make assumptions about the likelihood of transmission during various portions of the incubation and infectious periods, which are difficult to validate with reliable data.

For each infectious individual in the simulation, each of the transmissions from that individual is assigned an associated generation time, which is used to calculate the time at which each secondary case becomes

symptomatic. It assumed that, if there are multiple transmissions from one individual, the generation time associated with each transmission is independent of the others. Each generation time is drawn independently from the distribution associated with that pathogen.

L.2.3 Timing and Effect of Intervention Control Measures

For simulated outbreaks starting with initially infected individuals, it is assumed that transmission continues to occur under the values of R_0 and distribution of ν as described above until control measures are implemented. Until this intervention, the simulation is a model for a period of unchecked transmission before public health officials or hospitals are aware that an outbreak is occurring. The delay in implementing control measures (T_c) is modeled by first assuming a value for the delay in implementation of control measures, or the time between the onset of symptoms of the first case and the time at which control measures are put in place.

The following are some factors that may play a role in determining the length of the delay in implementation of control measures.

- The first symptomatic individual may delay going to see a doctor about the symptoms.
- There may be a delay in diagnosing the patient once he or she is examined.
- There may be a delay in mobilizing and implementing an intervention strategy once the patient is diagnosed.

All these delays contribute to the overall delay time. For each pathogen undergoing quantitative modeling, a range of values for the delay time was implemented in simulations in order to assess the sensitivity of the results to varying the length of the delay.

The effect of intervention measures is modeled by changing the parameters that contribute to the distribution of the individual reproductive number ν . As described above, the mean of ν was fixed at R_0 , which describes the average number of transmissions per infected individual early in an outbreak, before control measures are implemented. Once control measures are implemented, a new parameter is utilized called R_c , which is the post-control reproductive number, a constant parameter for the population-wide average number of secondary transmissions per infected individual, once control measures are implemented.

1 If a simulated individual becomes symptomatic at a time after control measures are implemented, the
2 value of ν for that individual is drawn from the new distribution with mean R_c . The assumption of a
3 sudden transition from R_0 to R_c for the average number of transmissions is potentially unrealistic. For
4 example, individuals becoming symptomatic just before the transition time are assumed to transmit to the
5 pre-control average R_0 , even though the transmissions themselves are likely to occur after the transition-
6 to-control time. On the other hand, individuals becoming symptomatic just after the transition time are
7 assumed to transmit to the post-control average R_c , even though the control measures are unlikely to be
8 fully implemented very soon after they have begun. It is assumed that occurrence of these two examples
9 balance each out in the simulations and that a more complicated model of the transition to control
10 measures would not provide insight beyond what is obtained by varying the assumed time of delay.

11
12 A branching process model containing most of the features described above was employed by Wallinga
13 and Teunis (2004) as a simulation for outbreaks of SARS. To test whether the branching process
14 simulation codes used for this risk assessment were in good working order, values and distributions for
15 parameters matching what was used in Wallinga and Teunis (2004) (as close as possible given the
16 published details) were used as input, and the output was in good agreement with the values published in
17 the study.

18 19 **L.2.4 Large Outbreaks**

20 If the control measures are implemented relatively quickly and the value of R_c is small, then it is likely
21 that the outbreak will extinguish before a large number of individuals become infected. However, if R_c is
22 approximately one or greater, and/or if a string of individuals in early generations of the outbreak are
23 atypical and transmit to a large number of individuals, then an outbreak has the potential to become large
24 even if it was started by a single initial case.

25
26 The use of R_0 or R_c as the average number of transmission from each individual as the outbreak
27 progresses assumes that infected individuals in later generations have the same average chance of
28 contacting susceptible individuals as did infected individuals in earlier generations. However, if an
29 outbreak is large enough that a significant portion of the local population becomes infected, infected
30 individuals in later generations should have a higher chance that one or more of their contacts have
31 already been infected, thereby eliminating the possibility of would-be transmissions that may have
32 occurred had those contacts happened earlier in the outbreak.

A simple way to model the effect of decreasing susceptibility of the population is to introduce a new parameter N , the size of the local population, and to adjust R_c based on the fraction of the population that are still susceptible when the number of transmission from an infected individual is being calculated. The equation

$$R^* = R_c \frac{S}{N},$$

where R^* is the effective reproductive number and S is the number of susceptible individuals in the population, was proposed by Gumel et al. (2004) as a good estimate of the average reproductive number as the number of susceptible individuals relative to the total population decreases. The full model in Gumel et al. (2004) is a considerably more complicated differential equation model that includes a large number of parameters that contribute to the value of R_c , including rates of placing exposed and infected individuals into quarantine and isolation and the relative effectiveness of quarantine and isolation in decreasing transmission. To test whether employing a similarly complicated model would be useful for purposes of this risk assessment, the model in Gumel et al. (2004) and the branching process model employing the above equation were each run for the same values of R_c and with the same average values for the incubation period and generation time. Values of $R_c > 1$ and a large number of infected individuals entering the post-control period were used to ensure that the simulated outbreaks would reach high levels compared to the total population. The average result from the branching process simulations for total number of infections agreed with the result from the more complicated model within approximately 5%. Given that these test-case results were not much different, and in the interest of simplicity, employing the above equation to model the effect of decreasing susceptible individuals, in conjunction with varying the value of R_c for uncertainty and sensitivity analyses, was determined to be appropriate for this risk assessment.

In the branching process model, S is calculated just before determining the value of Z for an infected individual by subtracting the current total number of infections from N . This assumes that everyone in the population who has not already been infected is susceptible. For large values of N (e.g., for $N \approx 1$ million daytime population in Boston), the number of infections would have to increase substantially in order to have a noticeable effect on changing the value of R_c . Therefore, this adjustment would only have a significant effect for outbreaks with very large numbers of cases in the local area.

L.2.5 Effect of Commuting

Additional model details are included to account for the possibility that an outbreak does not remain local. There are a number of reasons why a person infected locally might travel outside the local area and potentially transmit to others at new location. One large group of travelers that is relatively easy to quantify is commuters, or people who work outside their area of residence. Demographic data from the U.S. Census Bureau was obtained for areas in which the three sites are located to determine the percentage of residents in each area who work outside the area, as well as the percentage of the daytime population that reside elsewhere. These percentages are used to randomly assign simulated individuals a classification for having potential to transmit to someone outside the local area.

Non-local transmissions are considered branches of the transmission chain that have escaped from the local area. Transmissions from non-local individuals continue to be tracked in the model, so that the final output from each simulation includes the portion of the overall number of infections that were local and non-local. These results provide two potential insights. First, they provide an adjustment to the estimated risk to individuals local to each site. Second, they provide a measure of the risk that NEIDL might pose to individuals outside the local area at each site. For outbreaks originating at the suburban and rural sites, given their location relatively close to Boston and the large amount of travel that occurs between Boston and surrounding areas, the number of non-local transmissions is a measure of the risk to individuals in Boston. While not all of the non-local transmissions would occur in Boston, it is assumed that if the number of non-local cases is large, there is a strong likelihood that outbreak will have spread into Boston. Thus, these results allow for a rough comparison between the risk that NEIDL might pose at its current locations and at the other locations to individuals in Boston.

The following data are taken from the U.S. Census Bureau's estimated daytime population tables (U.S. Census 2011) derived from the 2000 census. Tables using data collected later than the year 2000 had not been provided by the U.S. Census Bureau as of July 2011. For the urban site, data from the city of Boston was used to derive commuter estimates. Data restricted to specific areas of Boston close to the NEIDL location are not available in the U.S. census tables. The suburban site is located in Tyngsborough, MA, and data from that town are not available in the U.S. census tables. As a replacement, data from Wilmington, MA, which is a suburban town in the same county as Tyngsborough, were used. The rural site abuts the towns of Peterborough, NH, and Hancock, NH. Data from the Peterborough census-designated place (CDP), which is a portion of the overall town of Peterborough, were used.

Table L-2: Commuting data and calculations

Data from 2000 U.S. Census (U.S. Census 2011)					
Place Name	Total resident population (A)	Total workers working in the place (B)	Total workers living in the place (C)	Estimated daytime population (D)	Workers who lived and worked in the same place (E)
Boston city, MA	589141	520555	278463	831233	184954
Wilmington CDP, MA	21363	20584	11357	30590	2287
Peterborough CDP, NH	2944	2779	1375	4348	599

Additional Calculations			
Place Name	Percent of workers in the place who are in-commuters $= (B - E) / B$	Percent of daytime population who are in-commuters $= (B - E) / D$	Percent of residents who are out-commuters $= (C - E) / A$
Boston city, MA	64.5%	40.4%	15.9%
Wilmington CDP, MA	88.9%	59.8%	42.5%
Peterborough CDP, NH	78.4%	50.1%	26.4%

The percentages in the lower part of the table above are used to randomly assign simulated individuals a classification for having potential to transmit to someone outside the local area. Each individual is assigned one of the following four categories. In these descriptions, the local area is defined as the city of Boston for the urban site, the town of Tyngsborough for the suburban site, and the towns of Peterborough and Hancock, NH for the rural site.

1. Fully local. These individuals live in the local area and either do not work or work in the local area. If infected they could potentially transmit to individuals in category 1, 2, or 3.
2. Out-commuter. These individuals reside in the local area and commute to work outside the local area. If infected, they could potentially transmit to individuals in category 1, 2, or 4.
3. In-commuter. These individuals reside outside the local area but commute to the local area for work. If infected, they could potentially transmit to individuals in category 1, 3, or 4.
4. Non-local. These individuals reside outside the local area and either do not work or work outside

the local area. If infected, it is assumed that they would only transmit to other individuals in category 4.

Under scenarios in which one or more laboratory workers are initially infected, those initial individuals are randomly assigned to category 1 or 3 according to a probability equal to the “percent of workers in the place who are in-commuters” from Table L–2. This assumes that NEIDL workers would be commuters at the same average rate as indicated for workers in the areas shown in Table L–2.

When transmissions occur in a simulation, the category of each secondary case must be chosen based on the category of the primary case. When deriving these probabilities, in some cases it is important to consider whether the transmission occurs during working hours (called “daytime”) or during home hours (called “nighttime”, although home hours also include non-working days). A person infected with SARS-CoV could potentially develop symptoms and become infectious at any time during a typical day. For the simulations, it is assumed that each transmission has a 1/3 probability of occurring during “daytime” and a 2/3 probability of occurring during “nighttime.” One week consists of 168 hours, and a 40-hour work week represents about 24% of those hours. This number was increased to 1/3 to account for commuting time and for the possibility that more contacts may occur during work hours than would occur at home.

The following procedures are used to randomly determine the category of each secondary case of a transmission.

- If the primary case is category 1:
For a daytime transmission, the secondary case will be category 3 according to “percent of daytime population who are in-commuters” from Table L–2, and category 1 otherwise. For a nighttime transmission, the secondary case will be category 2 according to “percent of resident population who are out-commuters” from Table L–2, and category 1 otherwise.
- If the primary case is category 2:
For a daytime transmission, the secondary case will be category 4. For a nighttime transmission, the secondary case will be category 2 according to “percent of resident population who are out-commuters” from Table L–2, and category 1 otherwise.
- If the primary case is category 3:
For a daytime transmission, the secondary case will be category 3 according to “percent of

daytime population who are in-commuters” from Table L–2, and category 1 otherwise. For a nighttime transmission, the secondary case will be category 4.

- If the primary case is category 4:
The secondary case will also be category 4.

For transmissions occurring after the implementation of control measures, the adjustment to the parameter R_c based on the local population, described in Section L.2.4, is applied for primary cases in categories 1, 2, and 3, but not category 4, as non-local individuals are assumed not to have contacts in the local population.

The results of these simulations are reported in terms of the risk to local individuals as well as non-local individuals. For this purpose, local individuals are defined as anyone in category 1, 2, or 3 as defined above. The results for risk to local residents (categories 1 and 2) are also reported.

L.2.6 Initial Conditions and Epidemiological Parameters

The branching process model requires an initial condition in the form of the number of initially infected individuals entering a community of susceptible individuals with potential for secondary transmission to occur. The exact number of initially infected individuals is important, because outbreaks starting with more infected individuals should have a higher probability of leading to an extended chain of transmission. Some events leading to initial infections have the potential to infect only one individual at a time (e.g., needlestick), while others have the potential to infect many individuals at once (e.g., earthquake maximum reasonably foreseeable release). In the initial infections analyses (Chapter 9 and Appendix K), each pathogen was paired with each event to determine the likelihood that one or multiple individuals would be infected by that pathogen if the event were to occur. The results of these analyses are used to determine possible initial conditions for each pathogen undergoing secondary transmission modeling.

The literature on epidemiological features of outbreaks of each pathogen was carefully examined to determine base-case values and uncertainty ranges for each input parameter that is used in the branching process model. The chosen values are shown in tables within the section dedicated to each pathogen.

L.2.7 Analysis of Base Case Model

When the base case parameter values for a pathogen are assumed, the branching process model is fully specified. However, because the model is stochastic, i.e., assumes variability in the events being modeled, the outcome for any particular simulated outbreak is not knowable in advance even when the input parameters are specified. Instead, results are given in terms of average outcomes or probabilities that various outcomes will occur. It is sometimes possible to calculate the probability that a specified event will occur directly from the input parameters. However, for most outputs of interest (such as the average size of an outbreak), such calculations are unwieldy due to the large number of random input variables that interact and contribute to the specified output. In these cases, Monte Carlo simulations are employed to simulate a large number of outbreaks all starting from the same initial conditions and the same input parameters. In each simulation, values for random variables (number of transmissions, generation time, etc.) are drawn from the assumed distributions specified by the base case parameter values. Finally, the outcomes of all the simulations are examined as a whole to estimate expected outcomes and probabilities of events of interest.

The following types of outcomes are evaluated:

- **Probability that the number of transmissions or fatalities exceeds various thresholds –** Probabilities are presented for both transmissions and fatalities for various thresholds, generally one or more, ten or more, 100 or more, and higher factors of ten if applicable, in tabular form, based on sorted outcomes of the Monte Carlo simulations.
- **Frequency of initial infections leading to given numbers of transmissions or deaths –** This is the product of the probabilities from the previous outcomes and the frequency of initial infections occurring from each of the event sequence analyses. These results are presented in both tabular and graphical form.

L.2.8 Uncertainty and Sensitivity Analysis

The base case results stem from fixing the input parameters to their base case values, all of which are uncertain. An uncertainty analysis attempts to systematically assess how varying the input values across their probable ranges affects the estimation of outcomes of interest. A sensitivity analysis attempts to separate the relative contribution from each uncertain input value to the uncertainty in each output in order to gain insight into which parameters affect the estimated outcomes in what ways.

Assumed distribution of input values

The uncertainty analysis techniques employed here require that each input variable be assigned a probability distribution. Each parameter was assigned a base case value along with an uncertainty range. The values and distributions assigned to each parameter are described in the Section L.3 for each pathogen, along with associated justification for each assumption in light of the relevant literature.

Sampling of input values

Given the distribution assumed for each value, random combinations of input parameters were drawn from each distribution using Latin Hypercube Sampling. This sampling scheme was also employed for initial infections modeling, and an explanation of the technique can be found in Appendix K. For each combination of input parameters, a large number of Monte Carlo simulations were run to generate statistics for the evaluation of uncertainty in the output values described in the previous section.

Sensitivity analysis

Sensitivity refers to the effect that variation in particular input values has on variation in results. A qualitative discussion of sensitivity is provided where notable results are observed in the uncertainty analysis. For example, if certain parameters cross a threshold above which results are appreciably different, that insight is provided. A quantitative sensitivity analysis is provided in the SARS-CoV section, using Partial Rank Correlation Coefficients, which were also used in the initial infections analysis (where the full description of the technique can be found). In this section, all relevant input parameters were tested against their effect on outputs for the frequency of public fatalities. The insights gained here for SARS-CoV are applicable to the other pathogens, which are modeled under similar frameworks.

L.2.9 Site-specific analyses

Characteristics of the population near each of the sites considered in this RA might affect the inputs and results for the secondary transmission analyses. Three site-specific characteristics are already incorporated into the analyses described above.

- **Population size** – As described in Section L.2.4, the size of the local population, which differs at the three sites, is incorporated by adjusting the average number of transmissions as the size of an outbreak becomes larger. It is again noted that this adjustment would only have a noticeable effect for very large outbreaks.

- **Initial conditions for earthquake release** – As described in Section L.2.6, the initial infections analyses provide the initial conditions for the number of infected individuals with the potential to transmit to others and start an outbreak among the general public. For the earthquake release scenario, the initial infections results are different for the three different sites because of differences in the size of the population potentially exposed to an aerosol release. Therefore, the results for the frequency of releases leading to outbreaks of different sizes will vary by site.

- **Effect of Commuting** – As described in Section L.2.5, commuting data from the area near each site are applied in simulations to determine the risk to local and non-local individuals.

There are other site-specific characteristics that could affect the assumed input values relevant for secondary transmission. For example, the population density, or number of residents and workers per unit of land area, near the three sites is different, and may affect the rate at which transmissions occur even before an outbreak becomes large, because the local population density is a factor in determining how many person-person contacts an infected individual is likely to have while moving about the local area. Attempting to specify the nature and magnitude of correlation between population density and rate of transmission necessarily requires the use of assumptions that are difficult to verify with data. The difficulty lies in the fact that human interactions are complicated and depend on many factors other than overall population density, and many of those factors are highly variable from person to person. For example, a person's family size, work or school environment, travel patterns, underlying health characteristics, typical social behavior, and how that social behavior changes when experiencing illness are all factors that play important roles in determining the likelihood of transmission.

In addition, the transmissibility characteristics of particular pathogens could affect the role that population density plays in determining the rate of transmission. For example, it is reasonable to assume that a person moving from place-to-place in a high-density urban area would likely come into brief, close proximity with many more others on average than would a person moving around a low-density rural area. The difference highlighted in this example would play a larger role for pathogens that are highly transmissible via an aerosol route than it would for pathogens that require more intimate contact for transmission. For pathogens of the latter type, an increase in the number of brief, casual contacts would have little to no effect on the rate of transmission. Even for highly transmissible pathogens, the relative importance of brief, casual contacts compared to more intimate contacts during historical outbreaks has often been unclear.

The formulation of quantitative models to address the issues described above is an open area of research, and at present there are no well established or validated methods for estimating the effects of these characteristics on rates of transmission for specific sites or populations. Nevertheless, because of the importance of some of these issues for this RA, a few relatively simple calculations are applied to investigate the possibility that certain site difference have a notable effect on the most relevant input parameters and, in turn, the resulting output of the quantitative models.

L.2.9.1 Contact rate estimates for local populations

Individuals differ with respect to the number of contacts with whom they interact on a daily basis. If an individual is infected with a transmissible pathogen, that person's contact rate is presumed to have an effect on the probability that the person would transmit infection to others. The contact rate depends on the number of people in the person's home, school, work location, places of service, or other locations where the person typically spends time. When considering average contact rates over populations at the three different sites, it is worth investigating whether there exist systematic differences between the local populations with respect to typical contact rates for individuals living in each place.

As contact rates are difficult to quantify through direct observation, researchers have developed techniques to simulate synthetic populations, based on available data from real populations, to computationally create interaction networks that can be used to estimate contact rates. One such procedure, described in Eubank et al. (2006) and Bisset et al. (2009), was used to create a synthetic population for areas in and around Boston, Massachusetts. Information from these synthetic populations and associated contact networks were provided for use in this RA by Dr. Stephen Eubank, as follows.

For specific zip codes within the study area, a synthetic resident population was created that is demographically representative of the actual population. A simulation of the synthetic population on a single day (a weekday in the Spring) spending time in various activity locations, such as homes, offices, and schools, was used to estimate the number of contacts of at least 10-minute duration for each individual. The results are as follows:

Urban site

For a synthetic population of 17,437 residing in zip code 02118 (the zip code at the NEIDL site in Boston), the average number of contacts per person was 44.0 (standard deviation 29.8 and range 0–246).

Suburban site

For a synthetic population of 12,192 residing in zip code 01879 (Tyngsborough, Massachusetts), the average number of contacts per person was 37.6 (standard deviation 24.2 and range 0–252).

Rural site

The towns of Hancock and Peterborough, NH were not included in the study area. As a replacement, the town of Ashby, MA was chosen. This town is geographically similar to the rural site, being about 20 miles southeast of Peterborough along the New Hampshire border and having a similar population density (about 129 people per square mile) to that of the combined area of Hancock and Peterborough (about 115 people per square mile). For a synthetic population of 2741 residing in Ashby, the average number of contacts per person was 20.83 (standard deviation 17.47, range 0–199).

The average numbers of contacts estimated for each location are used to calculate adjusted R values. For this purpose, it is illuminating to decompose R into a product of two components,

$$R = C \times p$$

Here, C = average number of contacts, and p = average probability of transmission per contact.

Assuming that the value of p would be the same across the three sites, the value of R would be directly proportional to the value of C . Under this assumption and using the relative average contact rates derived from synthetic populations, the following relationships between R values from infected individuals residing at the three sites are obtained.

$$R_{\text{suburban}} = \frac{37.6}{44.0} \times R_{\text{urban}} \approx 0.855 \times R_{\text{urban}}$$

$$R_{\text{rural}} = \frac{20.83}{44.0} \times R_{\text{urban}} \approx 0.473 \times R_{\text{urban}}$$

These conversions are applied to separate sets of simulations to investigate the implications of these assumptions on site-specific results for this RA.

L.2.9.2 Medically vulnerable sub-populations

Estimates of increased susceptibility to disease and mortality of medically vulnerable sub-populations (MVSP) are detailed in Appendix I. Differential susceptibility has potential implications for affecting the

average number of transmissions from an infected individual interacting with a susceptible population that includes members of MVSP. Recall that the population-wide reproductive number R (R_0 before intervention or R_c after) is used to model the average number of transmissions per infected individual. In the context of considering the effect of vulnerable portions of the susceptible population, it is illuminating to decompose R into a product of two components,

$$R = C \times p$$

Here, C = average number of contacts, and p = average probability of transmission per contact. Under this framework, one can consider the portion of contacts that is likely to represent contacts with individuals in each MVSP (based on the portion of the available contacts that are members of the sub-population) and then how the probability of transmission would change based on the differential susceptibility of that MVSP.

The general estimates of R that are used for this risk assessment were based on transmission data from real outbreaks among populations that contained some portion of individuals belonging to MVSP. In this sense, the effect of differential susceptibility is already incorporated into the R values being applied. However, because this risk assessment is concerned with specific populations for which data on sub-populations are available, it was determined to be worthwhile to include a framework for adjusting values of R based on how the local population characteristics may differ from a typical population.

The following assumptions are made.

- For a given scenario, the base case R value is relevant for a population containing portions of each sub-population that are in line with their overall frequency in the total U.S. population.
- The probability that any given contact of an infectious individual is a member of a given MVSP is equal to the portion of the local population that is a member of that MVSP.
- The average probability of transmission when an infectious individual contacts a member of a MVSP is higher than the probability resulting from contact with an individual who is not a member of an MVSP. The increase in this probability is calculated under similar methodology to that used in the context of initial infections.

- No differences in transmission *from* infected individuals belonging to different sub-populations are applied.

Input Values

This section specifies the values that are used in the calculations. For this part of the analysis, only single point estimates are applied for each input. While uncertainties do exist for these inputs, the given values are sufficient for the purpose of this exercise, which is to explore the potential role that MVSP proportions might play at each site in affecting secondary transmission estimates.

First, the index k is defined, which represents an index for the five MVSP described in Appendix I, as follows.

- $k = 1$ for children under five
- $k = 2$ for adults over 65
- $k = 3$ for people with diabetes
- $k = 4$ for people with HIV/AIDS
- $k = 5$ for pregnant women

With this index in hand, the following inputs are defined and specified.

Proportion of U.S. and local populations belonging to MVSP k (x_k, y_k). Appendix I provides estimates for proportions of each MVSP according to U.S. data and data and estimates from areas near the three sites. The assumed U.S. proportions are termed x_k , for $k = 1$ to 5, and the values are taken directly from Table 1 in Appendix I. The assumed urban resident proportions are taken from the column in Table 1 of Appendix I that estimates the proportion of each MVSP residing in the city of Boston. For the portion of the urban population working but not residing in Boston, as well as the contacts of these individuals during non-working hours, the Massachusetts statewide MVSP estimates were assumed. The suburban site estimates were taken from the Tyngsborough, MA data for residents and Massachusetts statewide data for non-resident local workers and their contacts outside of working hours. The rural site estimates were calculated by combining the data from Peterborough, NH and Hancock, NH for residents and New Hampshire statewide data for non-resident local workers and their contacts outside of working hours. Table L-3 specifies the values applied in this analysis.

Table L–3: Inputs for MVSP population values

MVSP (k)	Proportion of MVSP in U.S. population (x_k)	Proportion of MVSP in local population (y_k)				
		Urban resident	Suburban resident	Rural resident	Urban / Suburban non-resident	Rural non- resident
1: Children under five	0.069	0.059	0.055	0.058	0.063	0.061
2: Adults over 65	0.126	0.102	0.082	0.217	0.135	0.12
3: People with diabetes	0.057	0.092	0.078	0.066	0.074	0.067
4: People with HIV/AIDS	0.0045	0.0094	0.0020	0.0011	0.0028	0.00086
5: Pregnant Women	0.01	0.01	0.01	0.01	0.01	0.01

See Appendix I for sources of these estimates.

The values in the columns of Table L–3 are applied based on the classification of each infected individual with regard to commuting as described in Section L.2.5. When a transmission occurs in the local area during non-working hours, the MVSP population numbers applied to the secondary case are the local resident numbers. When a transmission occurs in the local area during working hours, the MVSP numbers applied to the secondary case are calculated as a weighted average between the local resident and the local non-resident numbers, weighted according to the numbers in Table L–2. When a transmission occurs non-locally but from an individual who either lives or works locally, the MVSP numbers applied to the secondary case are the local non-resident numbers. When a transmission occurs from a non-local individual (someone who neither lives nor works locally), the MVSP numbers applied to the secondary case are the overall U.S. numbers.

Increased susceptibility of MVSP k to pathogens (q_k). Appendix I includes a discussion of evidence for susceptibility to the 13 pathogens of members of the five MVSP. In rare cases, there exist enough data on the experience of a particular MVSP with a particular pathogen to derive a quantitative estimate for the mortality rate of that group (for example, the mortality rate among elderly from infection with SARS-CoV). In most cases, however, the quantitative estimates from experts on the Delphi panel (listed in Appendix I), which were estimates of percentage increase in susceptibility to disease and mortality for viruses and bacteria of each MVSP compared to healthy adults (denoted q_k), are used. For this analysis, the maximum estimate from each set of expert estimates was applied, to reduce the possibility of producing non-conservative results. These values are listed in Table L–4.

Table L–4: Inputs for MVSP relative susceptibility values

MVSP (k)	Increased susceptibility compared to healthy adult (q_k)			
	to disease from bacteria	to mortality from bacteria	to disease from viruses	to mortality from viruses
1: Children under five	0.33	0.2	0.33	0.2
2: Adults over 65	0.5	0.5	0.5	0.5
3: People with diabetes	0.3	0.25	0.25	0.25
4: People with HIV/AIDS	0.4	0.3	0.4	0.3
5: Pregnant Women	0.3	0.2	0.5	0.2

See Appendix I for sources of these estimates. The q_k numbers are the maximum values from the expert estimates

Calculations

To derive quantitative estimates, a procedure is applied that is similar to what was described in Appendix K for initial infections. In that case, the probability p represented the probability of infection at a particular inhaled dose, whereas in this case, p represents the probability that a transmission occurs as a result of a contact between an infectious and a susceptible individual. In Appendix K, the probability of infection of a member of MVSP k , p_k , was related to the probability of infection of a “healthy adult” (defined as an individual not belonging to any of the five MVSP), p_h , using the estimated increased susceptibility q_k and formulas based on the dose-response models being assumed. For example, for the exponential dose-response model, the following formula was applied:

$$p_k = 1 - (1 - p_h)^{1+q_k}$$

For purposes of the secondary transmission analysis in this Appendix, a linearized version of this equation is applied:

$$p_k = (1 + q_k)p_h$$

This linearized equation is approximately equivalent to the more complicated version when the values of p are small, which is a reasonable assumption in the context of transmission probability per contact. For example, the R_0 value of SARS-CoV is approximately 3 (see Section L.3.5 below), which, considering that individuals presumably average hundreds of contacts over an infectious period lasting 2-3 weeks, translates to a value of p on the order of 1% or less. The linear approximation is applied so that the

following calculations may be performed without requiring an absolute estimate of the average number of contacts, which is difficult to obtain.

As in Appendix K, x_k refers to the portion of the U.S. population belonging to MVSP k and y_k refers to the portion of a particular local population in MVSP k . When it is assumed that a baseline R value is applicable to a typical U.S. population, then the assumptions described above can be applied to derive an adjusted value, R_{local} for a local population.

$$R = Cp = C \left[\sum_{k=1}^5 (1 + q_k) p_h x_k + p_h \left(1 - \sum_{k=1}^5 x_k \right) \right] = Cp_h \left(1 + \sum_{k=1}^5 q_k x_k \right)$$

$$R_{\text{local}} = Cp_h \left(1 + \sum_{k=1}^5 q_k y_k \right)$$

$$R_{\text{local}} = R \left(\frac{1 + \sum_{k=1}^5 q_k y_k}{1 + \sum_{k=1}^5 q_k x_k} \right)$$

The final equation above is used to calculate an adjusted overall R value for each of the three sites.

Probability of x or more infections or deaths among each individual MVSP

Simulations were run in which infections and deaths among each MVSP k were recorded, using the y_k values for that site. Each time a transmission occurs in a simulation, the appropriate set of y_k values for the secondary case is selected and used in the following formula.

$$\text{Probability that transmission is to MVSP } k = \frac{(1 + q_k) y_k}{1 + \sum_{k=1}^5 q_k y_k}$$

A uniformly-distributed random number is drawn and compared to these probabilities to determine to which MVSP, if any, each secondary case belongs.

Once this MVSP identity is determined, the appropriate fatality rate is applied to randomly determine if the simulated case results in death. The case fatality rate (CFR) for each MVSP and for individuals not belonging to any MVSP is determined using the same procedure and calculations described in Appendix K.

This process is repeated using the values x_k instead of y_k , for the purpose of comparing what the estimated risk to the MVSP population at each site would be if all the local population proportions were in line with U.S. averages.

L.2.9.3 Effectiveness of control measures

It is possible that differences between the sites would lead to different expectations for the timing and effectiveness of control measures, as quantified by the parameters T_c and R_c in the quantitative transmission analyses. However, no convincing evidence was found to justify concrete assumptions about site differences in this regard, as explained in the following points.

- Any evaluation of the current facilities, resources, personnel, and outbreak preparedness at the suburban and rural sites may not be relevant if the NEIDL was actually located there. Presumably, the presence of NEIDL in the area would bring new medical resources to the area and potentially enhance the preparedness of the local area hospitals.
- Even if it could be concluded that there are differences in overall preparedness of hospitals at different sites, there are important factors contributing to the timing and effectiveness of control measures that are beyond the control of health officials. For example, i) decisions made by infected individuals in the pre-control phase of an outbreak, such as whether or not to seek medical attention, could contribute to delays; ii) the human factor, i.e., errors made by individual health care workers could contribute to delays and decrease control effectiveness; iii) variation in the biology infectious cases, for example, unusually contagious patients, could hinder control efforts. These examples could occur at any hospital, which supports the notion that the full range of possible delays and control effectiveness could be relevant at any site.
- There is no guarantee that medical facilities closest to the NEIDL location would be the ones primarily affected by an outbreak. Given the high rates of commuting observed at the three sites, an outbreak could easily spread outside the local area in the early stages, making it difficult to predict which area or hospital would begin seeing the first cases. For example, in the case of an outbreak started by an infected laboratory worker, the initial cases could be family members or individuals near the worker's home, which may or may not be close to the NEIDL.

L.3 Results

L.3.1 *Bacillus anthracis*

Bacillus anthracis (*B. anthracis*) causes inhalational, gastrointestinal or cutaneous forms of anthrax. There is no evidence of secondary transmission of inhalational or gastrointestinal anthrax. There are rare reports of person-to-person transmission of cutaneous anthrax. There are reports of humans acting as vectors in physically carrying spores on hands or inanimate items such as clothing to close contacts resulting in infection in the close contact (World Health Organization. 2008). The most recent example of this is the cutaneous anthrax that developed in a 7-month old infant who most likely came into contact with *B. anthracis* spores while being held by co-workers of his mother at her workplace in New York City that was contaminated with spores during the 2001 intentional release (Freedman, Afonja et al. 2002). As the person-to-person transmission of cutaneous anthrax is rare, secondary transmission modeling of spread of infection in the community after loss of bio-containment is not performed for *B. anthracis*.

L.3.2 *Francisella tularensis*

Francisella tularensis (*F. tularensis*) is the causative pathogen of tularemia, which is a disease of animals that also affects humans. *F. tularensis* can infect humans through the skin, mucous membranes, gastrointestinal tract, and lungs (Dennis, Inglesby et al. 2001; Ellis, Oyston et al. 2002). There are no reports of direct person-to-person transmission of *F. tularensis*, even from the pneumonic form of tularemia. There is one published report that suggests that bacteria are aerosolized from patients and in animal models of pneumonic tularemia and this could potentially cause secondary human infections (Jones, Nicas et al. 2005); these conclusions have not been validated by other authors or experts. As there is no known direct person-to-person transmission of *F. tularensis*, secondary transmission modeling of spread of infection in the community after loss of bio-containment is not performed for this pathogen

L.3.3 *Yersinia pestis*

Yersinia pestis (*Y. pestis*) causes plague and is transmissible from person to person, particularly in pneumonic form, as described in Chapter 3. Some detailed studies exist in the literature on epidemiological parameters and quantitative transmission modeling of pneumonic plague outbreaks that have occurred. Therefore, *Y. pestis* was selected for detailed quantitative modeling of potential secondary transmission, for purposes of assessing the risk posed to members of the public under the release scenarios analyzed in this RA. The remainder of this section describes the specification of the quantitative transmission modeling procedure for *Y. pestis* and summarizes the modeling outputs.

L.3.3.1 Specification of branching process model

This section describes the parameters, distributions, and assumptions used for specifying the branching process model to outbreak simulations for *Y. pestis*.

Individual reproductive number ν

The individual reproductive number ν is a random variable describing the expected number of transmissions from an infected individual. Gani and Leach (2004) tested two different assumptions on the distribution of ν , one equivalent to assuming an exponential distribution and one equivalent to assuming a constant value with no variation, and evaluated them on their ability to describe transmission data from several documented outbreaks of pneumonic plague. They found that the exponentially distributed ν assumption was superior. Lloyd-Smith et al. (2005), using the same data, also tested those two distributions as well as the gamma distribution, and also chose the exponential distribution as being more accurate than the constant- ν assumption and close to as accurate but more parsimonious than the gamma distribution, needing only one parameter to adequately describe the data instead of two. Therefore, the exponential distribution was chosen to be applied to ν in this RA. Specifically, ν is assumed to have the probability density function f defined as

$$f(x) = \frac{1}{R} e^{-x/R}.$$

As described in the methodology section, when generating numbers of transmissions from each case in the simulations, the Poisson distribution with mean ν is applied, which, when ν is exponentially distributed with mean R , is equivalent to applying the geometric distribution with mean R (Lloyd-Smith 2005). This distribution is used both before the implementation of control measures, using R_0 , and also after the implementation of control measures, using R_c . The values of these two parameters to be applied are discussed as follows.

Mean reproductive number R_0

Gani and Leach (2004) combined detailed contact-tracing data from several different pneumonic plague outbreaks before control measures were implemented to arrive at a estimate of $R_0 = 1.3$. Lloyd-Smith et al. (2005) analyzed the same data and arrived at the same estimate ($R_0 = 1.32$). No other estimates were found in the literature, so $R_0 = 1.32$ was applied as the base case assumption and the above analyses used as the basis for creating an uncertainty distribution. The raw data were not published, but an uncertainty distribution for R_0 can be constructed without the data by using the parametric bootstrap technique

described by Lloyd-Smith et al. (2005). The bootstrap sampling distribution was created by simulating 10,000 data sets of size $N = 74$ (the size of the data set from which the above R_0 estimate was generated) of randomly drawn numbers from the geometric distribution with mean $R_0 = 1.32$, and then calculating the average value of each simulated dataset (the R_0 estimate that would have been found under those data). The 10,000 values of R_0 were then used to generate random values of the parameter under the latin hypercube sampling scheme in the same manner that confidence intervals were calculated using the bias-corrected percentile method in Lloyd-Smith et al. (2005) and references therein. This procedure resulted in a 99% of randomly chosen R_0 values falling in the range (0.8 – 1.9), which is close to the range tested by Gani and Leach (2004) in their sensitivity analyses.

Mean post-control reproductive number R_c

Gani and Leach (2004) observed that in all but one of the six documented 20th century pneumonic plague outbreaks, transmissions were essentially completely curbed almost immediately after control measures were implemented. This observation is consistent with the notion that standard control measures can be highly effective at preventing transmission once awareness of an outbreak occurs. In their simulations, Gani and Leach essentially assume that $R_c = 0$ once control measures are put in place. The one exception among the historical outbreaks analyzed occurred in Mukden, China (Tieh 1948), during which 27 cases occurred after implementation of fairly substantial control measures. Lloyd-Smith et al. (2005) analyzed data from the post-control portion of the outbreak and arrived at an estimate $R_c = 0.41$. Since this outbreak was exceptional rather than typical in this regard, the value $R_c = 0.41$ is regarded as a worst feasible case, and the range $R_c = 0-0.4$ (uniform distribution) is applied for the uncertainty analysis, with the midpoint $R_c = 0.2$ applied as the base case.

Generation time (T_g)

Gani and Leach (2004) fit lognormal distributions to data on the incubation period and infectious periods from over 200 pneumonic plague cases. The average infectious period was short (2.5 days), and they argue that most transmissions would occur within one day of the end of the incubation period. In this sense, the incubation period, plus one day, would be a reasonable estimate for the generation time. Therefore, the Gani and Leach estimate of the incubation period (lognormal distribution with mean 4.3 days and standard deviation 1.8 days), shifted up by one day, is applied as the generation time distribution. This, then, gives an average generation time of 5.3 days. Uncertainty in the lognormal distribution parameters is not included in the analysis. The distribution provided a good fit to a large dataset consisting of observed events, so it is assumed that the estimated mean and standard deviation are relatively accurate values for pneumonic plague. Furthermore, the generation time affects the estimates

1 for the overall size of outbreaks through its relationship to the delay in implementation of control
2 measures. Therefore, it is assumed that testing the uncertainty range of this delay also covers the
3 potential implications of the average generation time being less or greater than 5.3 days.
4

5 **Delay in implementation of control measures (T_c)**

6 For six different pneumonic plague outbreaks, Gani and Leach (2004) documented the delay in
7 implementation of control measures as measured in days from the onset of symptoms of the first case.
8 The six different delays were 11, 12, 19, 20, 24, and 32 days, which average to approximately 20 days.
9 Massin et al. (2007) ran simulations of potential pneumonic plague outbreaks in France and assumed a
10 reference scenario in which the control delay was 10 days, and they tested a range of 1–41 days. Given
11 that the outbreaks analyzed by Gani and Leach occurred in the early 20th century before modern medical
12 advances and/or in underdeveloped countries, the average delay of 20 days is considered a worst feasible
13 case for an outbreak occurring in modern-day U.S. A range of 0–20 days (continuous uniform
14 distribution) is applied in the uncertainty analysis, and the midpoint of 10 days is applied for the base
15 case, consistent with what was assumed by Massin et al. (2007) for modern day France.
16

17 **Case fatality rate**

18 Estimating the CFR for pneumonic plague essentially comes down to estimating the probability that
19 patients would receive prompt care. At one extreme, patients who receive antibiotics before or very soon
20 after development of symptoms would have a very low mortality rate approaching zero. At the other
21 extreme, untreated patients would have a very high mortality rate approaching 100%. The time window
22 for effectiveness of antibiotic treatment is estimated at approximately 24 hours after the onset of
23 symptoms. Given this short window, it is assumed to be less likely that treatment would be delivered in
24 time to patients who develop symptoms before control measures are put in place, because patients and
25 caregivers may not immediately realize the cause of illness during this time. For these individuals, a CFR
26 of 75% is applied. For individuals developing symptoms after control measures are in place, a CFR of
27 15% (the overall observed CFR for all forms of plague) is applied.
28

Summary

Table L–5: Summary of assumed parameter values for *Y. pestis* transmission model

Parameter	Base Case Value	Uncertainty Distribution
R_0	1.32	Parametric Bootstrap (99% range: 0.8–1.9)
R_c	0.2	Uniform (min = 0, max = 0.4)
T_g	4.3 days	N/A
T_c	10 days	Uniform (min = 0, max = 20)
CFR	75% before intervention, 15% after	N/A

L.3.3.2 Transmission Results – Base Case

Given the introduction of one initially infected individual into the population, 100,000 simulations were run under the base-case input parameters listed in Table L–5. A summary of the results of the output from these simulations for secondary infections and deaths are presented in the following table.

Table L–6: *Y. pestis* base case results – number of public infections and fatalities given the occurrence of one undetected / unreported initial infection (urban site)

Consequence		Number of simulations in which consequence occurred (of 100,000)	
		Total	Among Boston City Residents
Number of Public Infections	1 or more	56776 (57%)	34227 (34%)
	10 or more	16925 (17%)	5586 (5.6%)
	100 or more	0 (<0.001%)	0 (<0.001%)
Number of Public Fatalities	1 or more	52214 (52%)	29743 (30%)
	10 or more	3521 (3.5%)	750 (0.8%)
	100 or more	0 (<0.001%)	0 (<0.001%)

These results suggest that, under the base case assumptions, a laboratory worker infected with pneumonic plague who enters the public would have about a 57% chance of transmitting infection to at least one contact. Under the commuting assumptions described in Section L.2.5, there is a chance that the worker would not live in Boston, which explains why the chance drops to 34% for at least one secondary

infection occurring among Boston residents. The estimated chance of at least 10 public infections is 17% (5.6% among Boston residents), while the chance of at least 100 infections is very small, as no outbreaks that large occurred in 100,000 simulations. The chances for each number of fatalities occurring are somewhat smaller, as not every infection would result in fatality.

L.3.3.3 Transmission Results – Uncertainty

The input parameter uncertainty distributions summarized in Table L–5 were simultaneously applied within the Latin hypercube sampling scheme described in the methodology. One hundred sets of input parameters were generated, and 10,000 simulations were run under each set of parameters to generate alternate estimates for the chance of public infections and fatalities after an undetected or unreported initial infection. The following table summarizes the range of estimates found for each designated consequence. Each range was generated by sorting the 100 different estimates and dropping the lowest two and the highest two, so that 96% of the estimates are within or at the boundaries of the range. The base case results are also displayed in the table for reference.

Table L–7: *Y. pestis* base case and uncertainty results – number of public infections and fatalities given the occurrence of one undetected / unreported initial infection (urban site)

Consequence		Estimated Chance of Consequence (given one undetected / unreported initial infection)	
		Total	Among Boston City Residents
Number of Public Infections	1 or more	57% (48% to 63%)	34% (26% to 40%)
	10 or more	17% (0.8% to 34%)	5.6% (0.1% to 15%)
	100 or more	<0.001% (≈0 to 2.4%)	<0.001% (≈0 to 0.2%)
Number of Public Fatalities	1 or more	52% (18% to 59%)	30% (8.1% to 36%)
	10 or more	3.5% (≈0 to 26%)	0.8% (≈0 to 9.2%)
	100 or more	<0.001% (≈0 to 0.05%)	<0.001% (≈0)

“≈0” at the lower end of an uncertainty range means that the given consequence was not observed in any of the simulations under at least three of the 100 input parameter combinations; when appearing as the entire range, then the consequence was not observed for at least 98 of the 100 parameter combinations.

The uncertainty ranges for the consequence of one or more public infections are relatively narrow (plus or minus less than 10 percentage points from the base case estimate), suggesting that the base case estimates are relatively robust to uncertainties in the likelihood of transmission occurring from the initial case. For the consequence of one or more public fatalities, the base case estimates of 52% (total) and 30% (local residents) could be substantial overestimates given that the ranges drop as low as 18% and 8%, but are

unlikely to be substantial underestimates. On the other hand, the chance of ten or more fatalities could be as high as 26% (total) and 9% (resident), appreciably higher than the base case estimates. Outbreaks leading to 100 or more fatalities are rare under all parameter combinations, less than 0.05% (1-in-2,000 chance) for total fatalities and much smaller for fatalities among Boston residents.

L.3.3.4 Transmission results linked to event sequences

The results in the previous section are estimates of the chance of public infections and fatalities *given that one initially infected individual enters the community*. The initial infection analyses from Chapter 8 and Appendix K provide estimates for the average frequency of such an initiating event occurring, for three different scenarios. The estimates for *Y. pestis* were as follows.

Table L–8: Summary of *Y. pestis* initial infections results

Event	Frequency Range
Undetected / Unreported Needlestick Infection	1 in 100 to 10,000 years
Undetected / Unreported Centrifuge Release and Infection	1 in 56,000 to >10 million years
Earthquake Release and Infection	1 in >10 million years

Of these three events, an undetected or unreported needlestick infection is estimated as the most frequent initial infection event by which an individual could pose a secondary transmission risk to the public. Therefore, the given frequency range for needlestick is applied in the remainder of this section as the representative event for estimating the frequency of public infections and fatalities.

The exact frequency for the needlestick event is uncertain, and no basis for was found for assuming a most likely frequency within the range. Therefore, a distribution of frequencies across the given range is applied as an additional layer of uncertainty within the overall Latin hypercube sampling scheme. Random return periods are drawn from a uniform distribution across the range (100 years to 10,000 years), and the frequency is calculated by taking the inverse. A given needlestick frequency is then multiplied by a probability of a given consequence (public infections or fatalities due to transmission) to calculate the estimated frequency of that consequence. This results in a range of estimated frequencies for each consequence. A sampling of these ranges is shown in the following table.

Table L–9: *Y. pestis* uncertainty results – frequency of public infections and fatalities due to an undetected / unreported needlestick (urban site)

Consequence		Frequency Range	
		Total	Among Boston City Residents
Number of Public Infections	1 or more	1 in 510 to 18,000 years	1 in 850 to 32,000 years
	10 or more	1 in 1,500 to 740,000 years	1 in 4,600 to 3.5 million years
	100 or more	1 in 130,000 to >10 million years	1 in 1.8 million to >10 million years
Number of Public Fatalities	1 or more	1 in 560 to 38,000 years	1 in 970 to 86,000 years
	10 or more	1 in 6,500 to >10 million years	1 in 21,000 to >10 million years
	100 or more	1 in 5.8 million to >10 million years	1 in >10 million years

The following table provides more insight into the distribution of estimated frequencies for each consequence, in terms of the portion of each distribution falling in each of the four frequency categories.

Table L–10: *Y. pestis* uncertainty results – frequency categories for public infections and fatalities due to undetected / unreported needlestick (urban site)

Consequence		Percentage of 100 estimates falling in each category							
		Total				Among Boston Residents			
		A	B	C	D	A	B	C	D
Number of Public Infections	1 or more	0	54%	46%	0	0	33%	67%	0
	10 or more	0	17%	82%	1%	0	4%	85%	11%
	100 or more	0	0	11%	89%	0	0	1%	99%
Number of Public Fatalities	1 or more	0	41%	59%	0	0	21%	79%	0
	10 or more	0	4%	61%	35%	0	2%	53%	45%
	100 or more	0	0	0	100%	0	0	0	100%

A = 1 in 1 to 100 years; B = 1 in 100 to 10,000 years; C = 1 in 10,000 to 1 million years; D = 1 in >1 million years

Finally, estimated ranges of frequencies for different consequences are conveyed graphically in Figure L–1. In the figure, numbers of fatalities are plotted against the estimated frequency with which a needlestick event leading to at least that number of fatalities in the public would be expected to occur. Under a given set of transmission parameters and a given needlestick frequency, a curve can be generated by connecting the points calculated by multiplying the needlestick frequency by the estimated chance that at least the

1 given number of fatalities would occur in the public. A different curve exists for each of the 100 sets of
2 input values that were used in the uncertainty analysis. Rather than plotting all 100 curves, four curves are
3 displayed, which form base case boundaries (thick curves) and full uncertainty boundaries (thin curves).

4
5 The base case boundaries were formed by multiplying the 95% uncertainty range for the needlestick
6 frequency by the base case estimates from the secondary transmission analysis. The full uncertainty range
7 represents the combined effects of uncertainty in the needlestick frequency and uncertainty in the
8 secondary transmission parameters. By choosing a given number of fatalities on the horizontal axis, one
9 can move vertically up the figure to find the boundaries for the estimated frequency range for that
10 consequence.

Figure L–1: Risk curves for total public fatalities from *Y. pestis* (pneumonic plague) due to undetected / unreported needlestick, urban site

L.3.4 1918 H1N1 influenza virus

1918 H1N1 influenza virus (1918 H1N1V) was transmitted person-person worldwide during the 1918 influenza pandemic, as described in Chapter 3. Numerous studies exist in the literature on epidemiological parameters and quantitative transmission modeling of the 1918 pandemic in addition to other influenza pandemics, including the most recent pandemic in 2009, which was also caused by an H1N1 influenza virus (2009 H1N1V). Therefore, 1918 H1N1V was selected for detailed quantitative modeling of potential secondary transmission, for purposes of assessing the risk posed to members of the

public under the release scenarios analyzed in this RA. The remainder of this section describes the specification of the quantitative transmission modeling procedure for 1918 H1N1V and summarizes the modeling outputs.

L.3.4.1 Specification of branching process model

This section describes the parameters, distributions, and assumptions used for specifying the branching process model to outbreak simulations for 1918 H1N1V.

Individual reproductive number ν

The individual reproductive number ν is a random variable describing the expected number of transmissions from an infected individual. One study was found (Fraser 2009) that attempted to apply multiple distributions for individual variation in infectiousness for influenza, and they applied the models to data from 2009 H1N1V in Mexico. One was a Poisson model, which is equivalent to assuming that there is no variation in ν , and the other was a negative binomial model, which is equivalent to assuming that ν follows a gamma distribution with mean R and shape parameter k . The Poisson model is a special case of the negative binomial model, with the same mean and k approaching infinity. The best fit negative binomial model in light of the outbreak data produced values of k that led the authors to suggest that the negative binomial model might be more plausible than the Poisson model. Finite values of k produce an overdispersed distribution, which, compared to the Poisson model, allows for a higher probability of a much-larger-than-average number of transmissions from an individual, i.e., a superspreading event (Lloyd-Smith 2005). Given that superspreading events have been observed for influenza (e.g., Moser 1979) and that such events would have important risk implications for scenarios analyzed in this RA, the gamma distribution was chosen to be applied to ν in this RA. Specifically, ν is assumed to have the probability density function f defined as

$$f(x) = \frac{(k/R)^k}{\Gamma(k)} x^{k-1} e^{-kx/R}.$$

The gamma distribution is used both before the implementation of control measures, using R_0 and k_0 as the two parameters, and also after the implementation of control measures, using R_c and k_c as the two parameters. The values of these four parameters to be applied are discussed as follows.

Mean reproductive number R_0 (and associated generation time T_g)

For the simulations created as part of the quantitative analysis for this RA, the mean reproductive number R_0 is used to estimate the average number of secondary transmissions from each infected individual at the beginning of a potential outbreak. According to the strict definition of R_0 , its value applies to a

1 population that is fully susceptible to the pathogen. Most of the pathogens analyzed in this RA have
2 occurred very rarely among humans in the United States, and it is reasonable to assume that none of the
3 potentially exposed individuals in the public would be immune or partially protected from infection due
4 to past exposure or vaccination. However, in the case of influenza, many members of the public have
5 recovered from or been immunized against infection with one or more strains of the virus, and past
6 experience with newly emerged strains that have caused pandemics suggests that some portion of the
7 population had pre-existing protection due to past infection with or immunization against related strains
8 (see Chapter 3 for references). Therefore, when reviewing the literature on past influenza pandemics for
9 values of R_0 that are appropriate for the way it used in this RA, it is important to focus on estimates of
10 what the average number of transmissions *actually* was in the early stage of the outbreak, rather than what
11 the average number of transmission *would have been* in a population that was fully susceptible. In this
12 sense, the estimated value of R_0 for 1918 H1N1V is interpreted as the average number of transmissions
13 per infected individual early in an outbreak among the current human population, rather than among a
14 fully susceptible population in the strict sense.

15
16 Estimates of R_0 from historical records about the 1918 pandemic and other influenza pandemics are
17 mostly based on times series data consisting of the number of new cases or deaths appearing over the
18 course of an outbreak. Detailed contact-tracing data (number of secondary cases infected by each primary
19 case) necessary for a direct calculation of R_0 are scarce even for modern influenza pandemics, so alternate
20 techniques are employed to infer the value of R_0 . One difficulty in pinning down the value of R_0 for
21 influenza implied by time series data of case counts is that the estimate of the R_0 value is sensitive to the
22 assumption of the average value and distribution of the generation time T_g (see Section L.2.2) (Wallinga
23 2007). That is, a range of values of R_0 can be consistent with a given data set depending on what is
24 assumed about the generation time. Therefore, the values of R_0 and T_g to be chosen for 1918 H1N1V
25 analyses in this RA are discussed together here.

26
27 Mills et al. (2004) estimated R (what we are calling R_0 as discussed above) from mortality data from 45
28 U.S. cities during the 1918 pandemic, and they arrived at range of 2–3 for the value. This range was
29 based on an assumed average generation time of approximately 4 days. Their figure assessing the
30 sensitivity of the R estimate to the assumed generation time shows that their R estimate would drop below
31 2 for a generation time less than about 3 days and rise above 3 for a generation time more than about 5 or
32 6 days. Chowell et al. (2007) arrived at the same estimated range of 2–3 for R derived from fitting
33 models to a different data set and under similar assumptions about the generation time. Chowell et al.
34 (2006) estimated a larger R value of 3.75 based model fitting to data from the fall wave 1918 influenza in

1 Switzerland, but they acknowledge that the data support much smaller values of R depending on what is
2 assumed about the relative contact rate of hospitalized vs. non-hospitalized cases. Gani et al. (2005) also
3 assumed approximately 4 days for the average generation time but came up with lower R estimates in the
4 range 1.55–2.0 based on 1918 data from England and Wales. They state that these numbers were lower
5 than those derived by Mills et al. “probably because our estimates were derived from data throughout
6 England and Wales, thereby incorporating spatial heterogeneity,” whereas the Mills et al. estimates were
7 based on urban data from individual U.S. cities treated separately. White and Pagano (2008) estimated R_0
8 values for various Maryland communities during the 1918 outbreak to be between 1.34 and 3.21 and also
9 attempted estimates of the serial interval based on this data and data from outbreaks that occurred on
10 ships, resulting in estimates as low as 2.83 days but as high as 8.28 days, associated with considerable
11 uncertainty.

12
13 Recent studies have assessed the available evidence for the characteristics of influenza A transmission
14 events more closely and found that the assumptions used in many of the above studies may result in
15 overestimates of the generation time, thereby skewing the derived estimates for R . Ferguson et al. (2006)
16 performed an extensive statistical analysis on data from influenza infections among members of
17 households and arrived at an estimate of 2.6 days for T_g (95% interval 2.1–3.0 days), values that would
18 shift the estimated R value by Mills et al. (2004) below 2. The Ferguson et al. (2006) study also provided
19 estimates of R_0 based on 1918 data from U.S. and British cities in the range 1.7–2.0. Wallinga et al.
20 (2007) similarly used household data from a different influenza study to arrive at an estimate of 2.85 days
21 for T_g (standard deviation 0.93 days), from which they derive a range of about 1.6–1.8 for R based on the
22 Mills et al. (2004) estimated growth rates of influenza cases in 1918.

23
24 The notion that transmission during the 1918 pandemic may have been characterized by short (three days
25 or less) average generation times and values of R less than 2 is consistent with several results pertaining to
26 the most recent 2009 H1N1 pandemic. Fraser et al. (2009) used detailed data from an outbreak in an
27 isolated community in Mexico to derive an independent estimate of the mean generation time at 1.91 days
28 (95% range 1.30–2.71 days), which was associated with an R_0 estimate of 1.58 (95% range 1.34–2.04).
29 This estimate for R_0 was consistent with estimates based on other epidemiological data sets provided in
30 the same report, which fell in the range 1.4–1.6, with alternative estimates and confidence intervals
31 spanning a range of about 1.1–2.0. Yang et al. evaluated data from 2009 H1N1V in the U.S. and also
32 estimated R_0 to be less than 2 (range 1.3–1.7) along with relatively short generation time estimates (range
33 2.6–3.2 days). Ghani et al. (2010) performed a detailed analysis of all laboratory-confirmed cases in the
34 UK and arrived at an average generation time estimate of 2.5 days, along with estimates for R in the range

1 1.2–1.5. Cauchemez et al. (2009) did not estimate R_0 but found a similar estimate for the average
2 generation time (2.6 days) based on household transmission data in the U.S. Similar results (R_0
3 approximately or less than 2 and T_g less than 3) were found based on data from outbreaks in the United
4 States (after adjusting for ascertainment bias) (White 2009), New Zealand (Paine 2010, Nishiura 2009b),
5 Thailand (de Silva 2009), and Canada (Hsieh, 2009).
6

7 At least three studies estimated R to be less than two in conjunction with longer generation time estimates
8 of more than three days. These results imply lower risk of large outbreaks occurring in a given horizon
9 (e.g., before control measures can be implemented) than the results outlined above. Tuite et al. (2010)
10 estimated a low R_0 (1.31) in conjunction with a longer average generation time of 4–5 days, based on data
11 from Ontario, Canada. Pourbohloul et al. (2009) estimated a low R (about 1.5), in conjunction with
12 assumptions implying a relatively long generation time greater than 4 days, based on data from Mexico
13 City. Hahne et al. (2009) estimated R to be less than one (0.5) in conjunction with a generation time of 3
14 days for cases occurring in the Netherlands, although they caution that this value of R may be an
15 underestimate.
16

17 A few studies estimated R values greater than two in conjunction with short generation times of less than
18 three days, values which imply higher risk of large outbreaks occurring in a fixed time. McBryde et al.
19 (2009) estimated the average generation interval at 2.9 days (standard deviation 1.4 days) based on 2009
20 H1N1V cases in Australia with an identified primary contact, and the associated estimate of R was 2.4,
21 although an alternate model accounting for potential case ascertainment bias shifts the R estimate to the
22 range 1.5–1.8. Boelle et al. (2009) used Mexican outbreak data to derive upper bound estimates of R of
23 about 2.2 and 2.6 in conjunction with assumed average generation times of 2.6–3.1 days. However, these
24 were upper bound estimates that were uncorrected against potential underreporting bias, which would
25 decrease the estimates of R . Nishiura et al. (2009a) estimated R at 2.3 (range 2.0–2.6) for an outbreak in
26 Japan, under the assumption of 1.9 days for the average generation time. A potential reason for a higher
27 R value and faster spread in Japan and possibly Australia compared to other places is that the outbreaks in
28 those countries were primarily fueled by transmission in schools among children, for whom high age-
29 specific transmission was estimated (McBryde 2009).
30

31 The Ghani et al. (2010) study was chosen as the basis for the base case assumed values to characterize the
32 generation time for this RA. This study was based on a large and varied data set for 2009 H1N1V, and
33 the results are consistent with other prominent studies as described above. Thus, the average generation
34 time is assumed to be 2.51 days, with a standard deviation of 1.55 days. It is assumed that the gamma

distribution characterizes variability of the generation time within the simulations for this RA, with a shape parameter of 2.62 and scale parameter of 0.957, which lead to a mean and standard deviation consistent with the Ghani et al. results. For the uncertainty analysis, values for the average generation time are tested over the range 1.5 days to 3.5 days. This range covers the possibility that the average generation time is less than two days, as implied by results from Mexico (Fraser 2009). The range also covers the possibility that the average generation time was longer for the 1918 H1N1V than it was for 2009 H1N1V, as potentially implied by White and Pagano (2008).

The uncertainty analysis techniques employed here require that each input variable be assigned a probability distribution. For T_g , it is not obvious how to assign a probability distribution over the assumed range, especially given the fact that the base case value and range of values were assigned by surveying many research studies that used a wide variety of techniques to arrive at their estimates. To construct a distribution, it was first assumed that the base case value is the *most likely* value for the parameter (i.e., the *mode* of the distribution), and that the limits of the given range are the *minimum* and the *maximum* of the distribution. Given that no criteria other than the mode, minimum, and maximum for choosing a distribution is readily apparent, it was determined that a simple distribution satisfying those three statistics would be appropriate – the triangular distribution, for which the probability density function $T_g(x)$ is defined as follows.

$$T_g(x) = \begin{cases} x - 1.5, & 1.5 \leq x \leq 2.5 \\ 3.5 - x, & 2.5 < x \leq 3.5 \end{cases}$$

For a given choice of the average generation time, the variance of the generation time distribution to be applied in simulations was chosen such that the variance-to-mean ratio is the same as that found by Ghani et al. (2010).

Given the above assumed values characterizing the generation time distribution, the assumptions for R_0 can be presented. For the base case example, a value of $R_0 = 1.6$ is assumed. This value is calculated based on the mean growth rate of 1918 influenza cases in the U.S. estimated by Mills et al. (2004), the most extensive study on 1918 H1N1V spread in the literature, combined with the base case estimate of the generation time distribution (Wallinga 2007). To account for other estimates in the literature associated with average generation times comparable to the base case, a range of 1.2–2.0 (triangular distribution) is assumed for the uncertainty analysis. This distribution is shifted according to the value of the average generation time chosen for a particular sample in the uncertainty analysis, such that range is 1.5–2.3 at the upper end average generation time of 3.5 days, and 0.9–1.7 at the lower end average

1 generation time of 1.5 days, to account for the fact that higher values of R_0 may be consistent with
2 outbreak data under the assumption of a longer average generation time.

3 4 **Shape / dispersion parameter k_0**

5 The parameter k_0 found in the probability density function of the gamma distribution (see equation under
6 individual reproductive number ν above) is often called the "shape" parameter of the distribution. If the
7 mean (in this case, R_0) is held constant, and the value of k_0 is changed, the shape of the distribution
8 changes, causing the variance of the distribution to increase as k_0 decreases. Specifically, the variance is
9 calculated as R_0^2/k_0 . The random variable ν for the individual reproductive number is assumed to be
10 gamma-distributed with mean R_0 and shape parameter k_0 . Then the random variable Z for the actual
11 number of transmissions from an infected individual is assumed to be Poisson distributed with mean ν . A
12 Poisson-distributed random variable with a mean that is gamma-distributed with mean R_0 and shape
13 parameter k_0 has a negative binomial distribution with mean R_0 and "dispersion parameter" k_0 .

14
15 Fraser et al. (2009) fit a negative binomial model to 2009 H1N1V outbreak data from Mexico and their
16 estimate of k indicated "low-to-moderate overdispersion." Any negative binomial distribution with finite
17 dispersion parameter is overdispersed compared to the Poisson distribution (which is equivalent to the
18 negative binomial distribution with the same mean and infinite dispersion parameter k). The authors
19 imply that k values less than 0.5 would indicate high overdispersion, in that an epidemic associated with k
20 values that low would be characterized by superspreading. Therefore, "low-to-moderate overdispersion"
21 is interpreted to mean a value of k_0 greater than 0.5. For the uncertainty analysis, a continuous uniform
22 distribution is applied for the inverse, $1/k_0$, on the range 0–2, so that values near 2 imply k_0 near 0.5, and
23 values near 0 imply large k_0 . The median of this distribution, at which $k_0 = 1$, is applied as the base case
24 estimate. This value is a special case implying that ν is exponentially distributed, which is a common
25 assumption made in conjunction with differential equation models of disease spread (Lloyd-Smith 2005),
26 including several influenza models.

27 28 **Mean post-control reproductive number R_c**

29 The parameter R_c is the average number of transmissions per infected individual after control measures
30 for the pathogen have been implemented. For influenza viruses exhibiting relatively short generation
31 times, control measures to reduce transmission can be difficult to implement at the hospital level through
32 antiviral treatment, isolation, and quarantine, because transmissions from a primary case to a secondary
33 case can occur close to, or possibly before, the time that a primary case develops symptoms and is aware
34 of being infected. Nevertheless, increased surveillance for new cases and implementation of community-

1 wide measures to encourage (through public education) or enforce (through, for example, school closures)
2 social distancing may serve to reduce transmission once implemented (Ferguson 2005).

3
4 No studies were found that attempted to measure R_c by averaging estimated reproductive numbers after
5 set dates from which control measures were implemented. However, several studies estimated the
6 evolution of R over time and found that the time-dependent value dropped and remained below one within
7 a few weeks after the first observed cases in the given area (Boelle 2009; Nishiura 2009a; McBryde 2009;
8 Paine 2010). By contrast, one study found that R had not dropped below one more than a month and half
9 after the first known case in the UK (Ghani 2010).

10
11 Given the above information, it was decided that a base case value of R_c less than one would be
12 appropriate, but that the uncertainty range should include values of R_c greater than one to account for the
13 possibility that control measures would fail to contain an outbreak that had grown substantially in the
14 initial phase. In addition, given that some values of R_0 in the uncertainty range are close to one, it was
15 decided to calculate R_c as a fraction of the associated R_0 value. This procedure avoids the possibility that
16 $R_c > R_0$ for a given parameter set in the uncertainty analysis. Under the base case, it is assumed that R_c is
17 50% of R_0 , resulting in $R_c = 0.8$. For the uncertainty analysis, it is assumed that the percentage decrease
18 from R_0 to R_c ranges from 25% to 75%, with a uniform distribution over this range.

19 20 **Shape / dispersion parameter k_c**

21 The same base case value and range applied for k_0 are also applied for k_c .

22 23 **Delay in implementation of control measures (T_c)**

24 Given that influenza infections are relatively common, initial cases of a potential 1918 H1N1V outbreak
25 might escape notice if they were not linked to a potential source in a laboratory. Ferguson et al. (2005)
26 estimated that it would take an initial cluster of about 20 cases before public health authorities would be
27 aware of an unusual outbreak and initiate control policies, and that this threshold corresponds to about a
28 14 day delay. They tested a range of 0–28 days for this delay as part of a sensitivity analysis. This range
29 is consistent with the range of control delays seen during the 2009 H1N1V pandemic in various locations,
30 as reflected among the references cited under the R_c section above. Therefore, 14 days is assumed as the
31 base case value of T_c , and a continuous uniform distribution over the range 0–28 days is applied for the
32 uncertainty analysis. A delay close to 0 days would reflect the possibility that the first case (e.g., initially
33 infected laboratory worker) would immediately recognize the source of infection and seek assistance in
34 reducing further transmission from contacts.

Summary

Table L–11: Summary of assumed parameter values for 1918 H1N1V transmission model

Parameter	Base Case Value	Uncertainty Distribution
R_0	1.6	Triangular (mode = 1.3-1.9, min = 0.9-1.5, max = 1.7-2.3) ^a
k_0, k_c	1	Uniform on $1/k$ (min: $1/k = 0$, max: $1/k = 2$)
R_c	0.8	Uniform (min = 25% of R_0 , max = 75% of R_0)
Average T_g	2.5 days	Triangular (mode = 2.5, min = 1.5, max = 3.5)
T_c	14 days	Uniform (min = 0, max = 28)
CFR	2.5%	N/A

^a mode, min, and max of R_0 are dependent on value chosen for the average T_g ; see text for details.

L.3.4.2 Transmission Results – Base Case

Given the introduction of one initially infected individual into the population, 100,000 simulations were run under the base-case input parameters listed in Table L–11. A summary of the results of the output from these simulations for secondary infections and deaths are presented in the following table.

Table L–12: 1918 H1N1V base case results – number of public infections and fatalities given the occurrence of one undetected / unreported initial infection (urban site)

Consequence		Number of simulations in which consequence occurred (of 100,000)	
		Total	Among Boston City Residents
Number of Public Infections	1 or more	61666 (62%)	38730 (39%)
	10 or more	39609 (40%)	19715 (20%)
	100 or more	28262 (28%)	8409 (8.4%)
	1,000 or more	3956 (4.0%)	24 (0.02%)
	10,000 or more	0 (<0.001%)	0 (<0.001%)
Number of Public Fatalities	1 or more	36332 (36%)	16193 (16%)
	10 or more	5586 (5.6%)	1447 (1.4%)
	100 or more	15 (0.02%)	0 (<0.001%)
	1,000 or more	0 (<0.001%)	0 (<0.001%)

These results suggest that, under the base case assumptions, a laboratory worker infected with 1918 H1N1V who enters the public would have about a 62% chance of transmitting infection to at least one contact. Under the commuting assumptions described in Section L.2.5, there is a chance that the worker would not live in Boston, which explains why the chance drops to 39% for at least one secondary infection occurring among Boston residents. There is an estimated 28% chance that an outbreak would grow to 100 total cases and less than 5% chance of 1,000 total cases. The relative low case fatality for 1918 H1N1V (compared to the other modeled pathogens) leads to an estimate of a less than 6% chance of 10 or more total fatalities occurring (less than 2% chance among Boston residents).

L.3.4.3 Transmission Results – Uncertainty

The input parameter uncertainty distributions summarized in Table L–11 were simultaneously applied within the Latin hypercube sampling scheme described in the methodology. One hundred sets of input parameters were generated, and 10,000 simulations were run under each set of parameters to generate alternate estimates for the chance of public infections and fatalities after an undetected or unreported initial infection. The following table summarizes the range of estimates found for each designated consequence. Each range was generated by sorting the 100 different estimates and dropping the lowest two and the highest two, so that 96% of the estimates are within or at the boundaries of the range. The base case results are also displayed in the table for reference.

Table L–13: 1918 H1N1V base case and uncertainty results – number of public infections and fatalities given the occurrence of one undetected / unreported initial infection (urban site)

Consequence		Estimated Chance of Consequence (given one undetected / unreported initial infection)	
		Total	Among Boston City Residents
Number of Public Infections	1 or more	62% (49% to 81%)	39% (30% to 51%)
	10 or more	40% (13% to 70%)	20% (4.1% to 39%)
	100 or more	28% (≈0 to 65%)	8.4% (≈0 to 29%)
	1,000 or more	4.0% (≈0 to 46%)	0.03% (≈0 to 11%)
	10,000 or more	<0.001% (≈0 to 30%)	<0.001% (≈0 to 2.2%)
	100,000 or more	<0.001% (≈0 to 30%)	<0.001% (≈0)
Number of Public Fatalities	1 or more	36% (8.2% to 69%)	16% (3.1% to 36%)
	10 or more	14% (≈0 to 53%)	1.4% (≈0 to 18%)
	100 or more	0.02% (≈0 to 31%)	<0.001% (≈0 to 6.3%)
	1,000 or more	<0.001% (≈0 to 30%)	<0.001% (≈0)

“≈0” at the lower end of an uncertainty range means that the given consequence was not observed in any of the simulations under at least three of the 100 input parameter combinations; when appearing as the entire range, then the consequence was not observed for at least 98 of the 100 parameter combinations.

The results for the consequence of one or more public infections suggest that about 50-80% is a reasonable range for the chance that an initially infected individual would transmit infection, and about 30-50% for the chance that a Boston resident becomes infected. Many of the estimates for the chance of larger outbreaks show substantial uncertainty, which reflects both the difficulty in pinpointing transmission parameters for 1918 H1N1V and the fact that the parameters are close to a threshold of outbreak controllability. For example, some sets of parameters lead to estimates suggesting that an outbreak reaching 100 total infections or 10 total fatalities would be extremely unlikely, while other sets of parameters lead to estimates of a 30% chance that a single initial case would cause an essentially unchecked outbreak.

The most extreme, high consequence estimates are only possible if it is assumed that the parameter R_c is greater than one, meaning that an outbreak that initially grows large and spreads over a wide area would remain uncontrolled. It should be noted that R_c staying above one for an extended period is potentially unrealistic, as public health officials in all areas would presumably step up control measures to more stringent levels in the face of a very large outbreak. However, these upper-limit results reflect the

implications of the possibility of an outbreak in which control of transmission remains elusive, a scenario which cannot entirely be ruled out.

The Boston resident results show a less than 3% chance of an outbreak reaching 10,000 infections among residents, even under extreme parameter assumptions. This is because the commuting assumptions and decreasing population susceptibility tend to reduce the effective R_c below the threshold required for long-term sustained resident-to-resident spread. However, sustained resident-to-resident spread leading to substantially more resident infections is possible for values of R_c just above those that were eliminated in constructing the $\approx 95\%$ interval (See Table L–16).

L.3.4.4 Transmission results linked to event sequences

The results in the previous section are estimates of the chance of public infections and fatalities *given that one initially infected individual enters the community*. The initial infection analyses from Chapter 8 and Appendix K provide estimates for the average frequency of such an initiating event occurring, for three different scenarios. The estimates for 1918 H1N1V were as follows.

Table L–14: Summary of 1918 H1N1V initial infections results

Event	Frequency Range
Undetected / Unreported Needlestick Infection	1 in 100 to 10,000 years
Undetected / Unreported Centrifuge Release and Infection	1 in 490 to >10 million years
Earthquake Release and Infection	1 in 450,000 to >10 million years

Of these three events, an undetected or unreported needlestick infection extends to a higher frequency range than the other two events. The centrifuge infection event is of comparable frequency at the high end of the uncertainty range, but the range also contains a substantial portion of estimates for much lower frequencies (categories C and D). Therefore, the frequency range for needlestick infection is applied in the remainder of this section as the representative event for estimating the frequency of public infections and fatalities.

The exact frequency for the needlestick event is uncertain, and no basis for was found for assuming a most likely frequency within the range. Therefore, a distribution of frequencies across the given range is applied as an additional layer of uncertainty within the overall Latin hypercube sampling scheme.

Random return periods are drawn from a uniform distribution across the range (100 years to 10,000 years), and the frequency is calculated by taking the inverse. A given needlestick frequency is then multiplied by a probability of a given consequence (public infections or fatalities due to transmission) to calculate the estimated frequency of that consequence. This results in a range of estimated frequencies for each consequence. A sampling of these ranges is shown in the following table.

Table L-15: 1918 H1N1V uncertainty results – frequency of public infections and fatalities due to an undetected / unreported needlestick (urban site)

Consequence		Frequency Range	
		Total	Among Boston City Residents
Number of Public Infections	1 or more	1 in 550 to 16,000 years	1 in 900 to 26,000 years
	10 or more	1 in 980 to 43,000 years	1 in 1,800 to 140,000 years
	100 or more	1 in 1,400 to >10 million years	1 in 3,900 to >10 million years
	1,000 or more	1 in 4,300 to >10 million years	1 in 15,000 to >10 million years
	10,000 or more	1 in 8,300 to >10 million years	1 in 350,000 to >10 million years
	100,000 or more	1 in 23,000 to >10 million years	>10 million years
Number of Public Fatalities	1 or more	1 in 1,100 to 70,000 years	1 in 2,300 to 170,000 years
	10 or more	1 in 2,700 to >10 million years	1 in 10,000 to >10 million years
	100 or more	1 in 5,800 to >10 million years	1 in 50,000 to >10 million years
	1,000 or more	1 in 23,000 to >10 million years	1 in >10 million years

The following table provides more insight into the distribution of estimated frequencies for each consequence, in terms of the portion of each distribution falling in each of the four frequency categories.

Table L-16: 1918 H1N1V uncertainty results – frequency categories for public infections and fatalities due to undetected / unreported needlestick (urban site)

Consequence		Percentage of 100 estimates falling in each category							
		Total				Among Boston Residents			
		A	B	C	D	A	B	C	D
Number of Public Infections	1 or more	0	62%	38%	0	0	38%	62%	0
	10 or more	0	39%	61%	0	0	17%	83%	0
	100 or more	0	28%	63%	9%	0	8%	71%	21%
	1,000 or more	0	11%	49%	40%	0	2%	32%	66%
	10,000 or more	0	3%	19%	78%	0	2%	3%	95%
	100,000 or more	0	2%	7%	91%	0	1%	1%	98%
Number of Public Fatalities	1 or more	0	37%	63%	0	0	15%	85%	0
	10 or more	0	18%	59%	23%	0	2%	56%	42%
	100 or more	0	3%	37%	60%	0	2%	7%	91%
	1,000 or more	0	2%	11%	87%	0	2%	0	98%
	10,000 or more	0	2%	4%	94%	0	0	0	100%

A = 1 in 1 to 100 years; B = 1 in 100 to 10,000 years; C = 1 in 10,000 to 1 million years; D = 1 in >1 million years

The results in the above table for the highest consequences reveal that a threshold is crossed for the most extreme 2-3% of parameter estimates, for which high consequence results are estimated to occur within frequency category B. On the other hand, it should also be noted that a substantial portion of estimates for 10 or more fatalities fall in frequency category D (less than one in one million years).

Finally, estimated ranges of frequencies for different consequences are conveyed graphically in Figure L-2. In the figure, numbers of fatalities are plotted against the estimated frequency with which a needlestick event leading to at least that number of fatalities in the public would be expected to occur. Under a given set of transmission parameters and a given needlestick frequency, a curve can be generated by connecting the points calculated by multiplying the needlestick frequency by the estimated chance that at least the given number of fatalities would occur in the public. A different curve exists for each of the 100 sets of input values that were used in the uncertainty analysis. Rather than plotting all 100 curves, four curves are displayed, which form base case boundaries (thick curves) and full uncertainty boundaries (thin curves).

The base case boundaries were formed by multiplying the 95% uncertainty range for the needlestick frequency by the base case estimates from the secondary transmission analysis. The full uncertainty range represents the combined effects of uncertainty in the needlestick frequency and uncertainty in the secondary transmission parameters. By choosing a given number of fatalities on the horizontal axis, one can move vertically up the figure to find the boundaries for the estimated frequency range for that consequence.

Figure L-2: Risk curves for total public fatalities from 1918 H1N1V due to undetected / unreported needlestick, urban site

This figure further emphasizes the extent of uncertainty associated with estimating the likelihood of consequences for 1918 H1N1V. The shape of the upper-limit thin curve is unusual because it reflects the fact that the uncertainty range for the post control reproductive number crosses the threshold $R_c = 1$ at the upper end of the uncertainty range, above which an outbreak will take off if it reaches a substantial size. On the other side, the lower limit curve drops quickly into frequency category D (less than one in one million years) for less than five fatalities. The narrower uncertainty range bounded by the thick curves perhaps represents a more realistic range of frequency estimates, but the more extreme estimates cannot be ruled out.

L.3.5 SARS-associated coronavirus

SARS-CoV is transmissible person-to-person, as observed in many locations during the 2003 outbreak described in Chapter 3. Numerous studies on epidemiological parameters and quantitative transmission modeling of SARS-CoV exist in the literature. Therefore, SARS-CoV was selected for detailed quantitative modeling of potential secondary transmission, for purposes of assessing the risk posed to members of the public under the release scenarios analyzed in this RA. The remainder of this section describes the specification of the quantitative transmission modeling procedure for SARS-CoV and summarizes the modeling outputs.

L.3.5.1 Specification of branching process model

This section describes the parameters, distributions, and assumptions used for specifying the branching process model to outbreak simulations for SARS-CoV.

Individual reproductive number ν

The individual reproductive number ν is a random variable describing the expected number of transmissions from an infected individual. Lloyd-Smith *et al.* (2005) examined contact-tracing data from outbreaks of SARS in Beijing and Singapore, and they compared the ability of different distributions of the individual reproductive number, ν , to describe the spread of transmission numbers from each infected individual documented in the data. They demonstrated that using the gamma distribution for ν was superior to the other distributions tried. Specifically, they used a gamma distribution with mean R and shape parameter k , which has a probability density function f defined as

$$f(x) = \frac{(k/R)^k}{\Gamma(k)} x^{k-1} e^{-kx/R}.$$

It was shown that this distribution is able to capture certain observed features of SARS outbreaks that have important implications for this RA, where other candidate distributions could not. Namely, it is able to estimate a relatively accurate proportion of cases not transmitting, which is important in assessing the likelihood that a single introduced case (e.g., an infected laboratory worker) would cause secondary infections, as well as a relatively accurate frequency of rapidly growing outbreaks, which is important in assessing the likelihood of the occurrence of an explosive outbreak. Given the success of the gamma distribution in describing variation in transmission observed in outbreaks in at least two cities and its ability to capture a range of outcomes with important implications for risk assessment, it was chosen as the distribution to be applied to ν in this RA. The gamma distribution is used both before the implementation of control measures, using R_0 and k_0 as the two parameters, and also after the implementation of control measures, using R_c and k_c as the two parameters. The values of these four parameters to be applied are discussed as follows.

Mean reproductive number R_0

The mean reproductive number R_0 was estimated directly by Lloyd-Smith *et al.* (2005) for early generations of transmission during the SARS outbreaks in Beijing and Singapore, using contact tracing data from the first 2-3 generations of transmission. In Beijing, R_0 was estimated at 1.88 (90% confidence interval: 0.41-3.32) over the first two generations of transmission. In Singapore, R_0 was estimated at 2.55 (90% confidence interval: 0.50-4.50) over the first two generations of transmission, and the estimate dropped to 1.63 (90% confidence interval: 0.54-2.65) when the third generation of transmission was included. The authors explain that the drop in the R_0 estimate when including the third generation could potentially be explained by the fact that those transmissions occurred after WHO's global alert on SARS, which could have affected informal changes in behavior among infected individuals and at hospitals, even though centralized control measures were not yet in place in Singapore at that time.

As reflected in the size of the confidence intervals from the Lloyd-Smith *et al.* results, estimates of R_0 based on early-generation transmission data often suffer from a shortage of documented cases, and contact tracing can be imperfect. Other researchers have developed techniques for estimating R_0 indirectly using more easily observed data from outbreaks, such as case incidence rates, in combination with other epidemiological parameters, such as incubation period and generation time. This information is then translated into R_0 through the use of formulas derived from a mathematical model. For SARS, Bausch *et al.* (2005) reviewed a number of papers and their estimates for R_0 . They determined a consensus estimate of $R_0 = 3$, which is reasonably consistent across quite different statistical and dynamic modeling techniques used in estimation procedures found in the literature. The review carefully

examined studies that estimated R_0 values significantly lower (Choi 2003, Chowell 2003, Wang 2004) or significantly higher (Gumel 2004, Hsieh 2004) than 3 and was able to reconcile those outliers by identifying inaccurate or questionable assumptions that led to the R_0 estimate. Note that $R_0 = 3$ is higher than the Lloyd-Smith et al. (2005) maximum likelihood estimates, but it's within their 90% confidence intervals for the first two generations of transmission in each city.

Based on this review of the literature, a base case value of $R_0 = 3$ was used in the branching process simulations. For uncertainty and sensitivity analysis, values in the range $2 \leq R_0 \leq 4$ were used. The upper limit of $R_0 = 4$ was chosen to reflect the fact that some researchers estimated values in the 3.5–4.0 range in papers whose methods were not called into question by the Bausch *et al.* review. For example, Wallinga and Teunis (2004) estimated $R_0 = 3.6$ for the Hong Kong outbreak, and Lipsitch et al. (2003) estimated $R_0 = 3.5$ for the Singapore outbreak.

The uncertainty analysis techniques employed here require that each input variable be assigned a probability distribution. For R_0 , it is not obvious how to assign a probability distribution over the assumed range, especially given the fact that the base case value and range of values were assigned by surveying many research studies that used a wide variety of techniques to arrive at their estimates. To construct a distribution, it was first assumed that the base case value is the *most likely* value for the parameter (i.e., the *mode* of the distribution), and that the limits of the given range are the *minimum* and the *maximum* of the distribution. Given that no criteria other than the mode, minimum, and maximum for choosing a distribution is readily apparent, it was determined that a simple distribution satisfying those three statistics would be appropriate – the triangular distribution, for which the probability density function $R(x)$ is defined as follows.

$$R(x) = \begin{cases} x - 2, & 2 \leq x \leq 3 \\ 4 - x, & 3 < x \leq 4 \end{cases}$$

Using this distribution within the latin hypercube sampling scheme results in 99% of randomly chosen values for R_0 falling between 2.1 and 3.9.

Shape / dispersion parameter k_0

The parameter k_0 found in the probability density function of the gamma distribution (see equation under individual reproductive number ν above) is often called the "shape" parameter of the distribution. If the mean (in this case, R_0) is held constant, and the value of k_0 is changed, the shape of the distribution

changes, causing the variance of the distribution to increase as k_0 decreases. Specifically, the variance is calculated as R_0^2/k_0 . The random variable v for the individual reproductive number is assumed to be gamma-distributed with mean R_0 and shape parameter k_0 . Then the random variable Z for the actual number of transmissions from an infected individual is assumed to be Poisson distributed with mean v . A Poisson-distributed random variable with a mean that is gamma-distributed with mean R_0 and shape parameter k_0 has a negative binomial distribution with mean R_0 and "dispersion parameter" k_0 .

Lloyd-Smith et al. (2005) reported an optimal value of $k_0 = 0.16$ for SARS by fitting the negative binomial distribution to transmission data from early generations of the Singapore outbreak. A similar k_0 value was found based on different SARS outbreak data from Beijing. The value of $k_0 = 0.16$ is used as the base case value for the simulations in this RA. This values of k_0 was calculated by Lloyd-Smith *et al.* using maximum likelihood methods that made use of an already calculated maximum likelihood estimate of R_0 that is different that the base case value of $R_0 = 3$ chosen for this RA. However, it was determined that using $R_0 = 3$ and $k_0 = 0.16$ together is not contraindicated by the Singapore and Beijing data in light of other important statistics. For example, when examining the proportion of cases not transmitting (p_0), the authors calculated $p_0 = 0.67$ directly from the Singapore data. For the negative binomial distribution, p_0 has the formula $p_0 = (1 + R_0/k_0)^{-k_0}$. Applying $R_0 = 3$ and $k_0 = 0.16$ to this formular results in $p_0 = 0.62$, close to the value calculated from the data and well within the 90% confidence intervals provided for estimates of p_0 from both Singapore and Beijing data. With this evidence in hand, it is assumed that the k_0 value estimated by Lloyd-Smith et al. is a reasonable estimate for use in this RA in conjunction with the assumed base case R_0 value.

To generate an uncertainty distribution for k_0 , one of the procedures used by Lloyd-Smith et al. (2005) was employed (the authors used five statistical different methods to assess uncertainty in k_0 , and resulting 90% confidence intervals were similar across all five methods). Specifically, a parametric bootstrap sampling distribution was created by simulating 10,000 data sets of size $N = 40$ (close to the size of the data sets from Singapore and Beijing outbreaks) of randomly drawn numbers from the negative binomial distribution with mean $R_0 = 3$ and dispersion parameter $k_0 = 0.16$, and then calculating the maximum likelihood value of k_0 from each simulated dataset. The 10,000 values of k_0 were then used to generate random values of the paramter under the latin hypercube sampling scheme in the same manner that confidence intervals were calculated using the bias-corrected percentile method in Lloyd-Smith et al. (2005) and references therein. This procedure resulted in a 90% of randomly chosen values falling in the range (0.10 – 0.30), which is very similar to the confidence intervals reported in Lloyd-Smith et al.

(2005). This similarity is evidence that the distribution of k_0 is not very sensitive to the choice of R_0 or to the size of the simulated data sets, which were different in the cited reference.

Mean post-control reproductive number R_c

The parameter R_c is the average number of transmissions per infected individual after control measures for the pathogen have been implemented. For SARS, the value of R_c has been estimated in a number of studies using data from locations in which a SARS outbreak occurred and control measures were implemented to reduce further transmissions. Lloyd-Smith et al. calculated $R_c = 0.68$ for the Singapore outbreak (generations 4 through 7 of transmission) and $R_c = 0.28$ for the Beijing outbreak (generations 3 and 4 of transmission). Wallinga and Teunis (2004) estimated R_c using a likelihood-based estimation procedure on case incidence data after the first global alert on SARS in four locations where an outbreak had already begun at that time (the assumption being that control measures would have started at that time in all locations). They calculated $R_c = 0.7$ for Hong Kong (95% confidence interval: 0.7, 0.8), $R_c = 0.3$ for Vietnam (95% confidence interval: 0.1, 0.7), $R_c = 0.7$ for Singapore (95% confidence interval: 0.6, 0.9), and $R_c = 1.0$ for Canada (95% confidence interval: 0.9, 1.2). Overall, they chose $R_c = 0.7$ for use in simulations.

Following Wallinga and Teunis, a base case value of $R_c = 0.7$ for SARS-CoV was applied for this RA. This value is consistent with the fact that every SARS outbreak in locations around the world was eventually brought under control. To cover lower or higher values estimated in studies cited in the previous paragraph, a range of 0.3–1.1 was applied as part of the uncertainty analysis. Specifically, a triangular distribution with mode 0.7, minimum 0.3, and maximum 1.1 was applied. Values near the maximum serve to test the implications of the possibility that control measures are barely able to stem transmission enough to bring an outbreak under control.

Shape / dispersion parameter k_c

Lloyd-Smith et al. (2005) calculated values of k_c based on transmission data from Singapore and Beijing after control measures were implemented at each location. The interpretation of and procedure for calculating the parameter are the same as described above for k_0 . The Beijing dataset was smaller and consisted almost entirely of cases not transmitting at all, so the analysis was unable to provide a confidence interval for k_c under the bootstrap resampling procedures. The Singapore dataset was sizable (114 cases), more amenable to a full uncertainty analysis on k_c , and more consistent with the base case estimate of R_c used for this risk assessment. Therefore, the results from model fitting to the Singapore data set are used as the base case estimate ($k_c = 0.071$), and an uncertainty distribution is generated using

parametric bootstrap resampling as described above in conjunction with the parameter k_0 . This procedure generates a 90% of estimates in the range (0.047, 0.13), which is well in line with the results from alternate procedures for generating confidence intervals as described in Lloyd-Smith et al. (2005).

Generation time (T_g)

Lipsitch et al. (2003) analyzed serial interval (generation time) data from 205 probable SARS cases in Singapore and found that the Weibull distribution, with mean 8.4 days and standard deviation 3.8 days, provided a good fit. Wallinga and Teunis (2004) chose the same distribution for use in their stochastic simulations. This distribution is used for simulations of SARS outbreaks for this RA, where the time between the onset of symptoms within each pair of cases involved in each transmission is drawn randomly from the given Weibull distribution. Uncertainty in the Weibull distribution parameters is not included in the analysis. The distribution provided a good fit to a large dataset consisting of observable events (onset of symptoms), so it is assumed that the estimated mean and standard deviation are relatively accurate values for SARS. Furthermore, the generation time affects the estimates for the overall size of outbreaks through its relationship to the delay in implementation of control measures. Therefore, it is assumed that testing the uncertainty range of this delay also covers the potential implications of the average generation time being less or greater than 8.4 days.

Delay in implementation of control measures (T_c)

Singapore: Counting from the date of onset of symptoms of the first case (day zero), the Singapore government was first notified of cases of atypical pneumonia on day 9 but were not yet aware that a SARS outbreak was occurring. WHO's first global alert on SARS was administered on day 15 and second global alert on day 18, after which transmission rates may have decreased in Singapore due to informal behavioral changes or hospital precautions. Centralized control measures were implemented in Singapore on day 25 and intensified on day 27 and further on day 43. In the analysis of Lloyd-Smith et al. (2005), it was assumed that the first implementation of centralized control measures was the point at which average transmission rates were reduced from R_0 to R_c , representing a value of T_c of about 25 days. This led to their assumption that the first three generations of transmission occurred under pre-control transmission rates and that control measures affected transmission rates starting in generation four.

Beijing: Lloyd-Smith et al. (2005) analyzed a SARS outbreak that occurred at a specific hospital in Beijing. They estimated that two generations of transmission occurred before the hospital implemented control policies to reduce contact rates. Assuming an average generation time of 8.5 days, this assumption would translate to a value of T_c of about 17 days.

1
2 Wallinga et al. assumed that the WHO's first global alert on SARS (March 12, 2003) represented the
3 transition from pre- to post-control average transmission rates for outbreaks in Hong Kong, Vietnam,
4 Singapore, and Canada. In those four locations, the first cases were introduced in late February. This,
5 then, is equivalent to an assumption of T_c equalling approximately 2–3 weeks.

6
7 Gumel et al. (2004) ran simulations assuming a date of March 30, 2003 for the beginning of quarantine
8 and isolation procedures to reduce the assumed rate of contacts in their model for outbreaks in Toronto,
9 Hong Kong, Singapore, and Beijing. Given that outbreaks started in those cities in late February, the
10 assumption was equivalent to using a value of T_c of approximately 4–5 weeks. They note that “in reality,
11 quite effective control measures were probably put into place at least as early as mid-March, but given we
12 are using a step function as an approximation for their implementation, choosing a slightly later starting
13 date is warranted” (Gumel 2004, Electronic Appendix B).

14
15 The studies described above, which used a framework for modeling the effect of control measures as a
16 step function in time similar to what is used in this RA, assumed values for T_c in the range of 2–5 weeks.
17 It is noted that these studies analyzed historical outbreaks of SARS that began during a time when SARS-
18 CoV had not yet been identified as the cause of the cases being seen and the epidemiology of and most
19 effective strategies for curbing SARS transmission were only beginning to be understood. It is assumed
20 that, if a new SARS outbreak were to begin in the present day, health officials would have a much better
21 chance of identifying the source of early cases and implementing effective control strategies in a more
22 timely manner than was possible in 2003 when SARS-CoV was first emerging.

23
24 An optimistic scenario would be that the first case to develop symptoms would suspect the source of
25 infection (for example, a laboratory worker who was unknowingly exposed but would likely be wary of
26 SARS-like symptoms during periods of experimental work with SARS-CoV). In this scenario, even if the
27 initial case transmitted infection to others during the early stages of the symptomatic period, health
28 officials would have a good chance of implementing effective control strategies before the second
29 generation of cases became symptomatic themselves, using the lessons learned from the SARS outbreaks
30 that occurred in 2003. This scenario is represented by assuming a minimum value of 3 days for the value
31 of T_c , which is less than half of the assumed average generation time for SARS.

32
33 A more conservative scenario would be that early cases of an outbreak would not suspect or report that
34 SARS-CoV was a possible source of infection, that health officials would not immediately diagnose early

cases, and/or that hospitals would delay in implementing effective control strategies due to ineffective preparation or imperfect execution of recommended policies. This scenario is represented by assuming a maximum value of 17 days for T_c , which is twice the assumed average generation time for SARS. This allows for the possibility that two and possibly three generations of transmission (or even more for a chain of below-average generation times) could occur before the transition.

The base case value was set at $T_c = 10$ days, the average of the minimum (3 days) and maximum (17 days) assumed values. It is not assumed that any delay within the range is more likely to occur than another; therefore, a uniform distribution across the range is applied for the uncertainty analysis.

Summary

Table L–17: Summary of assumed parameter values for SARS-CoV transmission model

Parameter	Base Case Value	Uncertainty Distribution
R_0	3.0	Triangular (mode = 3.0, min = 2.0, max = 4.0)
k_0	0.16	Parametric Bootstrap (90% interval: 0.10, 0.30)
R_c	0.7	Triangular (mode = 0.7, min = 0.3, max = 1.1)
k_c	0.071	Parametric Bootstrap (90% interval: 0.047, 0.13)
T_g	8.5 days	N/A
T_c	10 days	Uniform (min = 3, max = 17)
CFR	10%	N/A

L.3.5.2 Transmission Results – Base Case

Given the introduction of one initially infected individual into the population, 500,000 simulations were run under the base-case input parameters listed in Table L–17. A summary of the results of the output from these simulations for secondary infections and deaths are presented in the following table.

Table L–18: SARS-CoV base case results – number of public infections and fatalities given the occurrence of one undetected / unreported initial infection (urban site)

Consequence		Number of simulations in which consequence occurred (of 500,000)	
		Total	Among Boston City Residents
Number of Public Infections	1 or more	189233 (38%)	139175 (28%)
	10 or more	104160 (21%)	59252 (12%)
	100 or more	44085 (8.8%)	14906 (3.0%)
	1,000 or more	1160 (0.2%)	43 (0.009%)
	10,000 or more	0 (<0.0002%)	0 (<0.0002%)
Number of Public Fatalities	1 or more	119968 (24%)	73948 (15%)
	10 or more	45319 (9.1%)	15956 (3.2%)
	100 or more	1253 (0.3%)	44 (0.009%)
	1,000 or more	0 (<0.0002%)	0 (<0.0002%)

These results suggest that, under the base case assumptions, a laboratory worker infected with SARS-CoV who enters the public would have about a 38% chance of transmitting infection to at least one contact. Under the commuting assumptions described in Section L.2.5, there is a chance that the worker would not live in Boston, which explains why the chance drops to 28% for at least one secondary infection occurring among Boston residents. There is an estimated 8.8% chance that an outbreak would grow to 100 total cases and 0.2% chance of 1,000 total cases. The estimated 10% case fatality for SARS-CoV leads to an estimate of a less than 10% chance of 10 or more total fatalities occurring (less than 5% chance among Boston residents).

L.3.5.3 Transmission Results – Uncertainty

The input parameter uncertainty distributions summarized in Table L–17 were simultaneously applied within the Latin hypercube sampling scheme described in the methodology. One hundred sets of input parameters were generated, and 10,000 simulations were run under each set of parameters to generate alternate estimates for the chance of public infections and fatalities after an undetected or unreported initial infection. The following table summarizes the range of estimates found for each designated consequence. Each range was generated by sorting the 100 different estimates and dropping the lowest two and the highest two, so that 96% of the estimates are within or at the boundaries of the range. The base case results are also displayed in the table for reference.

Table L–19: SARS-CoV base case and uncertainty results – number of public infections and fatalities given the occurrence of one undetected / unreported initial infection (urban site)

Consequence		Estimated Chance of Consequence (given one undetected / unreported initial infection)	
		Total	Among Boston City Residents
Number of Public Infections	1 or more	38% (28% to 55%)	28% (20% to 39%)
	10 or more	21% (15% to 34%)	12% (6.7% to 19%)
	100 or more	8.8% (1.5% to 20%)	3.0% (0.3% to 9.2%)
	1,000 or more	0.2% (≈0 to 9.7%)	0.009% (≈0 to 2.1%)
	10,000 or more	<0.0002% (≈0 to 4.4%)	<0.0002% (≈0)
	100,000 or more	<0.0002% (≈0 to 2.8%)	<0.0002% (≈0)
Number of Public Fatalities	1 or more	24% (17% to 36%)	15% (10% to 24%)
	10 or more	9.1% (1.8% to 20%)	3.2% (0.4 to 9.4%)
	100 or more	0.3% (≈0 to 9.7%)	0.009% (≈0 to 2.0%)
	1,000 or more	<0.0002% (≈0 to 4.4%)	<0.0002% (≈0)
	10,000 or more	<0.0002% (≈0 to 2.8%)	<0.0002% (≈0)

“≈0” at the lower end of an uncertainty range means that the given consequence was not observed in any of the simulations under at least three of the 100 input parameter combinations; when appearing as the entire range, then the consequence was not observed for at least 98 of the 100 parameter combinations.

The results for the consequence of one or more public infections suggest that about 28-55% is a reasonable range for the chance that an initially infected individual would transmit infection, and about 20-40% for the chance that a Boston resident becomes infected. The uncertainty ranges for larger outbreaks are relatively narrow compared to those for 1918 H1N1V, but still notable. At one extreme, some sets of parameters lead to estimates suggesting that an outbreak reaching 100 total infections or 10 total fatalities would be less than 2%. At the other extreme, some parameter combinations produce estimates of about a 3% chance that a single initial case would cause an essentially unchecked outbreak.

The most extreme, high consequence estimates are only possible if it is assumed that the parameter R_c is greater than one, meaning that an outbreak that initially grows large and spreads over a wide area would remain uncontrolled. It should be noted that R_c staying above one for an extended period is potentially unrealistic, as public health officials in all areas would presumably step up control measures to more stringent levels in the face of a very large outbreak. However, these upper-limit results reflect the

implications of the possibility of an outbreak in which control of transmission remains elusive, a scenario which cannot entirely be ruled out.

The Boston resident results show about a 2% chance or less of an outbreak reaching 1,000 infections and 100 fatalities among residents, even under extreme parameter assumptions. This is because the commuting assumptions and decreasing population susceptibility tend to reduce the effective R_c below the threshold required for long-term sustained resident-to-resident spread.

L.3.5.4 Transmission results linked to event sequences

The results in the previous section are estimates of the chance of public infections and fatalities *given that one initially infected individual enters the community*. The initial infection analyses from Chapter 8 and Appendix K provide estimates for the average frequency of such an initiating event occurring, for three different scenarios. The estimates for SARS-CoV were as follows.

Table L–20: Summary of SARS-CoV initial infections results

Event	Frequency Range
Undetected / Unreported Needlestick Infection	1 in 100 to 10,000 years
Undetected / Unreported Centrifuge Release and Infection	1 in 9,100 to 600,000 years
Earthquake Release and Infection	1 in >10 million years

Of these three events, an undetected or unreported needlestick infection extends to a higher frequency range than the other two events. The centrifuge infection event is within the needlestick range at the high end of the uncertainty range, but the range also contains a substantial portion of estimates for lower frequencies. Therefore, the frequency range for needlestick infection is applied in the remainder of this section as the representative event for estimating the frequency of public infections and fatalities.

The exact frequency for the needlestick event is uncertain, and no basis for was found for assuming a most likely frequency within the range. Therefore, a distribution of frequencies across the given range is applied as an additional layer of uncertainty within the overall Latin hypercube sampling scheme. Random return periods are drawn from a uniform distribution across the range (100 years to 10,000 years), and the frequency is calculated by taking the inverse. A given needlestick frequency is then multiplied by a probability of a given consequence (public infections or fatalities due to transmission) to

calculate the estimated frequency of that consequence. This results in a range of estimated frequencies for each consequence. A sampling of these ranges is shown in the following table.

Table L–21: SARS-CoV uncertainty results – frequency of public infections and fatalities due to an undetected / unreported needlestick (urban site)

Consequence		Frequency Range	
		Total	Among Boston City Residents
Number of Public Infections	1 or more	1 in 760 to 27,000 years	1 in 1,000 to 37,000 years
	10 or more	1 in 1,100 to 59,000 years	1 in 1,800 to 120,000 years
	100 or more	1 in 2,500 to 440,000 years	1 in 5,600 to 3.2 million years
	1,000 or more	1 in 23,000 to >10 million years	1 in 160,000 to >10 million years
	10,000 or more	1 in 67,000 to >10 million years	1 in >10 million years
	100,000 or more	1 in 260,000 to >10 million years	1 in >10 million years
Number of Public Fatalities	1 or more	1 in 1,000 to 47,000 years	1 in 1,600 to 80,000 years
	10 or more	1 in 2,500 to 350,000 years	1 in 5,300 to 1.9 million years
	100 or more	1 in 23,000 to >10 million years	1 in 170,000 to >10 million years
	1,000 or more	1 in 67,000 to >10 million years	1 in >10 million years
	10,000 or more	1 in 260,000 to >10 million years	1 in >10 million years

The following table provides more insight into the distribution of estimated frequencies for each consequence, in terms of the portion of each distribution falling in each of the four frequency categories.

Table L–22: SARS-CoV uncertainty results – frequency categories for public infections and fatalities due to undetected / unreported needlestick (urban site)

Consequence		Percentage of 100 estimates falling in each category							
		Total				Among Boston Residents			
		A	B	C	D	A	B	C	D
Number of Public Infections	1 or more	0	40%	60%	0	0	30%	70%	0
	10 or more	0	22%	78%	0	0	9%	91%	0
	100 or more	0	7%	93%	0	0	3%	90%	7%
	1,000 or more	0	1%	42%	57%	0	0	14%	86%
	10,000 or more	0	0	7%	93%	0	0	0	100%
	100,000 or more	0	0	4%	96%	0	0	0	100%
Number of Public Fatalities	1 or more	0	28%	72%	0	0	14%	86%	0
	10 or more	0	8%	92%	0	0	3%	91%	6%
	100 or more	0	1%	42%	57%	0	0	15%	85%
	1,000 or more	0	0	7%	93%	0	0	0	100%
	10,000 or more	0	0	4%	96%	0	0	0	100%

A = 1 in 1 to 100 years; B = 1 in 100 to 10,000 years; C = 1 in 10,000 to 1 million years; D = 1 in >1 million years

The results in the above table for the highest consequences reveal that the most extreme 4% of parameter estimates place the frequency of a widespread uncontrolled outbreak within frequency category C. On the other hand, most estimates (57%) for 100 or more fatalities fall in frequency category D (less than one in one million years).

Finally, estimated ranges of frequencies for different consequences are conveyed graphically in Figure L–3. In the figure, numbers of fatalities are plotted against the estimated frequency with which a needlestick event leading to at least that number of fatalities in the public would be expected to occur. Under a given set of transmission parameters and a given needlestick frequency, a curve can be generated by connecting the points calculated by multiplying the needlestick frequency by the estimated chance that at least the given number of fatalities would occur in the public. A different curve exists for each of the 100 sets of input values that were used in the uncertainty analysis. Rather than plotting all 100 curves, four curves are displayed, which form base case boundaries (thick curves) and full uncertainty boundaries (thin curves).

The base case boundaries were formed by multiplying the 95% uncertainty range for the needlestick frequency by the base case estimates from the secondary transmission analysis. The full uncertainty range represents the combined effects of uncertainty in the needlestick frequency and uncertainty in the secondary transmission parameters. By choosing a given number of fatalities on the horizontal axis, one can move vertically up the figure to find the boundaries for the estimated frequency range for that consequence.

Figure L-3: Risk curves for total public fatalities from SARS-CoV due to undetected / unreported needlestick, urban site

L.3.5.5 Sensitivity Analysis

The uncertainty apparent in results from the previous section is driven by uncertainty in the input parameter values. The output for the frequency of needlestick events leading to large numbers of mortalities (500 or more) is most sensitive to the value of the input parameter R_c , the post-control reproductive number. For example, all six outputs for the frequency of a 1000-or-more mortality outbreak that fell in the LOW frequency category occurred using the parameter combinations with the six highest values of R_c (ranging from 0.97 – 1.1), despite the fact that all the other parameters varied extensively within those six combinations. The other parameters play a larger role in affecting output uncertainty for the frequency of events leading to smaller-sized outbreaks. The following table lists PRCC values for the six relevant parameters in relation to various outputs.

Table L–23: Sensitivity Results – Partial Rank Correlation Coefficients. The effect of changing each input on the estimated frequency of needlestick events leading to the given number of mortalities

Number of fatalities	R_0	k_0	R_c	k_c	T_c	Needlestick frequency
1 or more	0.40	0.80	0.19	–0.00*	0.55	0.98
10 or more	0.44	0.28	0.59	0.01*	0.81	0.90
100 or more	0.55	–0.30	0.89	–0.28	0.87	0.59

*Not statistically significantly different than zero ($p > 0.2$). All other entries are statistically significantly different than zero ($p < 0.05$).

Discussion:

- R_0 – the basic reproductive number plays a significant role in determining the estimates for each output, although other parameters play a larger role in each case. As the assumed value of R_0 is increased, the estimated frequency of mortalities tends to increase as well.
- k_0 – the dispersion parameter associated with variation around R_0 plays a large role in the estimated frequency of 1 or more deaths occurring, because the higher value of k_0 results in a higher probability that early cases will transmit and start an outbreak. This effect is diminished for the estimates of higher numbers of deaths. For 100-or-more deaths, the effect of k_0 is reversed, with smaller values of k_0 resulting in higher estimated frequencies. This reversal reflects the fact that smaller values of k_0 result in increased probability of both no transmissions occurring and of a large number of transmission occurring from a particular individual.

- R_c – The post-control reproductive number has a small effect on the estimated frequency of smaller numbers of deaths occurring, and a large effect on the estimated frequency of large outbreaks. As discussed above, R_c plays a dominant role in affecting the estimated frequency of very large outbreaks occurring (the PRCCs are difficult to calculate for these extreme events, as most simulations do not produce any outbreaks that large and thus are not amenable to direct calculation of frequencies).
- k_c – the dispersion parameter associated with variation around R_c does not have a statistically significant effect on the estimated frequencies for smaller numbers of mortalities occurring. It does affect the estimated frequency of a 100-or-more mortality outbreak, with smaller values of k_c resulting in higher frequency estimates. This occurs because smaller values of k_c result in higher estimated probabilities that individuals would transmit to atypically large numbers of contacts despite the fact control measures are in place.
- T_c – the delay in implementation of control measures has a significant effect on all estimates, with longer delays resulting in higher frequency of outbreaks leading to mortalities. This effect becomes large for higher-consequence events.
- Needlestick frequency – the estimated frequency with which needlestick events occur has the largest effect on the estimated frequency of smaller numbers of deaths occurring. The relative effect of this input becomes smaller for the estimates of higher-consequence event frequencies.

L.3.6 Rift Valley fever virus

Rift Valley fever virus is an RNA virus in the larger family of viral hemorrhagic fevers and causes Rift Valley fever. There is no direct person-to-person transmission of RVFV; transmission to humans is via arthropod vectors or by contact with infected animal products. Cattle, sheep, and goats serve as the primary amplifier of the virus. Upon developing adequate viremia, humans may also serve as a virus reservoir for mosquitoes.

There is a limited literature on disease transmission models of RVFV involving animals, arthropod vectors and human hosts. Several models have addressed other complex variables such as climate conditions and livestock in the prediction and transmission of RVFV in endemic areas (Clements, Pfeiffer et al. 2006; Favier, Chalvet-Monfray et al. 2006; Anyamba, Chretien et al. 2009; Metras, Collins et al. 2011; Mpeshe, Haario et al. 2011). The applicability of these published models and epidemiologic,

climate and livestock data to conditions in the US, specifically to NEIDL sites under study in the RA is unknown. Furthermore, data on ruminants and mosquito vectors are not uniformly available in a format suitable for use in secondary transmission modeling. For these reasons, secondary transmission modeling of spread of infection in the community following a loss of bio-containment is not performed for RVFV.

The needlestick, centrifuge release and earthquake release scenarios involving RVFV are considered and the subsequent potential for secondary transmission of RVFV in the community via arthropod vectors and infected animal products is qualitatively analyzed.

An initial infection after a needlestick event without prompt detection and reporting was estimated to occur in frequency category B (between once per 100 years and once per 10,000 years). An initial infection with RVFV following a centrifuge release event was estimated, under a higher risk set of dose response assumptions, to occur in frequency category A or B (between about once per 10 years and once per 300 years). An initial infection occurring in a member of the public after exposure to RVFV released during an earthquake event was estimated to occur in frequency category C (between about once per 10,000 years and once per 1 million years) (Appendix K).

In the event that a laboratory worker or a member of the public develops Rift Valley fever from any of the above events, there is no possibility of directly transmitting the virus to the workers' close social contacts. However, secondary transmission could potentially occur from an initially infected laboratory worker or member of the public developing sufficiently high viremia (virus in the blood) and then being bitten by a mosquito vector belonging to a permissive species. This mosquito could act as a biological vector and transmit the virus to another human while taking its next blood meal. This scenario is possible but considered unlikely because i) the primary amplifiers of RVFV are ruminants; ii) it is rare for humans to serve as a virus reservoir; and iii) very few permissive species of mosquitoes are native to the area.

Similarly, it is possible but unlikely that an initially infected laboratory worker or member of the public would transmit infection via mosquito to ruminants; hence it is considered unlikely that secondary transmission to other humans would occur via infected ruminants. This scenario is distinct from the issue of establishment of RVFV in the environment after a release which is discussed in Chapter 8.

L.3.7 Andes virus

Andes virus is a New World hantavirus that causes a severe cardio-pulmonary syndrome (HPS). A unique feature of ANDV is that direct person-to-person transmissions of ANDV have been reported. There are

reports of HPS in close contacts with genetic evidence of person-to-person transmission, from earlier outbreaks in the 1990s to more recent cases. In these circumstances, transmission generally occurred in close family contacts who exchanged bodily fluids, with evidence of ANDV RNA found in saliva of patients. (Enria, Padula et al. 1996; Padula, Edelstein et al. 1998; Martinez, Bellomo et al. 2005; Castillo, Nicklas et al. 2007; Lazaro, Cantoni et al. 2007). A recent study that prospectively studied 476 household contacts of 76 index patients with HPS in Chile found 16 contacts developed confirmed HPS (3.4%) (Ferres, Vial et al. 2007). A third of all the cases occurred in family clusters. Person-to-person transmission was definite in only 3 household contacts and probable in another 9. Sexual contacts were at the highest risk for HPS in this study.

In other reports from Argentina, 16 cases of HPS were suspected to be due to person-to-person transmission, though contact or exposure to rodents could not be completely ruled out for a majority of those patients (Wells, Sosa Estani et al. 1997; Cantoni, Padula et al. 2001). There did not appear to be any hospital- or healthcare-associated person-to-person transmission in one outbreak in Chile (Castillo, Villagra et al. 2004). Other reports have described cases in health care workers (Lopez, Padula et al. 1996; Wells, Sosa Estani et al. 1997; Toro, Vega et al. 1998; Mertz, Hjelle et al. 2006).

In summary, direct person-to-person transmission of ANDV has been documented; though the extent of this transmission is limited to close family and possibly health care contacts and has not resulted in large outbreaks of HPS. Moreover, there are limited studies available to provide epidemiologic data for detailed secondary transmission modeling and no published mathematical models for this pathogen. For these reasons, secondary transmission modeling of spread of infection in the community following a loss of bio-containment is not performed for this pathogen.

L.3.8 Ebola virus

Person-to-person transmission of EBOV has been observed during several outbreaks that have occurred in Africa (Legrand 2006). Several studies on epidemiological parameters and quantitative transmission modeling of EBOV exist in the literature. Therefore, EBOV was selected for detailed quantitative modeling of potential secondary transmission, for purposes of assessing the risk posed to members of the public under the release scenarios analyzed in this RA. The remainder of this section describes the specification of the quantitative transmission modeling procedure for EBOV and summarizes the modeling outputs.

L.3.8.1 Specification of branching process model

This section describes the parameters, distributions, and assumptions used for specifying the branching process model to outbreak simulations for EBOV.

Individual reproductive number ν

The individual reproductive number ν is a random variable describing the expected number of transmissions from an infected individual. Lloyd-Smith *et al.* (2005) attempted to compare the ability of three different distributions of the individual reproductive number, ν , to describe the spread of transmission numbers from each infected individual documented in a small data set from an EBOV outbreak. They were unable to demonstrate that any of the distributions were clearly superior to the others, suggesting that the simplest assumption, i.e., no variation in ν , might be most appropriate. However, they state that these results must be interpreted with caution, because the data set is small (13 cases), and they suspected that this subset of cases was biased towards cases that had transmitted and therefore was not a fair representation of variation in transmission that occurred during the outbreak.

In addition, Lloyd-Smith *et al.* (2005) identified three documented examples of EBOV transmission that were characterized as superspreading events, or cases where a single infected individual transmitted infection to an unusually high number of others (21–46 transmissions per case). These individuals were not included in the data set described above. If it is assumed that there is no variation in ν , then numbers of transmissions per case in the simulations would be drawn from a Poisson distribution with mean R , and under those assumptions, combined with the base case estimate for R_0 (see below), the probability of one case transmitting to more than 20 others is virtually zero. Given that the potential for occurrence of such extreme events would have important implications for this risk assessment, it was determined that it would be appropriate to assume a distribution for ν that can allow for the possibility (i.e., small but nonzero probability) of a large number of transmissions from a single case.

Therefore, the gamma distribution for ν is applied with mean R and shape parameter k which has a probability density function f defined as

$$f(x) = \frac{(k/R)^k}{\Gamma(k)} x^{k-1} e^{-kx/R}.$$

Varying the value of the parameter k serves to cover all distributions tried by Lloyd-Smith *et al.* (2005), so that the implications of the commonly used characterizations can be tested as part of the uncertainty

analysis (see discussion below under the parameter k_0). The gamma distribution is used both before the implementation of control measures, using R_0 and k_0 as the two parameters, and also after the implementation of control measures, using R_c and k_c as the two parameters. The values of these four parameters to be applied are discussed as follows.

Mean reproductive number R_0

The mean reproductive number R_0 for EBOV has been estimated by several studies which made use primarily of data from one or both of two relatively large outbreaks, one that occurred in the Democratic Republic of Congo (DRC) in 1995 involving 315 cases (Khan 1999) and one that occurred in Uganda in 2000 involving 425 cases (Oyok 2001). The R_0 estimates derived from these data sets by several authors are summarized in Table L–24.

Table L–24: Estimates of R_0 for EBOV from the literature

Citation	R_0 estimate for DRC 1995 outbreak	R_0 estimate for Uganda 2000 outbreak
Chowell 2004	1.83 (sd 0.06)	1.34 (sd 0.03)
Ferrari 2005	3.65 (3.05–4.33)	1.79 (1.52–2.30)
Lloyd-Smith 2005	-	1.50 (0.85–2.08) ^a
Légrand 2006	2.7 (1.9–2.8)	2.7 (2.5–4.1)
Lekone 2006	1.359 (sd 0.128)	-
White 2008	1.93 (1.74–2.78)	-
Clancy 2008	1.3–1.7	-
McKinley 2009	2.0 (sd 0.21) or 1.5 (sd 0.17)	-

^a based on a subset of 13 cases for which contact tracing data were available
sd = standard deviation

Conflicting estimates of R_0 based on the same data set can be explained by the fact that the data give only indirect clues to what R_0 might be, and there is a wide variety of mathematical models, statistical techniques, and associated assumptions that can be applied to arrive at an estimate. The highest estimate, by Ferrari et al. (2005) based on the DRC data, is not supported by any of the other estimates based on the same data set, as the confidence interval does not overlap any of the others. The same is true for the estimate by Légrand et al. (2006) for the Uganda outbreak. Their estimate based on the DRC data is also high, although the confidence interval overlaps other estimates. Overall, the estimates seem to favor values for R_0 in the range 1.3–2.0.

It is worth considering the fact that these outbreaks occurred in Africa, in an environment that differs in many ways from the sites at which transmission risk is being assessed for this RA. The value of R_0 is

1 partially a function of the environment and the community in which an outbreak takes place, because the
2 chance of transmissions occurring is affected by behavior, contact patterns, hygiene, environmental
3 conditions, and cultural practices. Some specific features of the areas where Ebola outbreaks occurred
4 were thought to have played a role in amplifying transmission, such as caregiving systems, certain aspects
5 of indigenous healing practices, and aspects of burial and funeral practices (Dowell 1999, Roels 1999,
6 Hewlett 2003).

7
8 However, it is unclear how much these location-specific features might have contributed to the estimates
9 of R_0 above and whether it would be warranted to assume that R_0 would be different during an outbreak in
10 a different location. One follow-up study of the Uganda outbreak (Hewlett 2003) determined that people
11 abandoned the riskiest cultural practices once they realized that an unusual outbreak was taking place, so
12 the potential amplification of transmission would have occurred only very early in the outbreak. A
13 quantitative study (Legrand 2006) attempted separate R_0 into components to determine how much
14 transmission could be attributed to transmission from hospitalized patients, transmission from deceased
15 persons during burial or funerals, and transmission in the general community. Their results suggested that
16 the “traditional burial component” may have been quite significant during the DRC outbreak, but that the
17 Uganda outbreak was dominated by the “community component.” However, the uncertainty ranges
18 around their component R_0 estimates were quite large, so these results are statistically inconclusive.

19
20 Given the lack of evidence to support a quantitative adjustment of Africa-based R_0 estimates to a different
21 location, the R_0 range 1.3–2.0 as stated above is applied for this RA. A uniform distribution over this
22 range is applied in the uncertainty analysis, and the center of the range, $R_0 = 1.65$, is applied as the base
23 case estimate.

24 25 **Shape / dispersion parameter k_0**

26 The parameter k_0 found in the probability density function of the gamma distribution (see equation under
27 individual reproductive number ν above) is often called the “shape” parameter of the distribution. If the
28 mean (in this case, R_0) is held constant, and the value of k_0 is changed, the shape of the distribution
29 changes, causing the variance of the distribution to increase as k_0 decreases. Specifically, the variance is
30 calculated as R_0^2/k_0 . The random variable ν for the individual reproductive number is assumed to be
31 gamma-distributed with mean R_0 and shape parameter k_0 . Then the random variable Z for the actual
32 number of transmissions from an infected individual is assumed to be Poisson distributed with mean ν . A
33 Poisson-distributed random variable with a mean that is gamma-distributed with mean R_0 and shape
34 parameter k_0 has a negative binomial distribution with mean R_0 and “dispersion parameter” k_0 .

As described under the discussion of the individual reproductive number ν , there is no reliable estimate of k_0 in the literature due to lack of data. Therefore, a range of values is implemented in order to investigate the implications of various assumptions about the nature of variation in transmission for EBOV. At one extreme, lower values of k_0 would imply a higher likelihood that an atypically large number of transmissions would occur from an individual. Conversely, lower k_0 values also imply a higher likelihood of no transmissions occurring from an individual, such that the average number R_0 is maintained. While there is no estimate of the percentage of cases not transmitting to anyone, there are three documented cases, among approximately 2000 confirmed cases that have occurred (Legrand 2006), of individuals transmitting to 20 or more others (Lloyd-Smith 2005). With these cases in mind, a lower limit value of $k_0 = 0.5$ is chosen. When combined with the assumed range of R_0 values given above, $k_0 = 0.5$ leads to approximately a 1-in-400 to 1-in-4000 chance of observing more than 20 transmissions from a single case.

At the other extreme, very high values of k_0 imply very low variation in ν from person-to-person (k_0 approaching infinity implies no variation), which could not be ruled out as an appropriate characterization for EBOV transmission (Lloyd-Smith 2005). To capture this possibility along with the low extreme in the uncertainty range, a continuous uniform distribution is applied for the inverse, $1 / k_0$, on the range 0–2, so that values near 2 imply k_0 near 0.5, and values near 0 imply large k_0 . The median of this distribution, at which $k_0 = 1$, is applied as the base case estimate. This value is a special case implying that ν is exponentially distributed, which is a common assumption made in conjunction with differential equation models of disease spread (Lloyd-Smith 2005), including models that have had success in fitting EBOV outbreak data sets (Chowell 2004).

Mean post-control reproductive number R_c

The parameter R_c is the average number of transmissions per infected individual after control measures for the pathogen have been implemented. All 14 confirmed EBOV outbreaks listed by Legrand et al. (2006) were eventually controlled, with total cases ranging from 12–425, and even the largest outbreak sizes are a very small percentage of the total population of the local area who might have been at risk if the outbreak had continued. This evidence strongly suggests that control measures were successful in reducing transmission such that $R_c < 1$. Control measures consisted of isolation of infected patients, quarantine of potentially exposed contacts (feasible due to relatively long incubation periods), reduction of social gatherings in the area, use of barrier precautions in treating symptomatic cases, and careful handling and burial deceased cases (WHO 2008).

Chowell et al. (2004) quantified values of R_c (R_p in their terminology) based on outbreak data and found $R_c = 0.51$ for the DRC outbreak and $R_c = 0.66$ for the Uganda outbreak, which are two of the largest outbreaks that have been documented. Given these data and the lack of any evidence for R_c being close to or above the $R_c = 1$ threshold, a uniform distribution on the range 0.4 to 0.8 is applied in the uncertainty analysis, with $R_c = 0.6$ as the base case.

Shape / dispersion parameter k_c

The same base case value and range applied for k_0 are also applied for k_c .

Generation time (T_g)

The average generation time for EBOV transmission appears not to have been measured directly, although estimates of the average incubation period of 6.3 days (Breman 1977), estimates of various symptoms lasting between 3.5 and 10.7 days before death or recovery (Piot 1977), and suggestions that transmissions usually occur during the peak or towards the end of the symptomatic period (Dowell 1999), point to an average generation time on the order of 10 days. However, these estimates are subject to substantial variation. For example, incubation periods have been observed to be as short as 1 day and as long as 21 days (Breman 1977).

Some modeling studies estimate average generation times shorter than ten days. White and Pagano (2008) estimated the generation time (serial interval) using statistical inference methods on the DRC 1995 outbreak data set and arrived at an estimate of 5.82 days (interquartile range 5.43–7.60 days), with associated variance 17.40 days² (10.02–19.43) under the assumption of a gamma-distributed serial interval. Chowell et al. (2004), based on model fitting to the Uganda outbreak data, estimated a mean incubation period of 3.35 days and a mean infectious period of 3.50 days, which together are roughly consistent with the White and Pagano estimate. For the DRC outbreak, the Chowell et al. estimates of the incubation and infectious periods are higher (5.30 and 5.61 days, respectively), although still potentially consistent with the range of generation times estimated by White and Pagano.

Given that the data from direct observations are spotty and that the estimate from White and Pagano is reasonably consistent with other estimates and observations, their estimate is applied for this RA: a gamma distributed generation time with mean 5.82 days and variance 17.4 days². Uncertainty in the gamma distribution parameters is not included in the analysis. The generation time affects the estimates for the overall size of outbreaks through its relationship to the delay in implementation of control

measures. Therefore, it is assumed that testing the uncertainty range of this delay also covers the potential implications of the average generation time being less or greater than 5.82 days.

Delay in implementation of control measures (T_c)

Estimates for the relatively large DRC and Uganda outbreaks suggest that control measures were not implemented until more than one month and perhaps multiple months after the first case (Chowell 2004). However, it is assumed that such a long delay would not occur should a case or cases of EBOV infection appear in the U.S. Given that symptoms are usually quite severe and the mortality rate high, it is presumed that the first case would generate alarm and trigger precautionary measures even if the cause of disease was not immediately identified.

An optimistic scenario would be that health officials would quickly implement effective control strategies before any cases in the second generation of cases became symptomatic themselves, so that the post-control reproductive number would apply to potential transmission to a third generation. A more conservative scenario would be that early cases of an outbreak would not be identified as an alarming case and/or that hospitals would delay in implementing effective control strategies due to ineffective preparation or imperfect execution of recommended policies. This range of scenarios is represented by assuming a range of 0–6 days for T_c (continuous uniform distribution). The upper limit of 6 days is just over the assumed average generation time, which allows for the possibility that two generations (or more for a chain of below-average generation times) of transmission could occur before the post-control parameters are applied. The midpoint of the range, 3 days, is applied for the base case.

Case Fatality Rate

Given that the CFR has varied widely during different outbreaks of EBOV, from approximately 40% - 90% (Legrand 2006), and given that this is an important parameter in assessing the consequences of potential outbreaks, it was decided to include the mortality rate assumption as part of the uncertainty analysis for EBOV transmission simulations. A uniform distribution on the range 40% - 90% was assumed, with the midpoint of the range (65%) being applied as the base case.

Summary

Table L–25: Summary of assumed parameter values for EBOV transmission model

Parameter	Base Case Value	Uncertainty Distribution
R_0	1.65	Uniform (min = 1.3, max = 2.0)
k_0, k_c	1	Uniform on $1/k$ (min: $1/k = 0$, max: $1/k = 2$)
R_c	0.6	Uniform (min = 0.4, max = 0.8)
T_g	5.82 days	N/A
T_c	3 days	Uniform (min = 0, max = 6)
CFR	65%	Uniform (min = 40%, max = 90%)

L.3.8.2 Transmission Results – Base Case

Given the introduction of one initially infected individual into the population, 100,000 simulations were run under the base-case input parameters listed in Table L–25. A summary of the results of the output from these simulations for secondary infections and deaths are presented in the following table.

Table L–26: EBOV base case results – number of public infections and fatalities given the occurrence of one undetected / unreported initial infection (urban site)

Consequence		Number of simulations in which consequence occurred (of 100,000)	
		Total	Among Boston City Residents
Number of Public Infections	1 or more	61913 (62%)	38073 (38%)
	10 or more	18092 (18%)	5987 (6.0%)
	100 or more	33 (0.03%)	2 (0.002%)
Number of Public Fatalities	1 or more	56095 (56%)	32891 (32%)
	10 or more	11644 (12%)	3202 (3.2%)
	100 or more	0 (<0.001%)	0 (<0.001%)

These results suggest that, under the base case assumptions, a laboratory worker infected with EBOV who enters the public would have about a 62% chance of transmitting infection to at least one contact. Under the commuting assumptions described in Section L.2.5, there is a chance that the worker would not live in

Boston, which explains why the chance drops to 38% for at least one secondary infection occurring among Boston residents. The estimated chance of at least 10 public infections is 18% (6% among Boston residents), while the chance of at least 100 infections is small, as about 0.03% simulations produced outbreaks that large. The chances for each number of fatalities occurring are comparable to the corresponding infection results, as the case fatality rate of EBOV is high.

L.3.8.3 Transmission Results – Uncertainty

The input parameter uncertainty distributions summarized in Table L–25 were simultaneously applied within the Latin hypercube sampling scheme described in the methodology. One hundred sets of input parameters were generated, and 10,000 simulations were run under each set of parameters to generate alternate estimates for the chance of public infections and fatalities after an undetected or unreported initial infection. The following table summarizes the range of estimates found for each designated consequence. Each range was generated by sorting the 100 different estimates and dropping the lowest two and the highest two, so that 96% of the estimates are within or at the boundaries of the range. The base case results are also displayed in the table for reference.

Table L–27: EBOV base case and uncertainty results – number of public infections and fatalities given the occurrence of one undetected / unreported initial infection (urban site)

Consequence		Estimated Chance of Consequence (given one undetected / unreported initial infection)	
		Total	Among Boston City Residents
Number of Public Infections	1 or more	62% (49% to 83%)	38% (31% to 50%)
	10 or more	18% (8.3% to 33%)	6.0% (2.1% to 13%)
	100 or more	0.03% (≈0 to 1.9%)	0.002% (≈0 to 0.1%)
Number of Public Fatalities	1 or more	56% (42% to 77%)	33% (24% to 45%)
	10 or more	12% (2.6% to 25%)	3.2% (0.5% to 9.3%)
	100 or more	<0.001% (≈0 to 1.0%)	<0.001% (≈0 to 0.05%)

“≈0” at the lower end of an uncertainty range means that the given consequence was not observed in any of the simulations under at least three of the 100 input parameter combinations; when appearing as the entire range, then the consequence was not observed for at least 98 of the 100 parameter combinations.

L.3.8.4 Transmission results linked to event sequences

The results in the previous section are estimates of the chance of public infections and fatalities *given that one initially infected individual enters the community*. The initial infection analyses from Chapter 8 and

Appendix K provide estimates for the average frequency of such an initiating event occurring, for three different scenarios. The estimates for EBOV were as follows.

Table L–28: Summary of EBOV initial infections results

Event	Frequency Range
Undetected / Unreported Needlestick Infection	1 in 100 to 10,000 years
Undetected / Unreported Centrifuge Release and Infection	N/A
Earthquake Release and Infection	1 in 480,000 to >10 million years

Of these three events, an undetected or unreported needlestick infection is estimated as the most frequent initial infection event by which an individual could pose a secondary transmission risk to the public. The centrifuge event is not applicable because no credible scenario was found for an aerosol exposure going undetected under BSL-4 conditions. Therefore, the given frequency range for needlestick is applied in the remainder of this section as the representative event for estimating the frequency of public infections and fatalities.

The exact frequency for the needlestick event is uncertain, and no basis for was found for assuming a most likely frequency within the range. Therefore, a distribution of frequencies across the given range is applied as an additional layer of uncertainty within the overall Latin hypercube sampling scheme. Random return periods are drawn from a uniform distribution across the range (100 years to 10,000 years), and the frequency is calculated by taking the inverse. A given needlestick frequency is then multiplied by a probability of a given consequence (public infections or fatalities due to transmission) to calculate the estimated frequency of that consequence. This results in a range of estimated frequencies for each consequence. A sampling of these ranges is shown in the following table.

Table L–29: EBOV uncertainty results – frequency of public infections and fatalities due to an undetected / unreported needlestick (urban site)

Consequence		Frequency Range	
		Total	Among Boston City Residents
Number of Public Infections	1 or more	1 in 550 to 18,000 years	1 in 920 to 29,000 years
	10 or more	1 in 1,900 to 76,000 years	1 in 5,000 to 250,000 years
	100 or more	1 in 110,000 to >10 million years	1 in 2.9 million to >10 million years
Number of Public Fatalities	1 or more	1 in 610 to 20,000 years	1 in 1,100 to 36,000 years
	10 or more	1 in 3,100 to 240,000 years	1 in 11,000 to 1.0 million years
	100 or more	1 in 420,000 to >10 million years	1 in 8.9 million to >10 million years

The following table provides more insight into the distribution of estimated frequencies for each consequence, in terms of the portion of each distribution falling in each of the four frequency categories.

Table L–30: EBOV uncertainty results – frequency categories for public infections and fatalities due to undetected / unreported needlestick (urban site)

Consequence		Percentage of 100 estimates falling in each category							
		Total				Among Boston Residents			
		A	B	C	D	A	B	C	D
Number of Public Infections	1 or more	0	65%	35%	0	0	40%	60%	0
	10 or more	0	18%	82%	0	0	6%	94%	0%
	100 or more	0	0	25%	75%	0	0	0%	100%
Number of Public Fatalities	1 or more	0	53%	47%	0	0	36%	64%	0
	10 or more	0	14%	86%	0	0	2%	94%	4%
	100 or more	0	0	11%	89%	0	0	0	100%

A = 1 in 1 to 100 years; B = 1 in 100 to 10,000 years; C = 1 in 10,000 to 1 million years; D = 1 in >1 million years

Finally, estimated ranges of frequencies for different consequences are conveyed graphically in Figure L–4. In the figure, numbers of fatalities are plotted against the estimated frequency with which a needlestick event leading to at least that number of fatalities in the public would be expected to occur. Under a given set of transmission parameters and a given needlestick frequency, a curve can be generated by connecting the points calculated by multiplying the needlestick frequency by the estimated chance that at least the given number of fatalities would occur in the public. A different curve exists for each of the 100 sets of

1 input values that were used in the uncertainty analysis. Rather than plotting all 100 curves, four curves are
2 displayed, which form base case boundaries (thick curves) and full uncertainty boundaries (thin curves).

3
4 The base case boundaries were formed by multiplying the 95% uncertainty range for the needlestick
5 frequency by the base case estimates from the secondary transmission analysis. The full uncertainty range
6 represents the combined effects of uncertainty in the needlestick frequency and uncertainty in the
7 secondary transmission parameters. By choosing a given number of fatalities on the horizontal axis, one
8 can move vertically up the figure to find the boundaries for the estimated frequency range for that
9 consequence.

10
11

Figure L-4: Risk curves for total public fatalities from EBOV due to undetected / unreported needlestick, urban site

L.3.9 Marburg virus

Marburg virus is a member of a group of hemorrhagic fever viruses and is closely related to Ebola virus. Direct person-to-person transmission of Marburg virus from index cases to family and community contacts has been described in the 1967 outbreak and the two large outbreaks in Africa. Secondary transmission is associated with close contact with the ill patient or their bodily fluids, mainly blood (Bausch, Nichol et al. 2006; Feldmann 2006; Towner, Khristova et al. 2006). Other body fluids from

1 infected humans (feces, vomitus, urine, saliva, and respiratory secretions) with high virus concentrations,
2 especially when these fluids contain blood, have also been implicated in transmission.

3
4 Secondary transmission modeling of the spread of infection in the community following loss of bio-
5 containment has been performed for the closely related Ebola virus. The results of this modeling are
6 broadly applicable to Marburg virus; for this reason, secondary transmission modeling of spread of
7 infection in the community following a loss of bio-containment is not performed for this pathogen.

8 9 **L.3.10 Lassa virus**

10 Lassa viruses are the causative pathogens of Lassa fever, which is a viral hemorrhagic fever. Direct
11 person-to-person transmission of Lassa viruses occurs, especially in hospital settings. Person-to-person
12 transmission is associated with direct contact with the blood or other bodily fluids containing virus
13 particles of infected individuals. Airborne transmission has also been postulated to occur. Contact with
14 objects contaminated with virus, such as medical equipment (reused needles), is also associated with
15 transmission in healthcare settings (Centers for Disease Control 2011). The viruses are generally not
16 known to be spread through casual contact, including skin-to-skin contact without exchange of bodily
17 fluids (Ogbu, Ajuluchukwu et al. 2007). Thus, the risk of direct person-to-person transmission is low and
18 involves close contact with infected body fluids. Furthermore, there are limited published mathematical
19 models of such transmission. For these reasons, secondary transmission modeling of spread of infection
20 in the community following loss of bio-containment is not performed for this pathogen.

21 22 **L.3.11 Junin virus**

23 Junín virus is the causative pathogen of Argentine hemorrhagic fever. As with other hemorrhagic fever
24 viruses in the Family *Arenaviridae* (Lassa fever virus and the New World arenaviruses), there is potential
25 for direct person-to-person transmission of Junín virus, postulated to occur via close contact with
26 infectious blood and body fluids (Borio, Inglesby et al. 2002). It is to be noted that there have been no
27 reports of person-to-person transmission of Junín virus from patients to health care workers, despite the
28 several hundred patients with hemorrhages cared for each year in Argentina (Charrel and de Lamballerie
29 2003). Thus, the risk of direct person-to-person transmission of Junín virus is considered low and
30 secondary transmission modeling of spread of infection in the community following loss of bio-
31 containment is not performed for this pathogen.

L.3.12 Tick-borne encephalitis virus, Far Eastern subtype

Tick-borne encephalitis virus, Far Eastern sub-type (TBEV-FE) was formerly known as Russian spring-summer encephalitis. This virus is one member of the tick-borne encephalitis virus complex. TBEV-FE is one of the causative pathogens of tick-borne encephalitis (TBE) (Lindquist and Vapalahti 2008). The virus is transmitted to humans through the bite of an infected tick. As there is no direct-to-person transmission of TBEV-FE, secondary transmission modeling of spread of infection in the community following loss of bio-containment is not performed for this pathogen.

L.3.13 Nipah virus

Nipah virus is an emerging pathogen that was first described in 1998 from an outbreak of encephalitis in Malaysia and Singapore (1999). The mode of transmission of Nipah virus has changed between the Malaysian/Singapore outbreaks and those in Bangladesh/India. In the Malaysian/Singapore outbreaks, it is postulated that the virus was transmitted from bats (natural reservoir) to pigs, causing an outbreak in pigs, which subsequently led to an outbreak in humans in close contact with the pigs (abattoir workers and pig farmers). In Bangladesh, the transmission from bats to humans appears to be ongoing and via at least three different routes (Luby, Rahman et al. 2006; Luby, Hossain et al. 2009). The most frequent mode is food-borne through ingestion of Nipah-virus-contaminated date palm sap which is a staple food source in that region. A second mode of transmission appears to be via domestic animals that feed on contaminated fruits or date palm sap that have been licked or partially eaten by fruit bats infected with Nipah virus. There do not appear to be any arthropod vectors in the transmission of Nipah virus.

Evidence from epidemiologic investigations of outbreaks in Bangladesh and India indicates that Nipah virus can be transmitted directly from person-to-person. This has occurred in patients with respiratory illness. Close physical contact with a known Nipah virus patient who later died was found to be the strongest risk factor for direct person-to-person transmission (Gurley, Montgomery et al. 2007). Nipah virus has been found in respiratory secretions of infected patients (Chua, Lam et al. 2001). Though direct transmissions have occurred and are known to be responsible for many of the Bangladeshi outbreaks, the risk of direct transmission appears to be low and requires close contact that may be culture- and region-specific (to Bangladesh) (Luby, Hossain et al. 2009). Given the limitations of conducting field investigations in rural areas of developing countries, this study (Luby, Hossain et al. 2009) estimated that only a few individuals transmitted to others and the generations of transmissions rarely exceeded two. The overall number of secondary cases resulting from an infected person was expected to be less than 0.5, indicating that it was unlikely that any one chain of transmission would result in a large outbreak.

In summary, there is a possibility of person-to-person transmission of Nipah virus via respiratory secretions; however the risk is low and requires close contact that may be culture- and region-specific (Luby, Hossain et al. 2009). Moreover, there are limited studies available to provide epidemiologic data for detailed secondary transmission modeling and no published mathematical models for this pathogen. For these reasons, secondary transmission modeling of spread of infection in the community following loss of bio-containment is not performed for this pathogen.

L.3.14 Site differences

This section describes and compares results from simulations based on details specific to the suburban and rural sites. The following differences in assumptions as compared to those for the urban site are applied.

Local population size – The estimates provided in the results sections above used a local population estimate of one million individuals, which is representative of the daytime population in the city of Boston. The suburban and rural site simulations were run using local populations of 12,000 (approximate population of Tyngsborough, MA) and 8,000 (approximate combined population of Hancock, NH and Peterborough, NH). These changes have an effect only on larger outbreaks in which the infected portion of the local population might become substantial enough to appreciably decrease the effective value of the parameter R_c (see Section L.2.4).

Effect of commuting – The suburban and rural site simulations incorporate the commuting estimates specific to those areas, as described in Section L.2.5. It is noted that chains of transmission occurring among non-locals (who neither work nor live in the local area) are not subject to the local population constraint noted in the previous bullet. I.e., non-locals have contacts among a wider pool of susceptible individuals than just the local area, so that an extreme outbreak could potentially exceed the local population size.

Contact rate differences – The procedure described in Section L.2.9.1 was applied to compare R estimates for transmission at the urban site and the suburban and rural sites. An example using SARS-CoV is described here. The estimates of R_0 and R_c listed in Table L–17 are assumed to be most applicable to the urban site, because the outbreak data used to derive those estimates were mostly observed in large cities (e.g., Beijing, Singapore, Toronto, and others). Therefore, the values used for suburban and rural site simulations are adjusted according to the equations given in Section L.2.9.1. Similar adjustments are made for the other pathogens undergoing quantitative analysis. The adjusted values are only applied to

infected individuals in the simulation if they are classified as local residents. Otherwise, the estimates provided in Section L.2.9.1 are not applicable, and the unadjusted R_0 and R_c estimates are applied.

Table L–31: Summary of assumed, contact-rate-adjusted R values for site-specific SARS-CoV transmission model

Parameter	Urban	Suburban	Rural
R_0	3.0 (min = 2.0, max = 4.0)	2.56 (min = 1.71, max = 3.42)	1.42 (min = 0.95, max = 1.89)
R_c	0.7 (min = 0.3, max = 1.1)	0.60 (min = 0.26, max = 0.94)	0.33 (min = 0.14, max = 0.52)

Base case and uncertainty range estimates are provided for all three sites in the following tables, in terms of the estimated chance of public infections and fatalities given that an infected individual is introduced into the public.

Table L–32: *Y. pestis* (pneumonic plague) results – number of public infections and fatalities given the occurrence of one undetected / unreported initial infection

Consequence		Estimated Chance of Consequence (given one undetected / unreported initial infection)					
		Total			Among Local Residents		
		Urban	Suburban	Rural	Urban	Suburban	Rural
Public Infections	≥1	57% (48-63%)	56% (47-63%)	53% (45-60%)	34% (26-40%)	22% (16-26%)	24% (17-30%)
	≥10	17% (0.8-34%)	16% (0.8-34%)	12% (0.6-27%)	5.6% (0.1-15%)	1.2% (0.02-5.1%)	0.2% (0-1.6%)
	≥100	0 (0-2.4%)	0 (0-2.0%)	0.001% (0-1.5%)	0 (0-0.2%)	0 (<0.01%)	0 (<0.01%)

Table L–35: EBOV results – number of public infections and fatalities given the occurrence of one undetected / unreported initial infection

Consequence		Estimated Chance of Consequence (given one undetected / unreported initial infection)					
		Total			Among Local Residents		
		Urban	Suburban	Rural	Urban	Suburban	Rural
Public Infections	≥1	62% (49-83%)	62% (49-82%)	58% (46-78%)	38% (31-50%)	24% (19-31%)	27% (22-35%)
	≥10	18% (8.3-33%)	17% (7.9-31%)	13% (5.8-24%)	6.0% (2.1-13%)	1.3% (0.3-3.1%)	0.3% (0.01-1.1%)
	≥100	0.03% (0-1.9%)	0.03% (0-1.7%)	0.03% (0-1.2%)	0.002% (0-0.1%)	0 (<0.01%)	0 (<0.01%)
	≥1,000	0 (<0.01%)	0 (<0.01%)	0 (<0.01%)	0 (<0.01%)	0 (<0.01%)	0 (<0.01%)
Public Fatalities	≥1	56% (42-77%)	56% (43-77%)	52% (39-72%)	33% (24-45%)	20% (14-27%)	21% (14-30%)
	≥10	12% (2.6-25%)	11% (2.5-25%)	8.1% (1.7-20%)	3.2% (0.5-9.3%)	0.5% (0.04-2.3%)	0.05% (0-0.5%)
	≥100	0 (0-1.0%)	0 (0-0.7%)	0 (0-0.6%)	0 (0-0.05%)	0 (<0.01%)	0 (<0.01%)
	≥1,000	0 (<0.01%)	0 (<0.01%)	0 (<0.01%)	0 (<0.01%)	0 (<0.01%)	0 (<0.01%)

In each of the above four tables, the estimated probability for total numbers of infections and fatalities are generally slightly smaller at the suburban and rural sites as compared to the urban site, but the uncertainty ranges largely overlap, so that no statistically significant difference can be concluded. The reason that the overall results from the suburban and rural sites are so similar to the urban site results is that there is a high estimated rate of commuting to and from the towns at those sites, so that a significant portion of transmissions occur among non-residents and are not subject to local population constraints or to the estimates for decreased contact rates that were based on residents only.

The effects of the site difference assumptions are more apparent when comparing the results for local residents. There tends to be a lower estimated chance of each consequence among local residents at the suburban and rural sites compared to the urban site, due to commuting and contact rate differences, although uncertainty ranges overlap in most cases. These differences suggest that a more substantial portion of the risk from an undetected / unreported laboratory worker infection at the suburban and rural sites would be borne by non-residents, particularly areas with a strong connection with the local area via commuting.

L.3.15 Medically Vulnerable Sub Populations

The procedure described in Section L.2.9.2 was applied to SARS-CoV outbreak simulations at the three sites. As described in that section, for most MVSP, the susceptibility to infection and mortality is generally calculated relative to the susceptibility of healthy adults using the values for viruses in Table L–4. However, for one MVSP, adults over 65, there is enough evidence from SARS-CoV outbreaks to infer that the death rate among those individuals could be substantially higher than what would be inferred from Table L–4. For adults over 65, the assumed fatality rate is 50%, which is consistent with observations from the SARS outbreaks in Hong Kong (WHO 2003) and Toronto (Varia 2003).

L.3.15.1 Adjusted overall R values and mortality rates

The calculations described in Section L.2.9.2 were applied using the base case R values and mortality rate for SARS-CoV, with the following results. Note that these adjustments do not include contact rate adjustments described in Section L.3.14, so that the potential effects of MVSP susceptibility can be separated.

Table L–36: Summary of estimated MVSP-adjusted SARS-CoV parameter values over specific populations

Parameter	U.S.	Boston, MA	Tyngsborough, MA	Peterborough + Hancock, NH	Mass. overall	N.H. overall
R_0	3.00	2.99	2.94	3.12	3.02	2.99
R_c	0.70	0.70	0.69	0.73	0.70	0.70
Mortality rate	0.10	0.09	0.08	0.14	0.10	0.10

The results in the table above show that the different R values across each row are well within the uncertainty ranges (2 to 4 for R_0 and 0.3 to 1.1 for R_c) derived in Section L.3.5. Furthermore, the site-specific adjustments based on contact rates that were tested and presented in Section L.3.14 exhibited a much larger effect on site-specific R values. The adjusted mortality rates also do not deviate far from the baseline estimate of 10%. Therefore, the MVSP profiles at the three sites do not contribute a substantial effect on site differences for overall risk to the population in light of the overall uncertainty and in comparison to the site differences already explored in Section L.3.14.

Because the inputs for susceptibility of MVSP relative to healthy adults shown in Table L–4 are based on expert opinion and not on data (except for the case fatality rate of adults over 65, as described above), it is

possible that they significantly underestimate the true differences in susceptibility. However, the results shown in Table L–36 exhibit low sensitivity to those inputs. For example, even if the relative susceptibility values in Table L–4 are multiplied by a factor of 10, the results for adjusted R values still fall within the overall uncertainty ranges of 2 to 4 for R_0 and 0.3 to 1.1 for R_c .

L.3.15.2 Risk to specific MVSP at the three sites

This section consists of results for the site-specific risk to each of the individual MVSP. For each MVSP, the risk of infections and deaths are presented, as determined by simulations incorporating and tracking MVSP as described in the methodology section. Each set of results is compared to what the results would be if the MVSP profile at each location were in line with overall U.S. proportions.

Table L–37. Base case results for SARS-CoV consequences among children under five, given that an undetected / unreported initial infection has occurred

Consequence		Estimated Chance of Consequence (given one undetected / unreported initial infection)					
		Using Local MVSP Estimates			Using U.S. Average MVSP Estimates		
		Urban	Suburban	Rural	Urban	Suburban	Rural
Public Infections	≥1	22%	22%	20%	23%	23%	20%
	≥10	7.6%	7.3%	5.8%	8.0%	7.7%	5.8%
	≥100	0.11%	0.08%	0.06%	0.11%	0.08%	0.06%
Public Fatalities	≥1	7.2%	6.9%	5.7%	7.5%	7.2%	5.8%
	≥10	0.02%	0.01%	0.006%	0.01%	0.008%	0.01%

Among children under five, the estimates are similar at all three sites, with the chance of one or more deaths being between 5 and 8% and ten or more deaths 0.02% or lower. These estimates do not change substantially when U.S. average proportions of MVSP are used as inputs rather than the locally estimated proportions. All differences across each row are small compared to the overall uncertainty range. Therefore, it is not possible to conclude that the differences in population of children under five near each of the three sites relative to the U.S. have a substantial effect on the estimated risk to that group.

Table L–38. Base case results for SARS-CoV consequences among adults over 65, given that an undetected / unreported initial infection has occurred

Consequence		Estimated Chance of Consequence (given one undetected / unreported initial infection)					
		Using Local MVSP Estimates			Using U.S. Average MVSP Estimates		
		Urban	Suburban	Rural	Urban	Suburban	Rural
Public Infections	≥1	27%	26%	26%	27%	27%	25%
	≥10	11%	11%	9.9%	12%	11%	9.0%
	≥100	0.95%	0.84%	0.68%	1.1%	0.85%	0.65%
Public Fatalities	≥1	23%	23%	22%	23%	23%	21%
	≥10	7.7%	7.5%	6.5%	8.2%	7.8%	5.9%
	≥100	0.13%	0.08%	0.08%	0.13%	0.10%	0.07%

Among adults over 65, the estimated risk is similar at all three sites, with the estimated chance of ten or more deaths between 6 and 8% and 100 or more deaths about 0.1%. These estimates do not change substantially when U.S. average proportions of MVSP are used as inputs rather than the locally estimated proportions. All differences across each row are small compared to the overall uncertainty range. Therefore, it is not possible to conclude that the differences in population of adults over 65 near each of the three sites relative to the U.S. have a substantial effect on the estimated risk to that group.

Table L–39. Base case results for SARS-CoV consequences among people with diabetes, given that an undetected / unreported initial infection has occurred

Consequence		Estimated Chance of Consequence (given one undetected / unreported initial infection)					
		Using Local MVSP Estimates			Using U.S. Average MVSP Estimates		
		Urban	Suburban	Rural	Urban	Suburban	Rural
Public Infections	≥1	23%	22%	20%	22%	21%	19%
	≥10	7.8%	6.7%	5.1%	6.8%	6.3%	4.7%
	≥100	0.11%	0.03%	0.02%	0.04%	0.02%	0.02%
Public Fatalities	≥1	7.5%	6.6%	5.4%	6.5%	6.2%	4.9%
	≥10	0.02%	0.002%	0.003%	0.006%	0.004%	0.002%

Among people with diabetes, the estimated risk is similar at all three sites, with an estimated chance of one or more deaths between 5 and 8% and ten or more deaths 0.2% or less. These estimates decrease slightly when U.S. average proportions of MVSP are used as inputs rather than the locally estimated proportions, because the proportion of people with diabetes is higher than the U.S. average at all three sites, but all differences across each row are small compared to the overall uncertainty range. Therefore,

it is not possible to conclude that the differences in population of people with diabetes near each of the three sites relative to the U.S. have a substantial effect on the estimated risk to that group.

Table L–40. Base case results for SARS-CoV consequences among people with HIV/AIDS, given that an undetected / unreported initial infection has occurred

Consequence		Estimated Chance of Consequence (given one undetected / unreported initial infection)					
		Using Local MVSP Estimates			Using U.S. Average MVSP Estimates		
		Urban	Suburban	Rural	Urban	Suburban	Rural
Public Infections	≥1	10%	7.8%	5.8%	9.1%	8.6%	7.1%
	≥10	0.16%	0.03%	0.03%	0.05%	0.05%	0.03%
Public Fatalities	≥1	1.2%	0.74%	0.59%	0.96%	0.84%	0.66%
	≥10	<0.001%	<0.001%	<0.001%	<0.001%	<0.001%	<0.001%

Among people with HIV / AIDS, the estimated risk is similar at all three sites, with the chance of one or more deaths about 1% or less and ten or more deaths less than 0.001%. It is noted that estimated urban site probability of one or more deaths (1.2%) is about twice that of the rural site (0.6%), although both probabilities are low and uncertainty ranges overlap. The estimates do not change substantially when U.S. average proportions of MVSP are used as inputs rather than the locally estimated proportions. All differences across each row are small compared to the overall uncertainty range. Therefore, it is not possible to conclude that the differences in population of people with HIV / AIDS near each of the three sites relative to the U.S. have a substantial effect on the estimated risk to that group.

Table L–41. Base case results for SARS-CoV consequences among pregnant women, given that an undetected / unreported initial infection has occurred

Consequence		Estimated Chance of Consequence (given one undetected / unreported initial infection)					
		Using Local MVSP Estimates			Using U.S. Average MVSP Estimates		
		Urban	Suburban	Rural	Urban	Suburban	Rural
Public Infections	≥1	13%	13%	11%	14%	13%	11%
	≥10	0.81%	0.68%	0.49%	0.82%	0.65%	0.47%
	≥100	<0.001%	<0.001%	<0.001%	<0.001%	<0.001%	<0.001%
Public Fatalities	≥1	1.9%	1.7%	1.4%	1.9%	1.8%	1.4%
	≥10	<0.001%	<0.001%	<0.001%	<0.001%	<0.001%	<0.001%

Among pregnant women, the estimated risk is similar at all three sites, with the chance of one or more deaths between 1 and 2% and ten or more deaths less than 0.001%. The assumed U.S. average proportion

1 of pregnant women is the same as the estimate for each of the sites (1% of the population), so any
2 differences between the left half and right half of the results in the table are entirely due to random
3 differences in the simulation outcomes.

4 Because the inputs for susceptibility of MVSP relative to healthy adults shown in Table L–4 are based on
5 expert opinion and not on data (except for the case fatality rate of adults over 65, as described above), it is
6 possible that they significantly underestimate the true differences in susceptibility. The numerical results
7 shown in Tables L–37 to L–41 do exhibit sensitivity to those inputs. The largest change in the results for
8 a particular MVSP would occur if the relative susceptibility of that MVSP is increased and the relative
9 susceptibility of all other MVSP remains the same, in which case the particular MVSP would be
10 disproportionately affected relative to not only healthy adults, but also to the other MVSP. If the relative
11 sensitivities for all MVSP are increased at the same time, then the estimated risk to each MVSP would
12 still increase, but to a much lesser extent. In all cases, however, the results regarding the risk estimates to
13 each local population as compared to what those results would be in a population with typical U.S.
14 proportions of MVSP would not change substantially. Therefore, the relative differences across each row
15 of Tables L–37 to L–41 are not sensitive to potential inaccuracies of the estimated susceptibility
16 differences of the MVSP.

17 In addition, the expert estimates of increased susceptibility to disease and mortality were based on
18 belonging to each MVSP individually; in reality, it is possible that individuals may have multiple
19 concomitant medical vulnerabilities such as being both elderly and diabetic, or both HIV-positive and
20 pregnant. The susceptibility in these situations is potentially increased due to compounding effects of the
21 individual conditions. Published data about the effects of each combination of vulnerabilities on
22 susceptibility are scarce, and as such the simplified approach for this analysis was to assess each medical
23 vulnerability separately. The sensitivity analysis discussed in the previous paragraph suggests that
24 assuming compounding effects of simultaneous conditions on susceptibility would not have a significant
25 effect on the comparative results.

26 In the simulations that produced the results in Tables L–37 to L–41, it was assumed that the probability
27 that a contact of an infected individual is a member of a MVSP is equal to the proportion of that MVSP in
28 the population. This assumption may be violated if the social mixing of MVSP in the overall population is
29 not homogenous. For people with diabetes and pregnant women, no data were found that would indicate
30 that individuals in those groups would be more or less likely to be contacted than a typical person in the
31 population. There are numerous studies on the sexual contact patterns of people with HIV/AIDS, but
32 those data have limited applicability to the spread of respiratory pathogens such as SARS-CoV.

1 Age-specific contact patterns in the context of person-to-person spread of disease have been studied, and
2 it has generally been found that children under five and adults over sixty-five have fewer numbers of
3 contacts as compared to school-age children and younger adults (Wallinga 2006, DelValle 2007).
4 Therefore, the assumption of proportionate mixing likely contributes to overestimating the risk to
5 individuals in those groups (Tables L-37 and L-38). Those studies also found that children under five and
6 adults over 65 tend to preferentially mix with individuals in their own age group (e.g., at day care centers
7 and nursing homes), so it is possible that, if members of those age groups became infected very early in
8 an outbreak, that they would be disproportionately affected in early generations of the outbreak. However,
9 analysis shows that age-specific incidence converges rapidly over the course of an outbreak (Wallinga
10 2006), so that young children and elderly groups would have fewer contacts with infected cases than other
11 age groups after just a few generations of transmission.

10. Environmental Justice

10.1 Introduction

The objective of the environmental justice analysis for this RA is to address the considerations associated with *Executive Order 12898, Federal Actions to Address Environmental Justice in Minority and Low-Income Populations*. CEQ, DOE, and NRC NEPA Guidance, were also used to inform this analysis. Available U.S. Census data was analyzed to determine and identify potential environmental justice areas at the urban, suburban and rural sites. Additionally, this RA examined two types of effects: (1) those that could directly expose environmental justice communities as a result of a release of pathogen from the facility and (2) those that expose people in environmental justice communities indirectly through secondary transmission of pathogens. Each of those types of impacts is addressed separately.

10.2 Environmental Justice—Regulatory Overview

10.1.1 Federal Guidance

In response to public concerns, EPA created the Office of Environmental Justice in 1992. EPA defines *environmental justice* as the fair treatment and meaningful involvement of all people regardless of race, color, national origin, or income with respect to the development, implementation, and enforcement of environmental laws, regulations, and policies. *Fair treatment* means that no group of people should bear a disproportionate share of the negative environmental consequences resulting from industrial, governmental, and commercial operations or policies. *Meaningful involvement* means that (1) people have an opportunity to participate in decisions about activities that could affect their environment or health; (2) the public's contribution can influence the regulatory agency's decision; (3) the public's concerns will be considered in the decision-making process; and (4) the decision makers seek out and facilitate the involvement of those potentially affected. EPA established the National Environmental Justice Advisory Council (NEJAC) on September 3, 1993, to provide independent advice, consultation, and recommendations to the EPA Administrator on matters related to environmental justice.

Executive Order 12898, *Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations*, directs federal agencies to develop environmental justice strategies to address disproportionately high and adverse human health or environmental effects of their programs on minority and low-income populations, and to focus federal attention on the environmental and human health conditions of minority and low-income populations with the goal of achieving environmental protection for all communities. The order is also intended to promote nondiscrimination in federal programs that affect human health and the environment and provide minority and low-income communities' access to

public information and public participation in matters relating to human health and the environment. In addition to Executive Order 12898, two guidance documents help define how to address environmental justice concerns: The Council on Environmental Quality's (CEQ's) December 1997 document, *Environmental Justice Guidance under the National Environmental Policy Act*, and an April 1998 document produced by an EPA working group titled *Final Guidance for Incorporating Environmental Justice Concerns in EPA's NEPA Compliance Analyses*.

The CEQ has oversight of the federal government's compliance with Executive Order 12898 and NEPA. EPA has lead responsibility for implementation of the Executive Order as Chair of the Interagency Working Group on Environmental Justice (CEQ 1997).

10.2.1.1 Minority Populations

The federal environmental justice criteria identify minority populations as Black or African American; American Indian and Alaska Native; Asian; Native Hawaiian and other Pacific Islander; persons of two or more races; and persons of Hispanic origin. Minority populations should be identified for environmental justice analyses where, either the minority population of the affected area exceeds 50 percent, or the minority population percentage of the affected area is meaningfully greater than the minority population percentage in the general population or other appropriate unit of geographic analysis (CEQ 1997). The latter guidance was used for this analysis to address the federal environmental justice criteria, identifying census tracts with minority population percentages exceeding that of the United States. Census tracts are subdivisions of a county and represent a level at which disproportionate impacts would be more noticeable. As of 2000, 25 percent of the U.S. population was of a minority race or ethnicity (U.S. Census Bureau 2000).

10.2.1.2 Low Income Populations

The federal environmental justice criteria use poverty thresholds established by the U.S. Census Bureau to identify low-income populations (CEQ 1997). Poverty status is reported as the number of persons or families with income below a defined threshold level. The Census defines the 2000 poverty level as \$8,791 (\$10,956 for 2009) of annual income, or less, for an individual and \$17,604(\$21,954 for 2009) of annual income, or less, for a family of four (U.S. Census Bureau 2010a). The federal environmental justice criteria identify low-income populations for those census tracts with poverty rates exceeding those of the United States. As of the 2000 Census, 12 percent (U.S. Census Bureau 2000) of U.S. residents were classified as living in poverty and in 2008 13.2 percent of the U.S. residents were classified as living in poverty (U.S. Census Bureau 2010b).

10.2.1.3 Disproportionately High and Adverse Human Health Effects

Adverse health effects are measured in risks and rates that could result in fatal or nonfatal adverse impacts on human health. Adverse health effects may include bodily impairment, infirmity, illness, or death. Agencies are required to identify programs, policies or activities which may cause disproportionately high and adverse human health or environmental effects. The agency's determination of disproportionately high and adverse impacts is made in consideration of whether the impacts as summarized in the RA meet the following criteria:

1. The impacts must be significant or above generally accepted norms, such as regulatory limits or state and local statutes and ordinances (NUREG 2003). The significance of impacts is determined in consideration of both the context and the intensity of the impact. The context includes factors such as extent of the impact, (i.e. whether the impact is local, regional, or national) and, therefore, the number of people that might be affected. Intensity refers to the severity of the impact. Direct and indirect impacts are considered as well as immediate and long-term impacts (40 CFR 1508.8).
2. Impacts are disproportionate if the risks to a minority individual, or low-income individual, appreciably exceed the risk to an individual in the general population (CEQ 1997).

10.2.2 State Guidance

The Massachusetts Executive Office of Energy and Environmental Affairs (EEA) designates environmental justice populations are those segments of the population that EEA has determined to be most at risk of being unaware of or unable to participate in environmental decision making or to gain access to state environmental resources. These groups are defined as neighborhoods that meet *one or more* of the following criteria:

- The median annual household income is at or below 65 percent of the statewide median income for Massachusetts; *or*
- 25 percent of the residents are minority; *or*
- 25 percent of the residents are foreign born, *or*
- 25 percent of the residents are lacking English language proficiency.

Neighborhoods, as defined by EEA's Environmental Justice Policy are U.S. Census Bureau census block groups (Massachusetts EEA 2002).

10.3 Environmental Justice Methodology

For purposes of this RA, the analysis for environmental justice is presented to address both the federal and state criteria, separately but sequentially. NIH performed an environmental justice analysis that includes input from the Boston community from January 9, 2004, to the present to identify the disproportionate placement of high and adverse environmental or health impacts from the NEIDL at the urban, suburban, or rural sites on minority or low-income populations. The public input gathered since January 9, 2004, assisted in identifying a geographic scale for which demographic information was obtained on the potential impact area(s). Per CEQ, available demographic data from the U.S. Census Bureau census tracts and block numbers were used to identify the composition of the potentially affected population. Census tracts are small relatively permanent statistical subdivisions of a county. Block Numbering Areas are small statistical subdivisions of a county for grouping and numbering blocks in nonmetropolitan counties where local census statistical committees have not established census tracts. A Block Group is a combination of a census blocks that is a subdivision of a census tract or Block Numbering Area. Census blocks are the smallest geographic area for which the U.S. Census Bureau collects and tabulates decennial census data. Both census tracts and Block Numbering Areas provide the geographic framework for delineating block groups, assigning census block numbers, and tabulating data (U.S. Census Bureau 2000a). It is important to note that the unit of analysis for determining environmental justice communities by the federal criteria is the census tract; whereas for the determination by Massachusetts criteria, the unit of analysis is the census block.

10.4 Considering Environmental Justice in Specific Phases of the NEPA Process

Identification of health and environmental issues under NEPA, CEQ, and the Massachusetts EEA Environmental Justice Policy is accomplished through public involvement and the scoping process. Public involvement and scoping are implemented to ensure fair treatment and meaningful involvement of all people as defined by EPA on matters related to environmental justice.

10.4.1 Scoping

On January 9, 2004, NIH published in the *Federal Register* its Notice of Intent to prepare an EIS on the proposed Boston-NBL. Publication of that notice initiated the NIH scoping activities. On February 9,

2004, NIH published in the *Federal Register* a notice of a public scoping meeting and an extension of the comment period. A public scoping meeting was held at Faneuil Hall in Boston on Tuesday, February 17, 2004, from 7 p.m. to 10 p.m. Comments were provided during the extended public scoping period, which began January 9, 2004, and ended March 2, 2004.

10.4.2 Draft EIS

NIH filed a Draft EIS with EPA on October 15, 2004. On October 22, 2004, EPA published notice that the Draft EIS had been filed, was available for public review and comment, and that a public meeting was scheduled for November 10, 2004. The public meeting was held at Faneuil Hall in Boston on Wednesday, November 10, 2004, from 7 p.m. to 9 p.m. Comments were received during an extended 75-day public comment period, which began October 22, 2004, and ended January 3, 2005.

10.4.3 Supplemental Draft EIS

NIH filed a Supplemental Draft EIS with EPA on March 25, 2005. On April 1, 2005, EPA published notice that the Supplemental Draft EIS had been filed, was available for public review and comment, and that a public meeting was scheduled for April 25, 2005. The public meeting was held at Faneuil Hall in Boston on Monday, April 25, 2005, from 7 p.m. to 9 p.m. Comments were received during an extended 48-day public comment period, which began April 1, 2005, and ended May 18, 2005.

10.4.4 Final EIS

On the basis of comments NIH received from EPA on the Draft EIS, a description of the public outreach efforts to date was provided, and the area of analysis for environmental justice issues in the Final EIS was expanded to include a 1.6-km (one-mile) radius including all of the South End and portions of South Boston, Roxbury, Dorchester, Chinatown, Back Bay, and Kenmore/Fenway (NIH 2005). The Final EIS identifies the NEIDL project area, at the urban location, as an environmental justice area per Massachusetts EEA because its population on average is made up of more than 25 percent minorities (NIH 2005). The environmental justice analysis was performed at just the urban location in the Final EIS and determined that

- The area surrounding NEIDL is an environmental justice community on the basis of the percentage of minorities.
- Within the study area, 52 percent of the residents are minority.

- The median household income in the South End is greater than the median household income of the City of Boston and is close to the statewide average.
- No neighborhoods in the study area have a resident population 25 percent or higher that are foreign born.
- No neighborhoods in the study area have a resident population 25 percent or higher that are lacking in English language proficiency.

The Final EIS also concludes, “It is unlikely that the Proposed Action would have proportionately greater impact on the disadvantaged (e.g. minority) population than any other population in the area”(NIH 2005).

10.5 Additional Considerations for this RA

To address the public and state and federal courts’ interest in the demographic and health information regarding the community surrounding the NEIDL and how it relates to environmental justice populations, apart from the demographic data, this RA considers the following.

10.5.1 Health Disparities among Populations Surrounding the Urban and Suburban Sites

Health disparities are differences in health outcomes and their determinants between segments of the population, as defined by social, demographic, environmental, and geographic attributes (Carter-Pokras and Baquet 2002; Truman, Smith et al. 2011). *Health inequalities* (often used interchangeably with disparities) is used in the scientific and economic literature to refer to summary measures of population health associated with individual- or group-specific attributes such as income, education, or race/ethnicity (Asada 2010). *Health inequities* are a subset of health inequalities that are modifiable, associated with social disadvantage, and considered ethically unfair (Braveman and Gruskin 2003).

On the basis of the public health practice, medical research and environmental justice literature, it is noted that there are differences in life expectancy, morbidity, risk factors, and quality of life among segments of the population by race/ethnicity, sex, education, income, geographic location, and disability status (Institute of Medicine (U.S.). Committee on Environmental Justice. and Health Sciences Policy Program (U.S.) 1999; Truman, Smith et al. 2011). For example, the infant mortality rates among black infants are more than double than that of whites (US Department of Health and Human Services 2011). Similarly, minorities experience higher rates of heart disease and diabetes, while they have lower rates of cancer screening and immunizations. Specific examples related to infectious diseases include a higher rate of

1 HIV/AIDS, syphilis, hepatitis, and tuberculosis among racial and ethnic minorities [reviewed in (US
2 Department of Health and Human Services 2011)]. Those disparities are believed to be the results of the
3 complex interaction among genetic variations, environmental factors, and specific health behaviors. The
4 health disparities are noted in Massachusetts (Office of Health and Human Services (EOHHS) 2011).

6 **10.5.2 Access to Healthcare at Urban and Suburban NEIDL Sites**

7 The Massachusetts Health Care Insurance Reform Law of 2006 mandates that nearly every resident of
8 Massachusetts obtain a state-government-regulated minimum level of healthcare insurance coverage and
9 provides health insurance for residents earning less than 150 percent of the federal poverty level who are
10 not eligible for Mass Health (Medicaid). The law also partially subsidizes health care insurance for those
11 earning up to 300 percent of the federal poverty level. Coverage to almost all residents of Massachusetts
12 is done through a combination of Medicaid expansions, subsidized private insurance programs, and
13 insurance market reforms. Massachusetts residents must demonstrate on their annual tax returns that they
14 have had health insurance meeting *minimum creditable coverage* standards during all months of the
15 previous year, excluding any lapse in coverage of 63 days or less. If unable to do that, filers will face tax
16 penalties as long as an affordable product is available to them. An individual may request an exemption
17 from this requirement if he or she does not obtain coverage because of his or her religious beliefs. The
18 Massachusetts Health Care Insurance Reform Law of 2006 applies to the populations at both the urban
19 and suburban sites in Massachusetts. However, the law does not apply to populations at the rural site
20 because it is in New Hampshire.

21
22 With regard to the urban site of NEIDL, a local resource for access to health care is the BMC. This
23 tertiary level care medical facility is a teaching hospital and has nearly one million patient visits per year,
24 more than half of those patients have an annual income at or below \$20,420.00 (BMC 2008). About 70
25 percent of patients come from underserved populations including low-income families, elders, and people
26 with disabilities, minorities and immigrants. The services provided to the patients include comprehensive
27 range of care, inpatient, clinical and diagnostic services, and more than 70 specialties and subspecialties
28 of medicine and surgery. BMC also is part of an integrated health care system that includes 15 community
29 health centers in the Boston area and serves more than 280,000 people annually. Additionally, BMC
30 Health Net Plan coordinates health coverage for Massachusetts residents with low to moderate incomes,
31 serves more than 240,000 members and is the state's largest managed care organization for both
32 MassHealth and Commonwealth care (BMC 2008).

Similarly, the environmental justice communities farther away from the suburban NEIDL site (in the 6- to 10-km radius away from the site) are in the urban community of Lowell, the fourth largest city of Massachusetts. There, access to medical care is available through two large facilities. One is the Lowell Community Health Center (<http://www.lchealth.org/Fact-Sheet-2010.pdf>), a nonprofit organization whose mission is to “to provide caring, quality and culturally competent health services to the people of Greater Lowell, regardless of their financial status; to reduce health disparities and enhance the health of the Greater Lowell community; and to empower each individual to maximize their overall well-being.” That health center served nearly 35,000 local residents in 125,000 visits during 2009; 94 percent of the patients were noted to have incomes below the federal poverty level, and the majority were racial and ethnic minorities with limited English proficiency. The other large provider is Saints Medical Center (<http://www.saintsmedicalcenter.com/Community/SaintsMedicalCenterCBreport2010.pdf>), which is a nonprofit, full-service, 157-bed acute care community hospital that provided care to nearly 315,000 residents in 25 towns in the greater Lowell area. It had 6,500 inpatients and 281,000 outpatients during the fiscal year 2010.

10.5.3 High Containment Laboratories and Guidelines for Biosafety and Biocontainment

Regardless of location, U.S. high biocontainment laboratories follow guidelines for biosafety and biocontainment. *Biosafety in Microbiological and Biomedical Laboratories*, (BMBL), 5th ed., has become the code of practice for biosafety—the discipline addressing the safe handling and containment of infectious microorganisms and hazardous biological materials. These principles are containment and risk assessment. The fundamentals of containment include the microbiological practices, safety equipment, and facility design and safeguards that protect laboratory workers, the environment, and the public from exposure to infectious microorganisms that are handled and stored in the laboratory. A risk assessment is the process that enables the appropriate selection of microbiological practices, safety equipment, and facility safeguards that can prevent laboratory-associated infections. The BMBL is periodically updated to refine guidance according to new knowledge and experiences and to address contemporary issues that present new risks that confront laboratory workers and the public health.

Thus, it is expected that NEIDL will be built and operated according to the highest standards of biosafety and biocontainment with administrative and engineering mitigative strategies in place to decrease risk of exposure to the community surrounding NEIDL, which includes environmental justice communities in the urban and suburban sites.

10.5.4 Lack of Occupational Exposure Limits for Biological Agents

An occupational exposure limit is an upper limit of an acceptable concentration of a hazardous substance for a material or class of material in the air at the workplace. Occupational exposure limits are set by legislation and are enforced by a governmental entity to protect the health and safety of the worker and the general public (29 CFR 1910.1000).

The Occupational Safety and Health Administration (OSHA) of the U.S. Department of Labor publishes and sets Permissible Exposure Limits (PELs) to protect workers against the health effects of exposure to hazardous substances. PELs are regulatory limits on the amount of concentration of a substance in the air, and they are enforceable (29 CFR 1910.1000). PELs do not include biological agents. Additionally, other industries such as the nuclear industry, have established occupational and public exposure standards that are set by a regulatory agency. The Nuclear Regulatory Commission sets and enforces standards of exposure for protection to workers and the general public from ionizing radiation resulting from activities conducted under licenses issued by the Nuclear Regulatory Commission. These regulations are issued under the Atomic Energy Act of 1954, as amended, and the Energy Reorganization Act of 1974 as amended. Nuclear Regulatory Commission regulations under 10 CFR Part 20 subpart C addresses occupational radiation dose exposure limits, and subpart D addresses radiation dose limits for individual members of the public.

Unlike the chemical and nuclear industry there are no explicit occupational or public exposure limit values for biological agents. Nor is there legislation or a governmental entity that has set occupational or public exposure limit values for biological agents. These limits have not been set because of the essential difference between biological agents and other hazardous substances are their ability to reproduce/replicate. A small amount of a microorganism can grow considerably in a very short time under favorable conditions, therefore the value/level/volume of an organism does not remain constant (Gorny 2007). According to the Department of Biohazards, Institute of Occupational Medicine and Environmental Health, World Health Organization, there is a need for occupational exposure limits for biological agents, however in contrast to chemical or physical hazards for which such criteria already exist, for example the higher the concentration, the longer the time of exposure the more severe the health outcome, biohazards do not show a proportional answer of the human body to the exposure to the risk, which makes it very difficult to determine universally valid evaluation criteria (Gorny 2007).

Thus, without guidelines regarding occupational exposure limits for biological agents, this RA faces the challenge of determining the significance of a release of a pathogen as a result of loss of biocontainment

1 on the basis of the amount of release of pathogen only. The significance of the release, is thus, based on
2 the consequences of the release of a pathogen, specifically in terms of infections and deaths due to the
3 pathogen.
4

5 **10.5.5 Public Outreach**

6 Because of human health issues raised in the public, judicial review process, and to respond to findings
7 from the NRC, a component of the RA is to perform an analysis and determine if the NEIDL's location
8 will have a disproportionate impact on low-income and minority populations in the adjacent community,
9 not just at the urban location as was performed in the EIS, but also at the suburban and rural sites. The
10 BRP was established as a Working Group of the Advisory Committee to the Director (ACD) of NIH to
11 guide its response to judicial requests and comments and concerns voiced by the local community, the
12 NRC, and the general public regarding the construction and operation of the NEIDL (BRP 2008). With
13 those objectives in mind, the BRP has engaged the Boston community from the inception of the RA in
14 2008 for purposes of gathering public input. All public input gathered has been compiled and considered
15 into the environmental justice methodology for the RA.
16

17 Table 10-1 lists key public outreach activities, which have occurred throughout the development of this
18 RA. The table includes meetings specifically aimed at informing the public and gaining public input, as
19 well as working meeting that were webcast for public access.
20

Table 10-1. NEIDL risk assessment: public involvement

Date	Event	Purpose
March 13, 2008	BRP Meeting, Bethesda	Boston community members were invited and participated in discussions regarding the charge of the BRP, NIH, NEIDL, overview of the principles of environmental protection laws, and RA studies
May 2, 2008	BRP/NRC Meeting Bethesda	BRP recommendations regarding RA work plan
May 16, 2008	BRP Meeting, Boston	Boston community members attended and provided comments on proposed RA work plan recommended by the BRP
June 6, 2008	BRP Presentation to the Advisory Committee to the Director NIH	Briefing to Advisory Committee to the Director NIH regarding the proposed scope and analytic approach for supplementary RA
July 16, 2008	BRP Meeting, Bethesda	Boston community members were invited and participated in roundtable discussions with BRP members on environmental justice and how to effectively engage communities
October 14, 2008	BRP Meeting, Boston	Boston community members attended and provided comments on BRP questions related to community engagement and communication regarding the planning and oversight of biocontainment laboratories
December 5, 2008	BRP Presentation to the Advisory Committee to the Director NIH, Bethesda	Progress update regarding NEIDL RA was presented: Phase I; Interim status of NEIDL; Boston prohibition on use of recombinant DNA at BSL-4; Phase II Tasks; BRP community meetings; Principles and practices for public involvement and communications; Best practices for institutional review
April 7, 2009	BRP Teleconference with the National Research Council	Boston community members attended and provided comments on the RA study design, agents, scenarios and methodology
June 4, 2009	Advisory Committee to the Director (ACD) of NIH, Meeting, Bethesda	BRP Chair presented the community with engagement document(s) developed to address fundamental principles and best practices for public and local community relations and communications regarding a national research resource. Approved by the ACD
March 19, 2010	BRP/NRC Meeting Bethesda	NRC reviewed and provided comments on Tetra Tech's proposed approach to quantitative modeling
April 28, 2010	BRP Meeting, Boston	Boston community members attended and provided comments on proposed approach to quantitative modeling
September 22, 2010	BRP/NRC Meeting Bethesda	NRC reviewed and provided comments on preliminary results on initial and secondary infection rates
October 5, 2010	BRP Meeting, Boston	Boston community members attended and provided comments on initial and secondary infection rates

2

All information cited in the above table is also available in greater detail on the BRP website at <http://nihblueribbonpanel-bumc-neidl.od.nih.gov/meetings.asp>.

10.6 Demographic Data

The source of offsite impacts considered for the NEIDL RA environmental justice analysis is the area within a 10-km (6-mile) radius from the center of the NEIDL at each of the three potential sites (urban, suburban and rural) of a potential release of any or all the 13 selected pathogens. A guideline of 1-km (0.6-mile) radius study area within city limits and a 2.4-km (4-mile) radius outside city limits is provided by the Nuclear Regulatory Commission as generally sufficient for assessing potential environmental justice impacts associated with activities other than nuclear power plants (NUREG 2003). For NEIDL, environmental justice data were collected for a radius of 10 km (6 miles) of each of the three sites, which is 10 times the city recommendation of the Nuclear Regulatory Commission. The larger radius is used to ensure that all potentially affected areas are considered. The population data are taken from the U.S. Census Bureau's 2000 decennial census for each tract within the 10-km (6-mile) area; that is the most recent year for which data are available at the census tract geographic level.

10.6.1 Urban Site Environmental Justice

10.6.1.1 Federal Criteria

Minority populations and poverty rates for each census tract in the Boston site's 10-km (6-mile) boundary area are listed in Table 10-2. Table 10-2 summarizes the totals within each 2-km (1.2 mile) radius boundary within the 10-km (6-mile) area. Of the 297 census tracts identified in the 10-km (6-mile) radius boundary, 152 (51percent) had a higher percentage of minority residents compared to the national average, and 156 of the census tracts (53 percent) had a higher percentage of persons living in poverty compared to the United States. As shown in Table 10-2, the portion of census tracts with a percentage of minority populations or a percentage of persons below poverty that is greater than the national average decreases going away from the interior 2-km (1.2-mile) circle of the Boston site

Table 10-2. Minority and low-income population data for the 10-km (6-mile) boundary area of the urban site

Boundary area radius	Total census tracts	Number of tracts with a minority population above the U.S. level of 31 percent	Percent of tracts with a minority population above the U.S. level of 31 percent	Number of tracts with a poverty level above the U.S. level of 12 percent poverty	Percent of tracts with a poverty level above the U.S. level of 12 percent poverty
Inside 2-km (1.2 mile)	32	24	75%	28	88%
2-4 km (1.2–2.4 mile)	62	40	65%	44	71%
4-6 km (2.4–3.6 mile)	68	42	62%	45	66%
6-8 km (3.6–4.8 mile)	64	28	44%	25	39%
8-10 km (4.8–6.0 mile)	71	18	25%	14	20%
Total for the 10-km (6-mile) area	297	152	51%	156	53%

Source: U.S. Census Bureau 2000

10.6.1.2 State Criteria

To assess environmental justice per the Massachusetts criteria, data were collected on minority populations, foreign-born populations, households lacking English language proficiency, and median annual household income for each neighborhood (defined as a census block group) within a 10-km (6-mile) area of the Boston site. Table 10-3 summarizes the totals within each 2-km (1.2-mile) radius boundary within the 10-km (6-mile) area. Of the 1,112 census block groups identified in the 10-km (6-mile) radius boundary, 622 block groups (56 percent) had a higher percentage of minority residents compared to the state's threshold of 25 percent; 474 census block groups (43 percent) had 25 percent or more residents who are foreign born; 78 block groups (7 percent) had households where 25 percent or more of the residents lacked English language proficiency; and 281 block groups (25 percent) had a median annual household income at or below 65 percent of the statewide median income of \$50,500. As shown in Table 10-3, the portion of census block groups meeting one or more of the state environmental justice guidance criteria was, for the most part, higher within the boundaries closest to the Boston NEIDL site and decreases moving away from the site.

Table 10-3. Massachusetts criteria for environmental justice for the 10-km (6-mile) boundary area of the urban site

Boundary area radius	Total census block groups	Percent of block groups with a minority population above the state guidance level of 25 percent	Percent of block groups with a foreign born population above the state guidance level of 25 percent	Percent of block groups lacking English language proficiency above the state guidance level of 25 percent	Percent of block groups with a median annual household income at or below 65 percent of the Massachusetts median income
Inside 2 km (1.2 mile)	100	79%	35%	17%	55%
2-4 km (1.2–2.4 mile)	203	71%	44%	4%	39%
4-6 km (2.4–3.6 mile)	228	66%	57%	11%	27%
6-8 km (3.6–4.8 mile)	252	53%	48%	8%	17%
8-10 km (4.8–6.0 mile)	329	35%	30%	2%	12%
Total for the 10-km (6-mile) area	1,112	56%	43%	7%	25%

10.6.2 Suburban Site Environmental Justice

10.6.2.1 Federal Criteria

Minority populations and poverty rates for each census tract in the Tyngsborough 10-km (6-mile) boundary area are listed in Table 10-4.

Table 10-4 summarizes the minority and low-income population totals within each 2-km (1.2-mile) radius within the 10-km (6-mile) boundary area. Of the 85 census tracts identified in the 10-km (6-mile) boundary area, 19 (22 percent) had a higher percentage of minority residents compared to the United States, and 20 of the census tracts (24 percent) had a higher percentage of persons living in poverty compared to the United States. As shown in Table 10-4, the portion of census tracts having a percentage of minority populations, or a percentage of persons living below the poverty level, that is greater than the overall U.S. levels, is higher in the exterior circles (6-8 km [3.6–4.8 miles]) and (8–10km [4.8–6.0

miles]), away from the Tyngsborough site. Those tracts with the higher percentages of minority and low-income populations are all in the southeast quadrant of the 10-km (6-mile) circle, near the city of Lowell.

Table 10-4. Minority and low-income population data for the 10-km (6-mile) boundary area of the suburban site

Boundary area radius	Total census tracts	Number of tracts having a percentage of minority persons above the U.S. level of 31 percent	Percent of tracts with a minority population above the U.S. level of 31 percent	Number of tracts having a percentage of persons in poverty above the U.S. level of 12 percent	Percent of tracts with a percentage of persons in poverty above the U.S. level of 12 percent

10.6.2.2 State Criteria

To assess environmental justice per the Massachusetts criteria, data were collected on minority populations, foreign-born populations, households lacking English language proficiency, and median annual household income for each neighborhood (defined as a census block group) within a 10-km (6-mile) area of the Tyngsborough site. Table 10-5 summarizes the totals within each 2-km (1.2-mile) radius boundary within the 10-km (6-mile) area. Of the 260 census block groups identified in the 10-km (6-mile) radius boundary around Tyngsborough, 72 block groups (28 percent) had a higher percentage of minority residents compared to the state's threshold of 25 percent; 32 block groups (12 percent) had 25 percent or more residents who are foreign born; 9 block groups (3 percent) had households where 25 percent or more of the residents lacked English language proficiency; and 31 block groups (12 percent) had a median annual household income at or below 65 percent of the statewide median income of \$50,500. As shown in Table 10-5, the portion of census block groups meeting one or more of the state environmental justice guidance criteria is higher in the exterior circles (6–8 km [3.6–4.8 miles]) out to (8–10 km [4.8–6.0

miles)). Those census block groups are southeast of the proposed Tyngsborough site, near the city of Lowell.

Table 10-5. Massachusetts criteria for environmental justice for the 10-km (6-mile) boundary area of the suburban site

Boundary area radius	Total census block groups	Percent of block groups with a minority population above the state guidance level of 25 percent	Percent of block groups with a foreign born population above the state guidance level of 25 percent	Percent of block groups lacking English language proficiency above the state guidance level of 25 percent	Percent of block groups with a median annual household income at or below 65 percent of the Massachusetts median income

10.6.3.2 State Criteria

Although the rural site of Peterborough is in New Hampshire, environmental justice analysis per the Massachusetts criteria was conducted for the rural site for consistency and comparison with the urban and suburban sites. Data were collected on minority populations, foreign-born populations, households lacking English language proficiency, and median annual household income for each neighborhood (defined as a census block group) within a 10-km (6-mile) area of the Peterborough site. Table 3-7 summarizes the totals within each 2-km (1.2-mile) radius boundary within the 10-km (6-mile) area. Of the 62 census block groups identified in the 10-km (6-mile) radius boundary around the rural site, none of the block groups exceed any of the Massachusetts environmental justice criteria.

Table 10-7. Massachusetts criteria for environmental justice for the 10-km (6-mile) boundary area of the rural site

Boundary area radius	Total census block groups	Percent of block groups with a minority population above the state guidance level of 25 percent	Percent of block groups with a foreign born population above the state guidance level of 25 percent	Percent of block groups lacking English language proficiency above the state guidance level of 25 percent	Percent of block groups with a median annual household income at or below 65 percent of the Massachusetts median income
Inside 2 km (1.2 mile)	10	0%	0%	0%	0%

10.7 Results

Demographic Data

Environmental justice populations, as defined by the federal environmental justice criteria and the Commonwealth of Massachusetts EEA criteria, were identified at the urban and suburban sites. No environmental justice communities meeting these same criteria were identified at the rural site. At the urban site, populations that met or exceeded the criteria were located throughout the 10-km (6-mile) study area, with the higher percentage of neighborhoods meeting one or more of the criteria located nearer to the center of the study area (see Tables 10-2 and 10-3). At the suburban site, the environmental justice populations are located farther away from the NEIDL location (6–10 km or 3.6–6 miles]) and are associated with the more urbanized, higher-density community of Lowell (the fourth largest city in Massachusetts), southeast of Tyngsborough.

Health Disparities/Chronic Disease

Health disparities are differences in health outcomes and in the determinants between segments of a population, as defined by social, demographic, environmental, and geographic attributes (Carter-Pokras and Baquet 2002; Truman, Smith et al. 2011). The literature shows that health disparities are generally more evident within environmental justice communities; therefore, health disparities are assumed to be present within the identified environmental justice communities at both the urban and suburban sites. If

the health disparities were a result of a health *inequity* factor, such as access to health care, this can somewhat be mitigated at the urban and suburban sites by remedies of the Massachusetts Health Care Insurance Reform Law of 2006. The Law mandates that nearly every resident of Massachusetts obtain a state-government-regulated minimum level of healthcare insurance coverage. The Law also provides health insurance for residents earning less than 150% of the federal poverty level who are not eligible for Mass Health (Medicaid). Additionally, based on available statistics, Boston Medical Center is Boston's largest provider of healthcare accessible to all, regardless of status or ability to pay. The Massachusetts Health Care Insurance Reform Law does not apply to the NEIDL rural site since it is located in the State of New Hampshire. However, there are no environmental justice communities present within 10 km (6 miles) of the rural site..

As noted in section 10.5.1 above, racial and ethnic minorities have increased prevalence and patterns of chronic diseases. These chronic diseases have the potential to contribute to increased susceptibility to pathogens. Preliminary reports from the 2009 H1N1 influenza pandemic have suggested a disproportionate impact on racial and ethnic minorities (Kwan-Gett, Baer et al. 2009; Centers for Disease Control and Prevention 2010; Truelove, Chitnis et al. 2011; Uscher-Pines, Maurer et al. 2011; Wenger, Castrodale et al. 2011), indicating higher rates of hospitalization, morbidity, and mortality among racial/ethnic minorities. No clear reason was noted for the increased hospitalization and mortality, although it was postulated that underlying chronic diseases may have played a role. A detailed study based on survey responses of minorities during the 2009 influenza pandemic has also expressed concern of the disproportionate impact of the pandemic; however, the authors were unable to demonstrate an increased risk of susceptibility when controlled for socioeconomic status and demographics (Quinn, Kumar et al. 2011).

Appendix I provides a discussion on the susceptibility of specific medically vulnerable populations (i.e., the very young and the elderly, diabetics, those with HIV/AIDS, and pregnant women) to the 13 pathogens studied in this RA

Location of NEIDL

With regard to the operations of NEIDL and event sequences that could lead to loss of biocontainment (Chapter 7), this RA assumes no difference with respect to the siting of the laboratory.

Types of Exposure

There are two types of operational impacts to consider: (1) those that may directly expose people in environmental justice communities to a release of pathogen from the facility; and (2) those that may indirectly expose people environmental justice communities by secondary transmission of a pathogen. Each of these types of impacts is addressed separately.

Direct Exposure

Event sequences (e.g., earthquake) could potentially lead to a release of pathogen and directly expose members of the surrounding community at the urban site. This RA has estimated that a person at 1 km (0.6 mi) from the NEIDL facility would be exposed to a very low amount of pathogen (Chapter 7). Environmental justice communities at the urban site are present within a 2-km (1.2-mi) radius of the NEIDL site; therefore, it is assumed that members of these environmental justice communities are potentially at risk for being exposed to pathogens in the event of such a release. The risk of exposure is estimated to be similar for all persons in the area, regardless of their environmental justice status. Based on the results of this RA, in the event of a maximum reasonably foreseeable release earthquake, the public would receive an average exposure that is unlikely to cause infection, with the possible exception of RVFV, for which a release leading to 1–5 infections and 1 fatality at the urban site may occur with an average frequency of once in 10,000 to 1 million years (frequency category C). Infections from other pathogens are mostly estimated to occur with an average frequency less than once in one million years (frequency category D). Initial infections are estimated to be in frequency category D at the suburban and rural sites. The rural and suburban sites do not have environmental justice communities within the 1-km (1.2-mi) radius of exposure and, therefore, impact is not considered significant at either of these two sites.

Secondary Transmission

The risk of exposure from work done at NEIDL is not based on the location of the facility, but on the potential that an infected worker leaves the facility and potentially transmits the pathogen to social contacts. Close social contacts include family members and friends. Other important social contacts include those individuals, regardless of environmental justice status, that are encountered during routine commute to work, including those on mass transit. If there are secondary exposures due to an infected worker leaving the facility, the potential for exposure extends well beyond the 10-km (6-mi) radius used for the demographic study, and those at greatest risk will be the worker's social contacts. If multiple generations of transmission occur, then infections could occur later in the outbreak among people who are not direct contacts of the initially infected laboratory worker. There are no data to indicate that any social

1 contacts, regardless of race, ethnicity, or economic status are or are not more likely to become infected
2 from an infected worker leaving NEIDL.

3
4 This RA considers event sequences that could potentially lead to secondary transmission of the pathogens
5 in the local community. These secondary transmissions are postulated to occur after an *undetected or*
6 *unreported* loss of biocontainment (i.e., exposure and initial infection from a primary-exposed laboratory
7 worker). For these event sequences, it is to be noted that the potential for secondary transmission exists
8 for pathogens such as *Yersinia pestis* (especially the pneumonic form of disease), 1918 H1N1 influenza
9 virus, SARS-associated coronavirus, Andes virus, Ebola virus, Marburg virus, Lassa virus, Junín virus
10 and Nipah virus.

11
12 For four of these pathogens, quantitative estimates were derived for their secondary transmission
13 potential, which provide insight into how frequently infections might be expected to occur in the public.
14 For example, a laboratory worker becoming infected with a transmissible pathogen via needlestick, who
15 subsequently leaves the facility and infects at least one member of the public, is a sequence of events that
16 is estimated to occur with a frequency between once in 500 years to once in 30,000 years. The frequency
17 with which outbreaks resulting in various numbers of infections and fatalities among the public might be
18 expected under this scenario is analyzed in detail in Chapter 9 and Appendix L. The extent to which local
19 individuals (defined as people in the city of Boston, the town of Tyngsborough, and the towns of
20 Peterborough and Hancock) would bear the risk estimated under secondary transmission scenarios is not
21 obvious, due to the unpredictability of where transmissions would occur among people traveling in and
22 out of the local area. Estimates of risk to local and non-local individuals (defined with respect to
23 commuting data, see Appendix L) were generated for this RA, which are relevant in considering potential
24 risk to environmental justice communities.

25
26 For the urban site, the estimated risk to local residents is relevant for the environmental justice analysis
27 because environmental justice communities were identified within the city of Boston. Estimates (shown
28 in Appendix L) for the frequency of 10 or more fatalities among Boston residents range from once in
29 5,300 years to once in more than 10 million years. For the frequency of 100 or more fatalities among
30 Boston residents, estimates range from once in 50,000 years to once in more than 10 million years. It is
31 also noted that outbreaks spreading outside of the city might pose a risk to any environmental justice
32 communities in the surrounding area as well.

1 For the suburban site, no environmental justice communities were found in the town of Tyngsborough,
2 Massachusetts. Nonetheless, as shown in Appendix L, the estimated effects of commuting into and out of
3 Tyngsborough result in a substantial portion of the risk for large outbreaks being potentially borne by
4 non-locals, a result which suggests that the environmental justice communities identified in nearby
5 Lowell, Massachusetts, could be at risk during a potential outbreak started in Tyngsborough. However,
6 the extent to which there might be a specific risk to residents of Lowell due to observed travel patterns in
7 that area has not been assessed.

8
9 For the rural site, no environmental justice communities were found in the towns of Hancock and
10 Peterborough or in towns within a 10-km (6-mi) radius of the site. However, as shown in Appendix L, the
11 estimated effect of commuting into and out of the local area may result in a substantial portion of the risk
12 for large outbreaks being potentially borne by non-locals, and it is possible that large outbreaks would
13 extend beyond the 10-km (6-mi) radius applied in this environmental justice analysis. Therefore, the
14 possibility that a large outbreak starting at the rural site would pose a risk to one or more environmental
15 justice communities in a wider radius cannot be ruled out.

16
17 For secondary transmission, the analysis did not determine that people in close proximity to the NEIDL
18 sites were at greater risk than people in the larger vicinity located farther away. Risk of exposure is
19 estimated to be similar for all persons in the area, regardless of their environmental justice status.

20 **Accessibility/Utilization**

21 Addressing environmental justice for purposes of this RA and for the communities at the urban, suburban,
22 and rural site is a very important yet complex topic. As a result, BU and NIH, based on EPA NEJAC
23 guidance initiated a public process going back to January 9, 2004. This process goes beyond that which is
24 regulatory required for public involvement under NEPA for the collection, assimilation, review of public
25 concern, and available data as it pertains to *Executive Order 12898, Federal Actions to Address*
26 *Environmental Justice in Minority and Low-Income Populations*. In addition, CEQ, DOE and NRC
27 NEPA Guidance were also used to inform this analysis.

28
29
30 The available literature recognizes that large proportions of EJ communities suffer from health
31 disparities(e.g life expectancy, morbidity, risk factors, quality of life). The literature also shows that
32 environmental justice communities most often are comprised of individuals that have lack of access to
33 health services. The analysis for this RA therefore considered factors and available data regarding
34 environmental justice communities and access to services in the state of Massachusetts, keeping in mind

that equal accessibility to health services and medical care is not necessarily the same as equal utilization of health services and medical care. The findings are unique for the State of Massachusetts as this State has a very different health care system than most states in the Union. Massachusetts has a state regulated health care insurance coverage system which was implemented in 2006. Health care insurance coverage for people above 100% poverty level and up to 300% of the poverty level began in February 2007. Additionally, BUMC, a tertiary level care facility, has one million patient visits each year. Annually, one half, or 500,000, of the patients seeking care at BUMC have an annual income below \$20,000.00 a year, and 70% of the patients come from underserved populations (BMC, 2008).

Medical Vulnerability

As discussed above in section 10.5.1, there are disparities in life expectancy, morbidity, risk factors, and quality of life among segments of the population by race/ethnicity, sex, education, income, geographic location, and disability status. Those disparities are believed to be the results of the complex interaction among genetic variations, environmental factors, and specific health behaviors. Furthermore, those who are medically compromised among EJ communities are likely to be at higher risk of infection and experience adverse outcomes as a result of those infections. There are reports of higher rates of infectious diseases such as HIV/AIDS, syphilis, hepatitis, and tuberculosis among racial and ethnic minorities. It is postulated in the literature that underlying chronic disease may be a contributing factor of the disproportionate impact of an infectious disease pandemic on racial and ethnic minorities. Published reports based on the experience with the recent 2009 H1N1 influenza pandemic have begun to address these issues. Thus, health disparities along with chronic diseases have the potential to contribute to increased susceptibility to any of the pathogens being studied in this RA. These disparities also have the potential to contribute to differences in how communities respond to exposure and infection with any of the pathogens. There are, however, limited published data on this topic.

Specific sub- populations such as children under 5 years of age, adults over 65 years of age, those with diabetes, those with HIV/AIDS, and pregnant women are likely to exhibit increased susceptibility/vulnerability in terms of increased morbidity and mortality to the pathogens addressed in this RA. With available data, to further address the impact of the effect of pathogens on these sub-populations, a separate analysis was performed to address this concern and is presented in Appendix I and Chapters 8 and 9.

M. Environmental Justice

M.1 Introduction

Environmental Justice is defined in Executive Order 12898, *Federal Actions to Address Environmental Justice in Minority and Low Income Populations*, and requires federal agencies to identify and address, as appropriate, disproportionately high and adverse human health or environmental impacts of federal programs, policies, and activities on minority and low income populations. The order also requires agencies to ensure greater public participation in their decision making process. The objective of the environmental justice analysis for this risk assessment (RA) is to identify and address potential disproportionately high and adverse human health and environmental impacts on minority or low income populations from the National Emerging Infectious Diseases Laboratory (NEIDL) within the defined region of analysis for the urban, suburban and rural sites. The analysis characterizes U.S. Census data available for each site and compares U.S. Census data between sites.

M.1.1 Federal Criteria

On February 11, 1994, President William J. Clinton signed Executive Order 12898, *Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations*, which directed federal agencies to develop environmental justice strategies to address disproportionately high and adverse human health or environmental effects of their programs on minority and low-income populations, as well as focusing federal attention on the environmental and human health conditions of minority and low-income populations with the goal of achieving environmental protection for all communities. The order is also intended to promote nondiscrimination in federal programs that affect human health and the environment and provide minority and low-income communities access to public information and public participation in matters relating to human health and the environment. In addition to Executive Order 12898, two guidance documents help define how to address environmental justice concerns: The Council on Environmental Quality's (CEQ's) December 1997 document, *Environmental Justice Guidance under the National Environmental Policy Act*, and an April 1998 document produced by an EPA working group titled *Final Guidance for Incorporating Environmental Justice Concerns in EPA's NEPA Compliance Analyses*. The CEQ has oversight of the federal government's compliance with Executive Order 12898 and National Environmental Policy Act (NEPA). EPA has lead responsibility for implementation of the executive order as Chair of the Interagency Working Group on Environmental Justice (CEQ 1997).

M.1.2 Minority Populations

The federal environmental justice criteria identify minority populations as, Black or African American, American Indian and Alaska Native, Asian, Native Hawaiian and other Pacific Islander, persons of two or more races, and persons of Hispanic origin. Minority populations should be identified for environmental justice analyses where, either the minority population of the affected area exceeds 50 percent, or the minority population percentage of the affected area is meaningfully greater than the minority population percentage in the general population or other appropriate unit of geographic analysis (CEQ 1997). The latter guidance was used for this analysis to address the federal environmental justice criteria, identifying census tracts with minority population percentages exceeding the U.S. level. Census tracts are subdivisions of a county and represent a level at which disproportionate effects would be more noticeable. As of, 25 percent of the U.S. population was of a minority race or ethnicity (U.S. Census Bureau 2000a).

M.1.2.1 Low-Income Populations

The federal environmental justice criteria use poverty thresholds established by the Census Bureau to identify low-income populations (CEQ 1997). Poverty status is reported as the number of persons or families with income below a defined threshold level. The Census defines the 2000 poverty level as \$8,791 (\$10,956 for 2009) of annual income, or less, for an individual and \$17,604 (\$21,954 for 2009) of annual income, or less, for a family of four (U.S. Census Bureau 2010a). As with the minority populations, the federal environmental justice criteria identify low-income populations for those census tracts with poverty rates exceeding those of the United States. As of the 2000 census, 12 percent (U.S. Census Bureau 2000a) of U.S. residents were classified as living in poverty, and in 2008 there were 13.2 percent of U.S. residents classified as living in poverty (U.S. Census Bureau 2010b).

M.1.2.2 Disproportionately High and Adverse Human Health Effects

Adverse health effects are measured in risks and rates that could result in fatal or nonfatal adverse effects on human health. Adverse health effects could include bodily impairment, infirmity, illness, or death. Agencies are required to identify programs, policies or activities that can cause disproportionately high and adverse human health or environmental effects. The determination, by the agency, of disproportionately high and adverse impacts is made in consideration of whether the impacts, as summarized in the RA, are both significant and disproportionate:

1. The impacts must be significant or above generally accepted norms, such as regulatory limits or state and local statutes and ordinances (NUREG 2003). The significance of

impacts is determined in consideration of both the context and the intensity of the impact. The context includes factors such as extent of the impact whether the impact is local, regional, or national. The context affects the number of people that could be affected. Intensity refers to the severity of the impact. Direct and indirect impacts are considered as well as immediate and long-term impacts (Title 40 of the *Code of Federal Regulations* section 1508.8).

2. The impacts are disproportionate if the risks to a minority individual or low-income individual appreciably exceed the risk to an individual in the general population (CEQ 1997).

M.1.3 State Guidance

The Commonwealth of Massachusetts Executive Office of Energy and Environmental Affairs (EEA) has an Environmental Justice Policy. The state criteria for environmental justice populations are those segments of the population that EEA has determined to be most at risk of being unaware of or unable to participate in environmental decision making or to gain access to state environmental resources. They are defined as neighborhoods that meet *one or more* of the following criteria:

- The median annual household income is at or below 65 percent of the statewide median income for Massachusetts; *or*
- 25 percent of the residents are minority; *or*
- 25 percent of the residents are foreign born, *or*
- 25 percent of the residents are lacking English language proficiency.

Neighborhoods, as defined by EEA's Environmental Justice Policy are U.S. Census Bureau block groups (Massachusetts EEA 2002).

M.2 Methodology

The National Institutes of Health (NIH) performed an environmental justice analysis and an analysis that includes input from the Boston community from January 9, 2004, to present to identify the disproportionate placement of high and adverse environmental or health impacts from the NEIDL at the urban, suburban, or rural sites on minority or low-income populations. The public input gathered since January 9, 2004, assisted in identifying a geographic scale for which demographic information was obtained on the potential impact area(s). Per CEQ, available

demographic data from the U.S. Census Bureau were used to identify the composition of the potentially affected population.

M.2.1 Environmental Justice Data Set

Census data are collected by the U.S. Census Bureau on a decennial (10-year) basis. Census tracts are small, relatively permanent statistical subdivisions of a county. Census tracts are delineated for most metropolitan areas and other densely populated counties by local census statistical areas committees following U.S. Census Bureau guidelines (more than 3,000 census tracts have been established in 221 counties outside metropolitan area's). Census tracts usually include between 2,500 and 8,000 persons and, when first delineated, are designed to be homogeneous with respect to population characteristics, economic status, and living conditions. Census tracts do not cross county boundaries. The spatial size of census tracts varies widely depending on the density of settlement. Census tract boundaries are delineated with the intention of being maintained over a long time so that statistical comparisons can be made from census to census (U.S. Census Bureau 2000b).

M.3 Demographic Data for The NIH NEIDL BUMC Site, Boston

A 10-kilometer (km) radius was defined around the proposed NIH Boston University Medical Center (BUMC) NEIDL site. A guideline of 1-km radius study area within the city limits and a 2.4-km radius outside city limits is provided by the U.S. Regulatory Commission as generally sufficient for assessing potential environmental justice impacts associated with activities other than nuclear power plants (NUREG 2003). For NEIDL, environmental justice data were collected for a radius of 10 km of each of the three sites, which is 10 times the city recommendation of the U.S. Nuclear Regulatory Commission. The larger radius is used to ensure that all potentially affected areas are considered. Demographic data were collected from the U.S. Census Bureau's 2000 decennial census for each census tract within the 10-km area; that is the most recent year for which data are available at the census tract geographic level. This 10 km radius was then subdivided into concentric 2-km circles (see Figure 1). For census tracts that covered multiple circles, the tract was included in the circle in which the majority of the tract resided; or, if the tract was largely divided over multiple circles, the data were divided between the defined areas. This 10-km area covers portions of three Massachusetts counties: Suffolk, Middlesex, and Norfolk. For comparative purposes, data for the city of Boston; Suffolk, Middlesex, and Norfolk counties; Massachusetts; and the United States are presented. In addition, this analysis was performed when the 2007 data were the most recent data available. Therefore, the 2007 data are

presented for Boston; Suffolk, Middlesex, and Norfolk counties; Massachusetts; and the United
States.

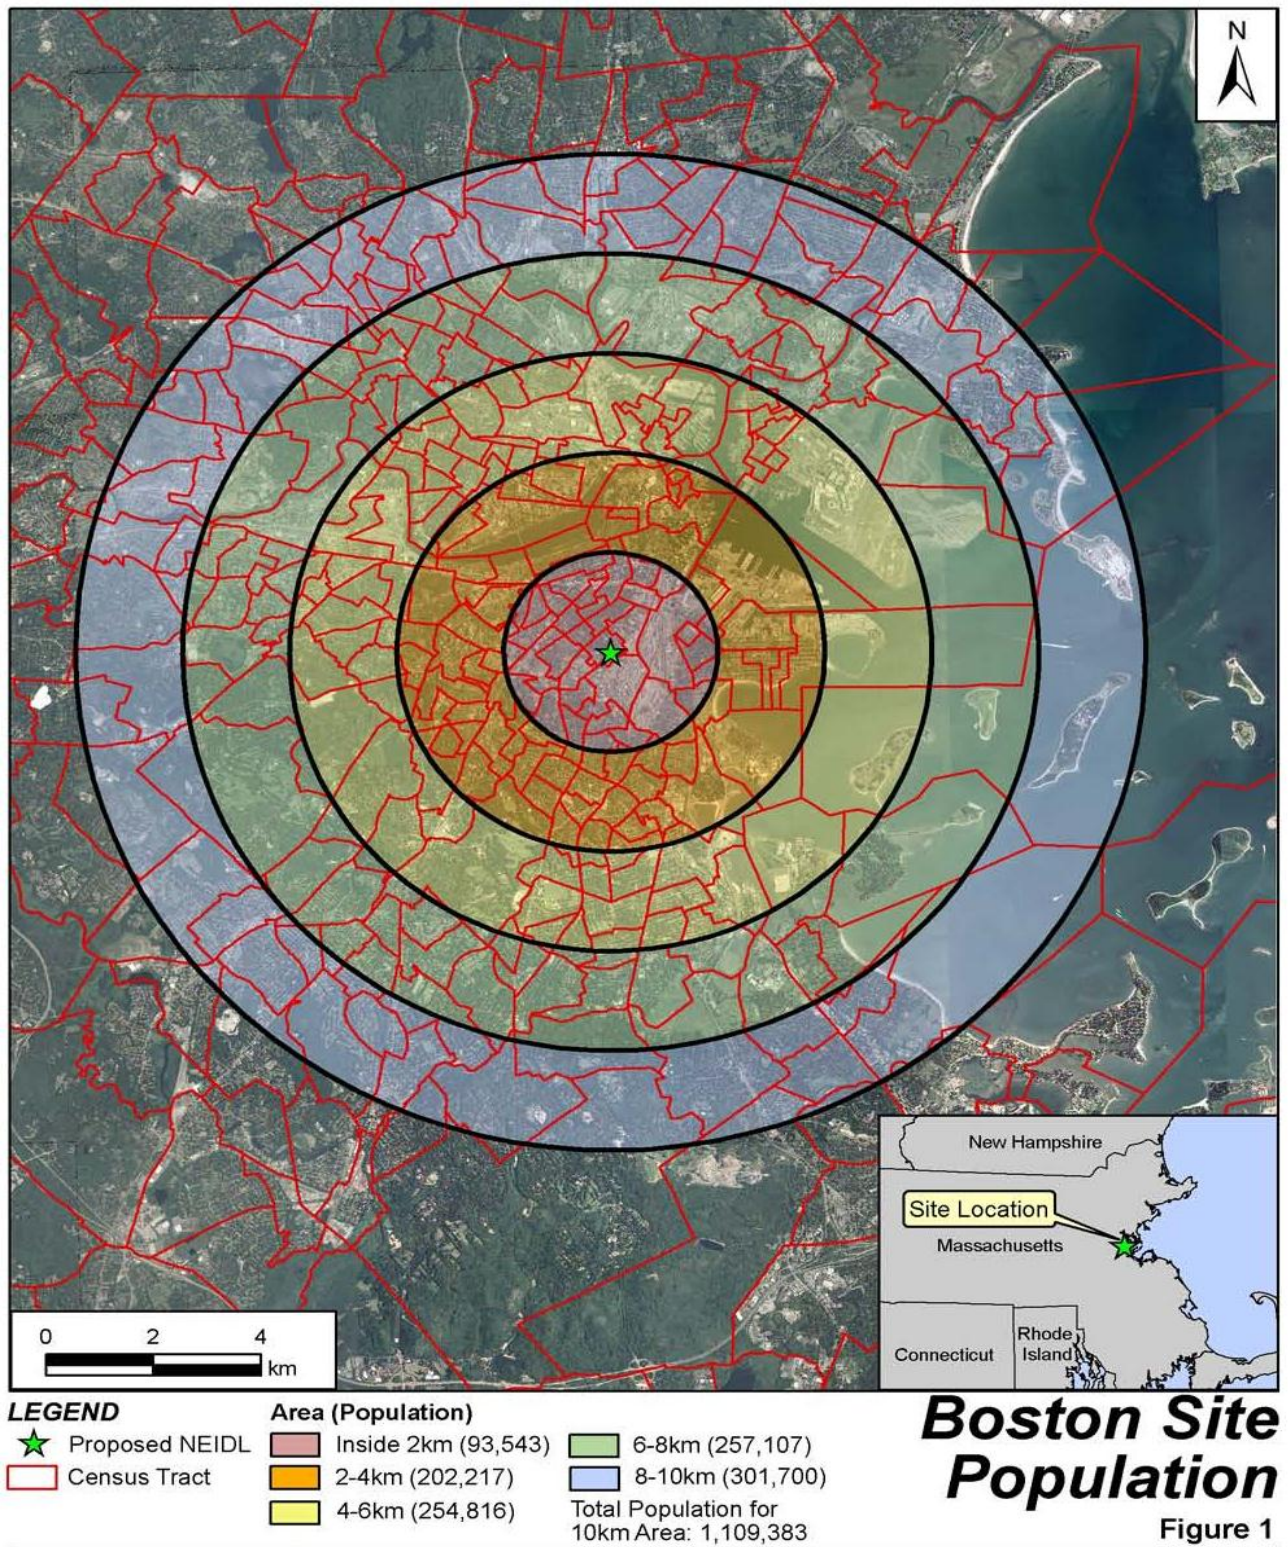

Figure 1. Boston site population

M.3.1 Population

Population data for the census tracts in the 10-km area are listed in Tables 1 through 5. The tracts are sorted first by boundary (inside 2 km, 2–4 km, 4–6 km, 6–8 km, and 8–10 km) and then numerically in ascending order by tract number. Tract 711 corresponds to the BUMC site. The population for the census tracts inside the 2-km boundary ranges from 723 to 9,346; the 2–4 km boundary ranges from 960 to 8,064; the 4–6 km boundary tract populations range from about 200 to 8,880; the 6–8 km population ranges from about 200 to 8,965; and the 8–10 km boundary census tract population ranges from about 200 to more than 8,300 (see Tables 1 through 5).

Table 6 summarizes the totals within each 2km (i.e., 2–4 km, 4–6 km, and so on) radius boundary within the 10-km area. As of 2000, the total population in the 10-km boundary was more than 1.1 million, and the area was categorized almost entirely as urban (Table 6). The boundary covers a total area of 314 square km. The population and land area of each 2-km boundary range increases moving outward from the proposed site (Table 6).

Table 6. Boston population for 10-km boundary area

Area/boundary	Total population	Total urban population	Total rural population	Land area (square kilometers)
Inside 2 km	93,543	93,543	0	12.5
2–4 km	202,217	202,217	0	37.7
4–6 km	254,816	254,816	0	62.8
6–8 km	257,107	257,107	0	87.9
8–10 km	301,700	301,568	132	113.1
Total for 10-km area	1,109,383	1,109,251	132	314

Source: U.S. Census Bureau 2000, 2008

The most recent population data (2007) for Boston, Suffolk County, and the adjacent counties of Middlesex and Norfolk, Massachusetts, and the United States are in Table 7. Boston and Suffolk had significantly higher population densities compared to the adjacent Middlesex and Norfolk counties and compared to Massachusetts and the United States. Boston and Suffolk County population increased 4 percent and 3 percent, respectively, between 2000 and 2007. That growth rate was higher than Middlesex and Norfolk counties and the state, but lower than U.S. population growth during the same period of 7 percent (U.S. Census Bureau 2007).

Table 7. 2007 Population data for jurisdictions surrounding the proposed BUMC NEIDL site

	Population density 2007 (persons per square km)	2000 Population	2007 Population	Population change, 2000–2007
Boston	4,944	589,141	613,117	4%
Suffolk County	4,691	689,807	713,049	3%
Middlesex County	691	1,465,396	1,473,416	1%
Norfolk County	633	650,308	654,909	1%
Massachusetts	318	6,349,097	6,449,755	2%
United States	33	281,421,906	301,621,159	7%

M.3.2 Environmental Justice

To identify potential environmental justice areas, data were collected on minority and low-income populations for census tracts in the 10-km boundary area of the proposed BUMC NEIDL Site, Boston, Massachusetts. Census tracts are subdivisions of a county and represent a level at which disproportionate impacts would be more noticeable. Tables 8 through 12 list the census tracts and minority and low-income data for the 10-km boundary area. Census tract 711 coincides with the land area of the proposed BUMC NEIDL. Tracts identified by shading indicate those tracts with a percentage of minority residents higher than the U.S. level of 25 percent or a percentage of residents living in poverty higher than the U.S. poverty rate of 12 percent.

Source: U.S. Census Bureau 2000

Note: Shading for minority indicates a percentage of minority residents higher than the U.S. percentage of 25%.
Shading for poverty indicates a percentage of residents living in poverty higher than the U.S. percentage of 12%.

Table 13 summarizes the totals within each 2-km radius boundary within the 10-km area. Of the 297 census tracts identified in the 10-km area, 154, or 52 percent, had a higher percentage of minority residents compared to the United States, and 156 tracts, or 53 percent, had a higher percentage of persons living in poverty compared to the United States. As shown in Table 13, the portion of census tracts with a percentage of minority populations or a percentage of persons below poverty that is greater than the U.S. levels decreases going outward from the interior 2-km circle of the proposed BUMC NEIDL site.

Table 13. Boston minority and low-income data by census tract for the 10-km area

Area/boundary	Total census tracts	Number tracts with percentage of minority persons above U.S. level of 25%	Portion of tracts with percentage of minority persons above U.S. level of 25%	Number tracts with percentage of persons in poverty above U.S. level of 12%	Portion of tracts with percentage of persons in poverty above U.S. level of 12%

The most recent (2007) minority and low-income data for Boston, Suffolk County and the adjacent counties of Middlesex and Norfolk, Massachusetts, and the United States are listed in Table 14. Boston and Suffolk had a notably higher percentage of minority residents and persons living below poverty compared to the adjacent counties of Middlesex and Norfolk and compared to Massachusetts and the United States.

Table 14. 2007 Minority and low-income data for jurisdictions surrounding the BUMC NEIDL site

	Percent minority	Percent living below poverty
Boston	44%	20.4%
Suffolk County	42%	19.7%
Middlesex County	18%	6.8%
Norfolk County	15%	6.6%
Massachusetts	17%	9.9%
United States	26%	13.0%

M.3.3 State Criteria

To assess environmental justice per the Massachusetts state criteria, data were collected on minority populations, foreign-born populations, households lacking English language proficiency, and median annual household income for each neighborhood (defined as a census block group) within a 10-km (6-mile) area of the Boston site. Table 15 summarizes the totals within each 2-km (1.2-mile) radius boundary within the 10-k (6-mile) area. Of the 1,112 census block groups identified in the 10-k (6-mile) radius boundary, 622 block groups (56 percent) had a higher percentage of minority residents compared to the state's threshold of 25 percent; 474 census block groups (43 percent) had 25 percent or more residents who are foreign born; 78 block groups (7 percent) had households where 25 percent or more of the residents lacked English language proficiency; and 281 block groups (25 percent) had a median annual household income at or

below 65 percent of the statewide median income of \$50,500. As shown in Table 15, the portion of census block groups meeting one or more of the state environmental justice guidance criteria was, for the most part, higher within the boundaries closest to the Boston NEIDL site and decreases moving outward from the site.

Table 15. Massachusetts state criteria for environmental justice for the (10-km) 6-mile boundary area of the urban site

Boundary area radius	Total census block groups	Percent of block groups with a minority population above the state guidance level of 25 percent	Percent of block groups with a foreign born population above the state guidance level of 25 percent	Percent of block groups lacking English language proficiency above the state guidance level of 25 percent	Percent of block groups with a median annual household income at or below 65 % of the Massachusetts statewide median income
Inside 2 km (1.2 mile)	100	79%	35%	17%	55%
2–4 km (1.2–2.4 mile)	203	71%	44%	4%	39%

M.4 Demographic Data for the NIH NEIDL Boston University Corporate Education Center Site, Tyngsborough, Massachusetts

A 10-km radius was defined around the proposed NIH Boston University Corporate Education Center, NEIDL site in Tyngsborough, Massachusetts. Demographic data were collected from the U.S. Census Bureau's 2000 decennial census for each census tract within the 10-km area; that is the most recent year for which data are available at the census tract geographic level. The 10-km radius was then subdivided into concentric 2-km circles (see Figure 2). For census tracts that covered multiple circles, the tract was included in the circle in which the majority of the tract resided; or, if the tract was largely divided over multiple circles, the data were divided between the defined areas. The 10-km area covers portions of Middlesex County, Massachusetts, and

1 Hillsborough County, New Hampshire. For comparative purposes, data for Middlesex and
2 Hillsborough counties; Massachusetts and New Hampshire; and the United States are presented.
3 In addition, this analysis was performed when the 2007 data were the most recent data available.
4 Therefore, the 2007 data are presented for Middlesex and Hillsborough counties; Massachusetts
5 and New Hampshire; and the United States.

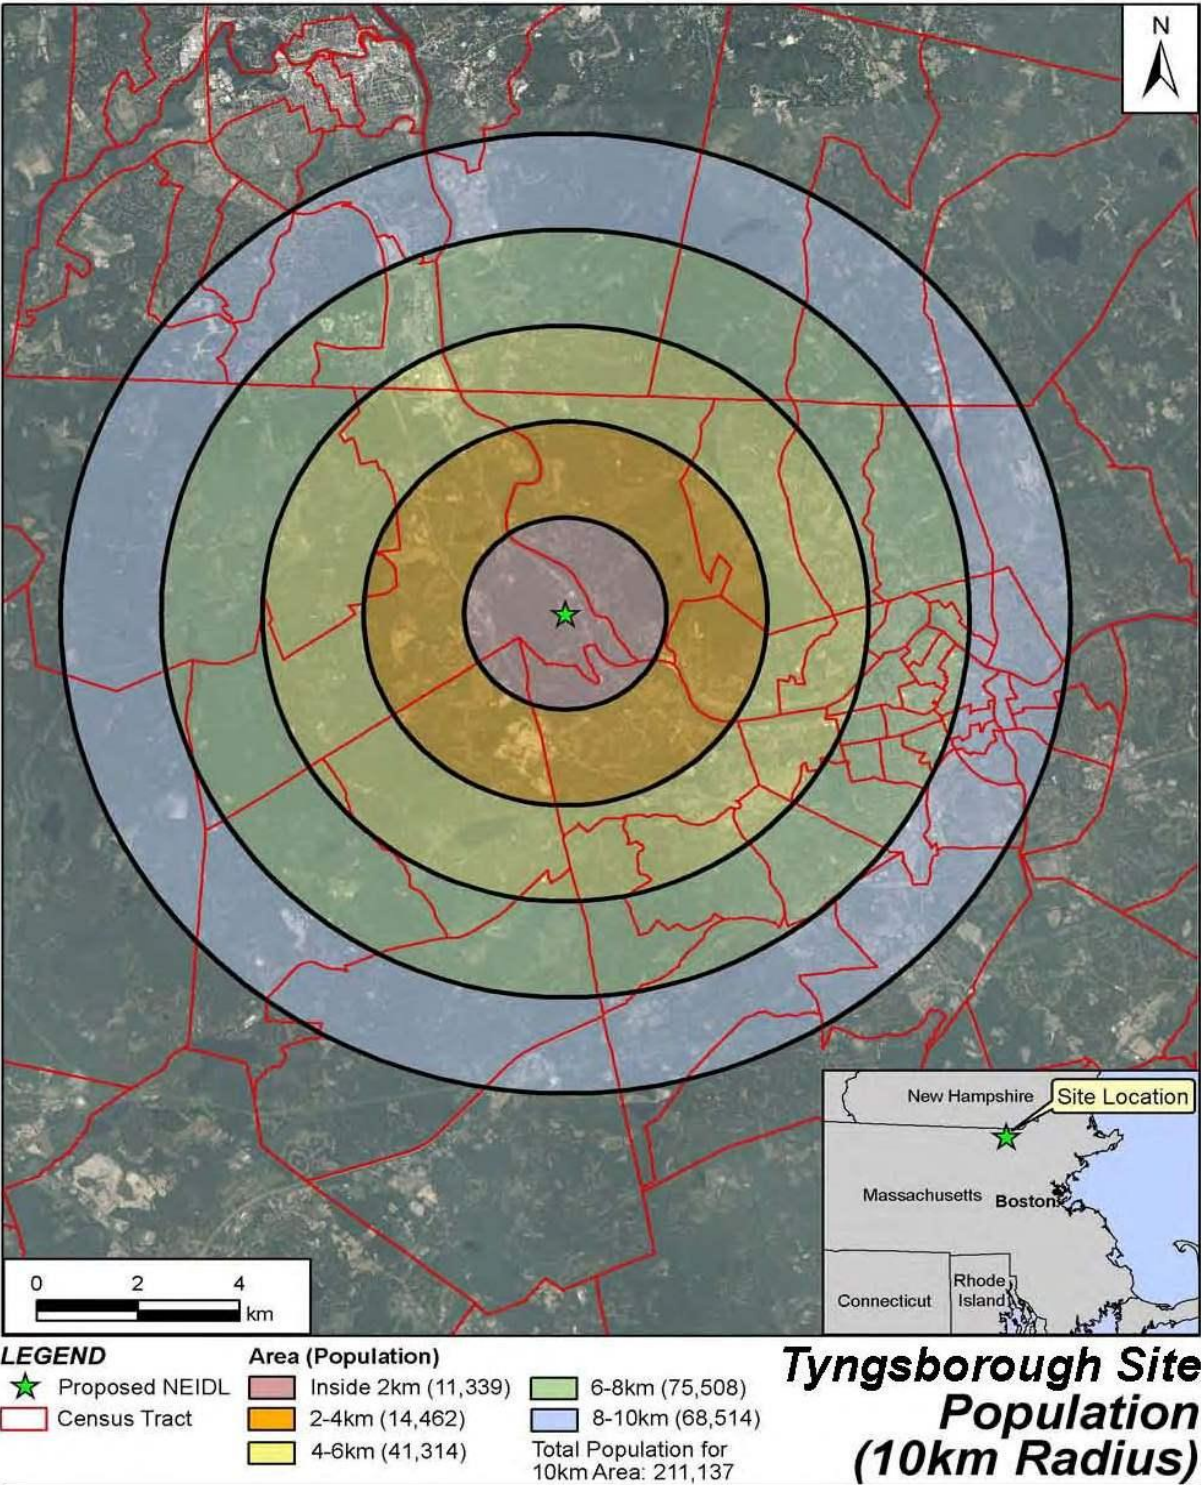

Figure 2

Figure 2. Tyngsborough site population

M.4.1 Population

Population data for the census tracts in the 10-km area are listed in Tables 16 through 20. The tracts are sorted first by boundary (inside 2 km, 2–4 km, 4–6 km, 6–8 km, and 8–10 km) and then numerically in ascending order by tract number. Tract 3131.01 corresponds to the Boston University Corporate Education Center site in Tyngsborough. The population for the census tracts inside the 2-km boundary ranges from about 1,200 to 6,100; the 2–4 km boundary ranges from about 1,200 to 3,900; the 4–6 km boundary tract population ranges from about 700 to 5,800; the 6–8 km population ranges from about 350 to 5,100; and the 8–10 km boundary census tract population ranges from about 350 to more than 6,000 (see Tables 16 through 20).

3 Table 21 summarizes the totals within each 2-km radius boundary within the 10-km area. As of
4 2000, the total population in the 10-km boundary was more than 211,000 and the area was
5 categorized as mostly (96 percent) urban (Table 21). The 10-km area covers a total area of 314
6 square km. The population and land area of each 2-km boundary range increases moving outward
7 from the proposed site (Table 21).

8 **Table 21. Tyngsborough population for the 10-km area**

Source: U.S. Census Bureau 2000, 2008

The most recent population data (2007) for Middlesex County, Hillsborough County, Massachusetts and New Hampshire, and the United States are in Table 22. Middlesex County had a significantly higher population density compared to the adjacent county of Hillsborough and compared to Massachusetts, New Hampshire, and the United States. Middlesex County's population increased by only 1 percent between 2000 and 2007. That growth rate was lower than Hillsborough County, the states, and the U.S. population growth during the same period (U.S. Census Bureau 2007).

Table 22. 2007 Population data for jurisdictions surrounding the proposed Tyngsborough NEIDL site

M.4.2 Environmental Justice

To identify potential environmental justice areas, data were collected on minority and low-income populations for census tracts in the 10-km boundary area of the proposed BU Corporate Education Center NEIDL Site Tyngsborough, Massachusetts. Census tracts are subdivisions of a county and represent a level at which disproportionate impacts would be more noticeable. Tables 23 through 27 list the census tracts and minority and low-income data for the 10-km boundary area. Census tract 3131.01 coincides with the land area of the proposed Boston University Corporate Education Center NEIDL site. Tracts identified by shading indicate those tracts with a percentage of minority residents higher than the U.S. level of 25 percent or a percentage of residents living in poverty higher than the U.S. poverty rate of 12 percent.

Note: Shading for minority indicates a percentage of minority residents higher than the U.S. percentage of 25%. Shading for poverty indicates a percentage of residents living in poverty higher than the U.S. percentage of 12%.

Table 28 summarizes the minority and low-income population totals within each 2-km radius boundary within the 10-km area. Of the 85 census tracts identified in the 10-km area, 19 (22 percent) had a higher percentage of minority residents compared to the United States, and 20 of the census tracts (24 percent) had a higher percentage of persons living in poverty compared to the United States. As shown in Table 28, the portion of census tracts with a percentage of minority populations or a percentage of persons below poverty that is greater than the U.S. levels is higher in the exterior circles (6–8 km and 8–10 km), away from the proposed Tyngsborough NEIDL site. The tracts with the higher percentages of minority and low-income populations are all in the southeast quadrant of the 10-km circle, near the city of Lowell.

Table 28. Tyngsborough minority and low-income data for the 10-km boundary area

Source: U.S. Census Bureau 2000

The most recent (2007) minority and low-income data for Middlesex and Hillsborough counties; Massachusetts and New Hampshire; and the United States are in Table 29. Middlesex County has a higher percentage of minority residents compared to Hillsborough County and New Hampshire; similar to its home state of Massachusetts; but lower than the United States. The percent living below poverty is the same for both Middlesex and Hillsborough counties (6.8 percent) and less than the state and national levels.

**Table 29. 2007 Minority and low-income data for jurisdictions surrounding the proposed
Tyngsborough NEIDL site**

	Percent minority	Percent living below poverty
Middlesex County	18%	6.8%
Hillsborough County	8%	6.8%
Massachusetts	17%	9.9%
New Hampshire	5%	7.1%
United States	26%	13.0%

M.4.3 State Criteria

To assess environmental justice per the Massachusetts criteria, data were collected on minority populations, foreign-born populations, households lacking English language proficiency, and median annual household income for each neighborhood (defined as a census block group) within a 10-km (6-mile) area of the Tyngsborough site. Table 30 summarizes the totals within each 2-km (1.2-mile) radius boundary within the 10-km (6-mile) area. Of the 260 census block groups identified in the 10-km (6-mile) radius boundary around Tyngsborough, 72 block groups (28 percent) had a higher percentage of minority residents compared to the state's threshold of 25 percent; 32 block groups (12 percent) had 25 percent or more residents who are foreign born; 9 block groups (3 percent) had households where 25 percent or more of the residents lacked English language proficiency; and 31 block groups (12 percent) had a median annual household income at or below 65 percent of the statewide median income of \$50,500. As shown in Table 30, the portion of census block groups meeting one or more of the state environmental justice guidance criteria is higher in the exterior circles (from 6-8km [3.6–4.8 miles] out to 8-10km [4.8–6.0 miles]). Those census block groups are southeast of the proposed Tyngsborough site, near the city of Lowell.

M.5 Demographic Data for The NIH NEIDL Boston University Sargent Center For Outdoor Education (SCOE), Hancock/Peterborough, NH

A 10-km radius was defined around the proposed NIH BU SCOE, NEIDL site in Hancock/Peterborough, Massachusetts. Demographic data were collected from the U.S. Census Bureau's 2000 decennial census for each census tract within the 10-km area; that is the most recent year for which data are available at the census tract geographic level. This 10-km radius was then subdivided into concentric 2-km circles (see Figure 3). For census tracts that covered multiple circles, the tract was included in the circle in which the majority of the tract resided; or, if the tract was largely divided over multiple circles, the data were divided between the defined areas. This 10-km area covers portions of Hillsborough and Cheshire counties, New Hampshire. For comparative purposes, data for Hillsborough and Cheshire counties; New Hampshire; and the United States are presented. In addition, this analysis was performed when the 2007 data were the most recent data available. Therefore, the 2007 data are presented for Hillsborough and Cheshire counties; New Hampshire; and the United States.

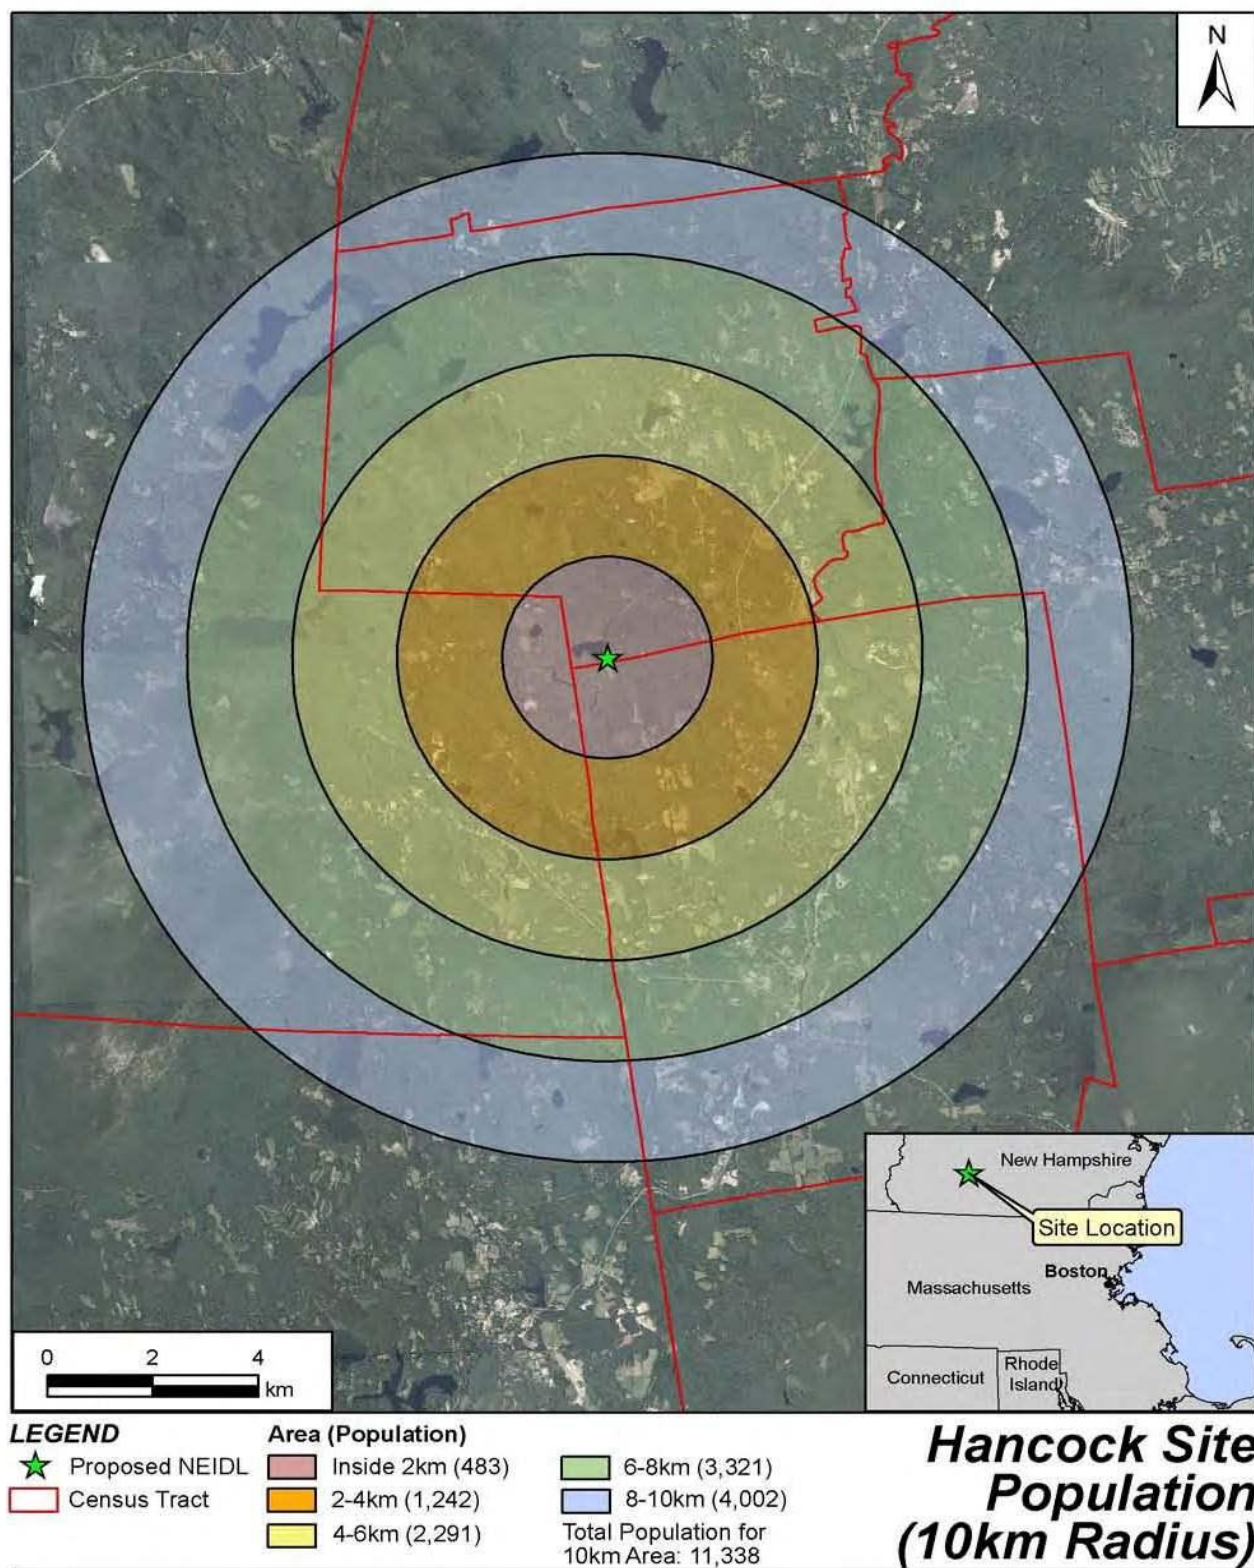

Figure 3

Figure 3. Hancock site population

M.5.1 Population

Population data for the census tracts in the 10-km area are listed in Tables 31 through 35. The tracts are sorted first by boundary (inside 2 km, 2–4 km, 4–6 km, 6–8 km, and 8–10 km) and then numerically in ascending order by tract number. Tract 240 corresponds to the BU SCOE site in Hancock/Peterborough. The population for the census tracts inside the 2-km boundary ranges from about 90 to 300; the 2–4 km boundary ranges from about 300 to almost 600; the 4–6 km boundary tract populations range from about 80 to almost 1,200; the 6–8 km population ranges from about 250 to almost 1,800; and the 8–10 km boundary census tract populations range from about 90 to almost 1,800 (see Tables 31 through 35).

Table 36 summarizes the totals in each 2-km radius boundary within the 10-km area. As of 2000, the total population in the 10-km boundary was more than 11,300 and the area was categorized as primarily (71 percent) rural (Table 36). The 10-km radius covers a total area of 314 square km and is sparsely populated. The population and land area of each 2-km boundary range increases moving outward from the proposed site (Table 36).

Table 36. Hancock population for the 10-km boundary area

Area/boundary	Total population	Total urban population	Total rural population	Land area (square km)
Inside 2 km	483	167	317	12.5
2-4 km	1,242	334	908	37.7
4-6 km	2,291	667	1,624	62.8

The most recent population data (2007) for Hillsborough and Cheshire counties; New Hampshire; and the United States are in Table 37. Hillsborough County had the highest population density compared to the adjacent county of Cheshire and compared to New Hampshire and the United States. Hillsborough County has the highest population of all the counties in New Hampshire and is home to the two largest cities in the state: Manchester and Nashua (the county seat). Manchester and Nashua are on the Route 3 corridor, which connects to Interstate 95 outside Boston. Hancock/Peterborough is 37 miles southwest of Manchester and 30 miles west/northwest of Nashua. Population growth between 2000 and 2007 was very similar among the geographic areas listed in Table 37, ranging from 5 to 7 percent (U.S. Census Bureau 2007).

Table 37. 2007 Population data for jurisdictions surrounding the proposed Hancock NEIDL site

	Population density 2007 (persons per square km)	2000 Population	2007 Population	Population change, 2000–2007
Cheshire County, NH	42	73,825	77,725	5%
Hillsborough County, NH	177	380,841	402,302	6%
New Hampshire	57	1,235,786	1,315,828	6%
United States	33	281,421,906	301,621,159	7%

M.5.2 Environmental Justice

To identify potential environmental justice areas, data were collected on minority and low-income populations for census tracts in the 10-km boundary area of the proposed NEIDL BU SCOE site in Hancock/Peterborough, Massachusetts. Census tracts are subdivisions of a county and represent a level at which disproportionate impacts would be more noticeable. Tables 38 through 42 list the census tracts and minority and low-income data for the 10-km boundary area. Census tract 240 corresponds to the Boston University SCOE site.

Minority populations and poverty rates for each census tract in the 10-km boundary area are listed in Tables 38 through 42. There were no tracts in the 10-km area with a percentage of minority residents higher than the U.S. level of 25 percent or a percentage of residents living in poverty higher than the U.S. poverty rate of 12 percent.

M.5.3 State Criteria

Although the rural site of Peterborough is in New Hampshire, environmental justice analysis per the Massachusetts criteria was conducted for the rural site for consistency and comparison with the urban and suburban sites. Data were collected on minority populations, foreign-born populations, households lacking English language proficiency, and median annual household income for each neighborhood (defined as a census block group) within a 10-km (6-mile) area of the Peterborough site. Table 45 summarizes the totals within each 2-km (1.2-mile) radius boundary within the 10-km (6-mile) area. Of the 62 census block groups identified in the 10-km

(6-mile) radius boundary around the rural site, none of the block groups exceeded any of the Massachusetts environmental justice criteria.

Table 45. Massachusetts criteria for environmental justice for the 10-km boundary area of the rural site

Boundary area radius	Total census block groups	Percent of block groups with a minority population above the state guidance level of 25 percent	Percent of block groups with a foreign born population above the state guidance level of 25 percent	Percent of block groups lacking English language proficiency above the state guidance level of 25 percent	Percent of block groups with a median annual household income at or below 65 % of the Massachusetts statewide median income

M.6 Results

Environmental justice populations as defined by the federal and Massachusetts criteria were identified at the urban (Boston) and suburban (Tyngsborough) sites. No environmental justice communities meeting the federal or Massachusetts criteria were identified at the rural (Peterborough) site; therefore, no environmental justice impacts would be expected at the rural site. At the Boston site, populations that met or exceeded the criteria are throughout the 10-km (6-mile) study area, with the percentage of neighborhoods meeting one or more of the criteria generally higher toward the center of the study area. At the Tyngsborough site, the environmental justice populations are farther away from the NEIDL location (about 6–10 km [3.6–6 miles]) and are associated with a more urban, higher-density community, which is the city of Lowell (the fourth largest city in Massachusetts), southeast of Tyngsborough.

Chapter Highlights: This chapter summarizes and integrates the information from the RA, starting with the initiating events, then initial exposures, and finally the potential for secondary transmission of pathogens if loss of biocontainment occurs. This chapter also draws overall conclusions that are supported by these results.

- Potential events were identified that could lead to loss of biocontainment at NEIDL.
- Risks to laboratory workers are from events that result in sufficient exposure to pathogens to cause initial infections in the exposed individual; these are represented by centrifuge release and needlestick injury. The risk varies among pathogens and events.
- Risks to the public are from events that either directly expose the public to pathogens such as earthquakes leading to loss of biocontainment or from undetected and unreported initial infections in laboratory workers from a centrifuge release or needlestick injury event. The risk varies among pathogens.
- For direct exposure events such as an earthquake, there are potential differences (in risk to the public among the urban, suburban, and rural sites, but this risk is almost totally beyond reasonably foreseeable.
- For secondary transmission of pathogens in the public from an undetected and unreported centrifuge release or needlestick event, there are potential differences in risk to the public among different sites, but the estimated differences are small compared to the overall uncertainty.

11. RISK CHARACTERIZATION

11.1 Introduction

The NRC guidance for analyzing risks associated with operating NEIDL suggested that future RA studies be organized around the following three domains (NRC 2008):

1. What could go wrong?
 - a. Scenarios of release of an infectious agent (pathogen)
 - b. Agents (pathogens) to consider for RA
2. What are the probabilities?
3. What would be the consequences?

In seeking an understanding of the risks of operating NEIDL, federal and Massachusetts courts, the NRC, and the NIH BRP have expressed interest in three related topics:

1. What are the risks to the workers at NEIDL?
2. What are the risks to the public in the communities surrounding NEIDL?
3. Are there differences in risks if NEIDL were located in a less-densely populated site?

This chapter on risk characterization summarizes the RA performed and applies each of the three NRC questions to the three related topics.

What is risk characterization?

“Risk characterization is the summarizing step of risk assessment. The risk characterization integrates information from the preceding components of the risk assessment and synthesizes an overall conclusion about risk that is complete, informative and useful for decision makers.” (USEPA 2000)

11.2 Approach

11.2.1 Overview

This RA follows guidelines established by federal agencies for conducting and reporting RAs (USEPA 2000) and has been performed by using available scientific data and established methods of analyses. The RA acknowledges the uncertainty associated with the data and the appropriate role of judgment (expert opinion) in estimating key parameters required for RA.

The four essential principles of RA are applied as follows to this RA and are described in the preceding chapters and associated appendices:

1. **Transparency:** This is achieved by providing details of the assessment approach applied at each step of the analyses; stating the assumptions used for the analyses and the basis for those assumptions; addressing data gaps and the methods used to overcome the data gaps such as expert judgment; the uncertainties in the available data, qualitative discussions, and quantitative assessments of the impact of the uncertainties in the data and sensitivity analyses to determine impact of variability in key parameters.
2. **Clarity:** This is achieved by attempting to convey details with brevity; providing lay language summaries and discussions in chapters; providing details in appendices and using tables and graphs where possible to present technical data.
3. **Consistency:** This is achieved by following established guidance and guidelines, following precedence wherever possible and using established and published methods for all analyses.

4. Reasonableness: The RA is based on best available scientific information, uses generally accepted scientific knowledge and guidance and has been subjected to review by the BRP and NRC.

Furthermore this RA strives to include reasonableness and realism in the analyses based on *real-world experience*; however, the limited operational data poses a significant challenge in that regard, and, in several cases, the event sequence assumptions are expected to overestimate the likelihood or consequences of potential events. Such a use of conservative assumptions (i.e., overestimations) to account for uncertainty is consistent with NEPA accident analysis guidance (DOE 2002).

This RA follows the four-step paradigm outlined by EPA for health RAs (USEPA 2000) and includes hazard identification (pathogens and events), dose-response assessment, exposure assessment, and risk characterization.

11.2.2 Selection of Pathogens for Analysis

To address the NRC question of which agents to consider for RA (Question 1b above), 13 pathogens were selected for analysis on the basis of guidance from NIH, the BRP, and discussion of emerging infections (NIH 2009). The pathogens differ in key characteristics such as their ability to be spread from person to person (transmissibility), the method by which they are spread from one person to the next (either directly or via vectors, such as insects), their ability to cause human disease (pathogenicity) and their ability to cause deaths among those infected (case fatality rate). The details of the pathogens are provided in Chapter 3 and Appendix C (Pathogen Characteristics). The pathogens are classified as requiring BSL-3 or BSL-4 biocontainment precautions and are analyzed separately for this RA (Table 11-1).

Table 11-1. Pathogens selected for analysis

<u>Pathogen</u>	<u>Abbreviation</u>
BSL-3	
1. <i>Bacillus anthracis</i> (either BSL-2 or BSL-3)	<i>B. anthracis</i>
2. <i>Francisellatularensis</i>	<i>F. tularensis</i>
3. <i>Yersiniapestis</i>	<i>Y. pestis</i>
4. 1918 H1N1 influenza virus	1918 H1N1V
5. SARS-associated coronavirus	SARS-CoV
6. Rift Valley fever virus	RVFV
7. Andes virus (either BSL-3 or BSL-4 ^a)	ANDV
BSL-4	
8. Ebola virus	EBOV
9. Marburg virus	MARV
10. Lassa virus	LASV
11. Junín virus	JUNV
12. Tick-borne encephalitis virus, Far Eastern sub-type, formerly known as tick-borne encephalitis complex (Russian spring-summer encephalitis virus)	TBEV-FE
13. Nipah virus	NIPV
a. BSL-4 is required when infecting rodent species permissive for (susceptible to) chronic infection.	

11.2.3 Event Sequence Analyses

In addressing possible scenarios for the release of a pathogen from NEIDL as a result of a loss of biocontainment (NRC Question 1a above), the following analyses were performed:

- Selection of events for analysis: This RA considers a broad spectrum of reasonably foreseeable¹ events and generally truncates the analysis at events with a frequency of less than 1 in 10 million years. More than 300 incidents described as occurring at other comparable biocontainment facilities and postulated events with relevance to NEIDL were considered. Many of the 300 incidents were similar, so they were consolidated into about 30 candidate events for further consideration. Many of the 30 candidate events are bounded by (i.e., have a frequency and consequence that is less than) other candidate events. A set of events was selected for analyses that were considered to be the highest risk events, those that provide broad coverage of the routes

¹Reasonably foreseeable events include events that could have catastrophic consequences, even if their probability of occurrence is low, provided that the analysis of the impacts is supported by credible scientific evidence, is not based on pure conjecture, and is within the rule of reason (DOE 2002).

of exposure and potentially exposed groups. From those candidate events, centrifuge aerosol release, needlestick, earthquake, transportation accident, malevolent acts (as discussed in the threat assessment), and environmental persistence (including escaped animals) were selected for detailed analyses. Those are discussed in Chapter 4 and Appendices D and E (Event Sequence Analysis); Chapter 5 (Transportation Analysis); Chapter 6 (Threat Assessment for malevolent acts); and Chapter 7 (Potential for Released Pathogens to Become Established in the Environment).

- Analysis of event sequences: For each event selected for detailed analysis, scenarios were developed that account for NEIDL-specific operations on the basis of NEIDL equipment and SOPs. The frequency, number of people potentially exposed, and the extent of exposure were estimated for each scenario. Relevant operational experience from similar laboratories was used to the extent possible, and conservative analyses (i.e., use of assumptions that tend to overestimate the frequency or consequences or both) were used to account for variability and uncertainty where data are lacking. Chapter 4 and Appendix F provide details of those analyses.

Operating Experience at BSL-3 and BSL-4 Laboratories:

This RA relies on past experience at similar laboratories to the extent data are available and useful. Appendix D summarizes various sources of this operating experience and includes the recent CDC report of 395 potential release events and 7 laboratories associated infections (LAIs) from 2003 to 2009 nationwide at laboratories working with select agents (NRC 2011). The CDC report shows the LAI rate has decreased by more than an order of magnitude over the past decades due to enhanced practices, equipment, and facilities (see Section D.1.1 of Appendix D).

The operating experience was used to identify potential initiating events, develop scenarios, and estimate the scenario frequencies. While helpful for qualitative analyses, the data were not used for quantitative analyses as details of appropriate measures of operating time (e.g., researcher-hours), descriptions of individual incidents leading to loss of biocontainment and biosafety protocols in place at the time of the events are not specified in available reports.

Therefore, past BSL-3 and BSL-4 experience was used to support the RA wherever appropriate, but they are not suitable for quantitative use.

NEIDL safety programs: An overview of NEIDL operations is provided in Chapter 2. Aspects particularly relevant to these analyses include the sharps safety practices (see Section F.7.2.1) and the Culture of Safety Enhancement Program (see Section 2.1 of Chapter 2). The effectiveness of these efforts cannot be fully predicted and incorporated into this analysis, so actual risk may be lower than predicted.

11.2.4 Health Effects Analyses

To address the NRC questions about probabilities and consequences of the loss of biocontainment and the three topics of interest such as risks to workers and the public and differences in risk at an alternate site, the following analyses were performed:

- Qualitative assessments were performed for all 13 pathogens in terms of their characteristics, review of the available scientific literature on their biology, transmission, human disease potential, natural outbreaks, morbidity and mortality (Chapter 3 and Appendix C).
- Quantitative assessments were performed for all 13 pathogens in terms of assessing their dose-response relationships and estimates of initial infections and fatalities in those exposed directly to the pathogens as a result of loss of biocontainment.
 - Estimation of dose-response relationships: On the basis of published evidence from exposures and infections of humans and animals and input from an expert consultation, dose-response relationships were estimated for each of the 13 pathogens. Dose-response relationships describe the likelihood that infection would occur at the levels of exposure estimated for each scenario. Chapter 8 and Appendix J provide details of those analyses.
 - Estimation of initial infections and fatalities: The risk of initial infections and fatalities was estimated for workers and the public under each scenario. Estimates are provided for each event-pathogen pair as appropriate based on BSL status. Chapter 8 and Appendix K provide details of those analyses.
- Estimates of secondary transmission in the community: The potential for secondary transmission was assessed qualitatively for each of the 13 pathogens. To supplement that assessment, secondary transmission estimates were developed for four pathogens for which sufficient epidemiological data and published mathematical models were available (*Y. pestis*, 1918 H1N1V, SARS-CoV and EBOV). Estimates are provided of the risk of secondary infections and fatalities in the community following each relevant event for the four pathogens. Chapter 9 and Appendix L provide details of those analyses.

11.3 Measures of Likelihood

The likelihood of events can be described and calculated in several ways. Table 11-2 compares several equivalent ways of describing (using numbers and measures) the likelihood of events. Because uncertainties are associated with many of the events analyzed, the likelihoods are presented as a range of values (as opposed to a single point estimate).

Table 11-2. Measures of likelihood

Average return period ^a (years)	Average frequency ^b (per year)	Probability/chance of occurrence in facility lifetime ^c (in 50 years)	
1	1	Virtually 100%	Virtually 100-in-100
10	0.1	99%	99-in-100
100	0.01	39%	1-in-2.5
1,000	0.001	4.9%	1-in-21
10,000	0.0001	0.5%	1-in-200
100,000	0.00001	0.05%	1-in-2,000
1,000,000	0.000001	0.005%	1-in-20,000
10,000,000	0.0000001	0.0005%	1-in-200,000

^a **Average return period in years:** This is the average time, in years, before the event would be expected to occur. If the event was to occur multiple times, this would be the average time between occurrences. This way of describing events is often used in characterizing flood levels; for example, a *1,000-year flood* is a water level that is estimated to occur with a 1,000-year average return period or *1 per 1,000 years*.

^b **Average frequency per year:** This is the average number of occurrences of the event per year.

^c **Probability/chance of occurrence in facility lifetime (50 years):** This is the chance that the event would occur at least once in a 50-year period.

In addition to the numeric values, frequency categories that encompass a range of numeric values are also used to facilitate comparison of results. Table 11-3 identifies the frequency categories (i.e., A, B, C, and D) used in this RA and provides the corresponding average return period.

Table 11-3. Frequency categories used in this RA

Frequency category	Average return period (1 in “this many” years)
A	1 to 100 years
B	100 to 10,000 years
C	10,000 to 1 million years
D	>1 million years

11.4 Summary of Events Analyzed

Two types of potential primary exposure events were analyzed: laboratory associated infections (LAIs) and direct-to-public exposure events. The LAI events analyzed for this RA are centrifuge aerosol releases and needlesticks. As infected workers have the potential for secondary transmission to the public and public risk is a primary focus of this RA, the LAIs analyzed in this RA are assumed to be undetected or

unreported events. Severe earthquake events are direct to public exposure events. Chapters 4, 8, and 9 report the analyses of the LAIs and direct exposure events. Those events are summarized below in this section and the numeric results and conclusions drawn from the results are presented in subsequent sections.

11.4.1 Centrifuge Aerosol Release

NEIDL operations will include use of centrifuges to separate materials. Because of the high centrifugal forces associated with centrifugation, pathogenic aerosols can be generated during centrifugation. A number of preventive and mitigative measures protect the laboratory worker from potential centrifuge aerosol releases, including the following:

- NEIDL protocol requires that both aerosol-tight containers and aerosol-tight rotors/cups be used to contain potential aerosols.
- BSL-3 laboratory workers are required to wear a PAPR at all times, and BSL-4 laboratory workers are required to use one-piece totally encapsulating positive pressure suits at all times.
- Vaccines are offered to all BSL-3 and BSL-4 laboratory workers when such vaccines are available for the pathogens on which they are working.
- If an incident occurs that has the potential to expose a worker to a pathogen, NEIDL procedures and training require that the event be reported and that appropriate medical interventions be implemented. Laboratory workers would be treated and quarantined if such action is deemed appropriate.

Because a primary focus of the RA is risk to the public, the RA focused primarily on scenarios that involve a failure to detect or report the potential exposure because those scenarios have greater potential to expose the public to secondary transmission of the pathogens. Section 4.2.2 of Chapter 4 provides details of the centrifuge release events, which are summarized below.

Exposure frequency—It is conservatively estimated that an undetected or unreported BSL-3 centrifuge aerosol release event is in frequency category A (one in 1 to 100 years) with all PAPRs providing full respiratory protection. However, even with PAPRs performing at their full efficiency, laboratory workers can be exposed to low concentrations (i.e., 0.1 percent of the airborne concentration) of the infectious aerosols in the room. The potential that a worker's PAPR provides only partial respiratory protection was also included in the analyses. To account for the possibility that a PAPR does not provide its full respiratory protection, it was assumed that there is a 1 percent chance that one worker's PAPR would operate with only 1 percent of its normal filtering efficiency (i.e., removes only 90 percent of the particles), which means the worker using the PAPR would receive a 100 times greater exposure. (Note:

the results of Appendix K show that this potential reduction in PAPR effectiveness would not occur frequently enough to significantly affect overall worker risk.)

No credible mechanisms were found for a positive pressure suit failure that results in exposure from an undetected or unreported centrifuge aerosol release, so BSL-4 centrifuge scenarios were not analyzed further.

Laboratory worker infections and fatalities—Based on information from the dose-response estimates combined with the known quantities of pathogens that would be present in the laboratory, it was determined that the amount of exposure estimated from a centrifuge release could result in infection of at least one laboratory worker from any of the BSL-3 pathogens. Some pathogen exposures are estimated to be much more likely than others to result in an infection because: (1) some pathogens are present in greater concentrations so the aerosol release results in greater worker exposures, and (2) some pathogens cause infection at lower levels of exposure than other pathogens. Estimates for the risk of laboratory worker infections and fatalities are summarized in Table 11-4a, with further details provided in Chapter 8.

Public infections and fatalities—A laboratory worker who is infected from a centrifuge release and does not detect or report the exposure could leave the laboratory and pose a risk to the public through secondary transmission. Of the BSL-3 pathogens, *Y. pestis* (pneumonic plague), 1918H1N1V, and SARS-CoV pose the highest risk for secondary transmission. Sufficient data from past outbreaks involving those three pathogens were available in the published literature and used to generate quantitative estimates of transmission (secondary transmission modeling), which are summarized in Section 11.5.2. A centrifuge release involving BSL-4 pathogens is not considered to pose a risk to the public because no credible scenario was found in which an aerosol exposure of a laboratory worker would go undetected under BSL-4 laboratory conditions.

11.4.2 Needlestick

NEIDL operations would include use of syringes and other sharp objects that have the potential to puncture the skin of laboratory workers and expose them to pathogens. A needlestick event (i.e., a potential exposure due to a puncture from the needle of a syringe) was analyzed as a surrogate for all other puncture events. A number of preventive and mitigative measures protect the laboratory worker from sharp objects like needles, including the following:

- NEIDL procedures and training on the use of sharp objects reduces the likelihood a skin puncturing event (see Section F.7.2.1 of Appendix F).
- Personal protective equipment (e.g., use of stainless steel mesh gloves when changing knife blades) protects the worker.
- Vaccinations and procedures and training for reporting and medical interventions reduce the likelihood of infection if a potential exposure does occur.
- The NEIDL culture of safety enhancement program (see Section 2.1 of Chapter 2) is intended to reduce the likelihood of mishaps and increase reporting.

As with the centrifuge events, the RA focused primarily on scenarios that involve a failure to detect or report the potential exposure because those scenarios have the potential to expose the public to secondary transmission of the pathogens. Section 4.2.3 of Chapter 4 provides details of the needlestick events, which are summarized below.

Exposure frequency—As with the centrifuge event, the only needlestick events that were analyzed in detail are those that involve a failure to detect or report the potential exposure. An undetected or unreported needlestick would affect only one worker and is estimated to be in frequency category B (one in 100 to 10,000 years). This frequency category assignment is appropriate and even conservative based on: (1) the historic rates indicate that the frequency is on the border of categories A and B, (2) historic values likely overstate the value for current facilities due to enhanced practices, equipment, and facilities (see Section D.1.1 of Appendix D), and (3) the NEIDL is expected to have lower incident rates due to its attention to sharps safety (see Section F.7.2.1 of Appendix F) and the enhancement of safety (see Section 2.1 of Chapter 2). Section F.7.3.2 of Appendix F provides additional details. A needlestick in a BSL-4 laboratory is estimated to be as likely as a needlestick in a BSL-3 laboratory.

Worker infections and fatalities—For each of the 13 pathogens, it was conservatively assumed that all needlestick exposures would result in a laboratory worker infection; therefore, an infection is in the frequency category B (one in 100 to 10,000 years). Those results, along with estimates of laboratory worker fatalities, are displayed in Table 11-4b and described in further detail in Chapter 8.

Public infections and fatalities—A laboratory worker who is infected from a needlestick and does not detect or report the exposure may leave the laboratory and pose a risk to the public through secondary transmission. Of the BSL-3 pathogens, *Y. pestis* (pneumonic plague), 1918H1N1V, and SARS-CoV pose

the highest risk for secondary transmission. EBOV represents the highest transmission risk among BSL-4 pathogens. Sufficient data from past outbreaks and mathematical models for those four pathogens were available in the published literature and used to generate quantitative estimates of transmission, which are summarized in Section 11.6.2.

11.4.3 Earthquake

Two severe earthquake events beyond the design basis were analyzed, (1) an earthquake that does not result in structural failure but does partially reduce the filtration of a potential release and (2) the maximum reasonably foreseeable (MRF) event, which is defined as the event with the largest potential pathogen release. The MRF earthquake assumes a loss of all biocontainment features and a ground-level release (effectively a full collapse) that has the potential to expose the public to pathogenic aerosols. The less severe earthquake was analyzed to put the MRF earthquake into perspective, and it shows that public infections or fatalities would be extremely unlikely (occurring with an average frequency much less than 1 in 10 million years); therefore, the more severe, MRF earthquake is the only event addressed further in this section. Section 4.2.4 of Chapter 2 provides details of the earthquake events, which are summarized below.

Exposure frequency—The NEIDL structure was designed to withstand an earthquake with a peak acceleration of 0.12g (g is the acceleration of gravity), per the requirements of the Massachusetts Building Code. The fundamental period of the NEIDL structure is 2 seconds and seismic shaking at the fundamental period has the potential of causing the greatest damage. Based on the U.S. Geological Survey (USGS) seismic hazard maps, the annual exceedance probability for a 2-second 0.12 earthquake is estimated to be 1×10^{-5} (see Attachment E of Appendix F), which corresponds to frequency category C (1 in 10,000 to 1 million years). The MRF earthquake is assigned to frequency category C, but this is considered conservative because a significantly more severe, hence less likely, earthquake would be required to result in a total collapse of the NEIDL structure.

Airborne dispersion calculations for the MRF earthquake show that individual members of the public beyond the NEIDL exclusion fence (i.e., at least 30 m from the facility) would receive an average of less than one unit of any pathogen. Exposures from the release were analyzed for a radius of 1 km from the point of release. The exposure level is pathogen-specific because the maximum working volume and suspension concentration differs for each pathogen.

Public infections and fatalities—Estimates from the dose-response assessment were applied to the exposure and population estimates to calculate the likelihood of infections and fatalities occurring in the public from direct exposure. Of all pathogens, the highest risk was estimated for RVFV, for which a release leading to one to five infections and one fatality at the urban site could occur with average frequency more than 1 in 1 million years, but less than 1 in 10,000 years (category C). Infections could occur from other pathogens as a result of a release, but most of the associated frequency estimates fall in frequency category D (less than 1 in one million years).

11.4.4 Aircraft Crash

The potential for direct public exposure as a result of an aircraft accidentally crashing into the NEIDL was also evaluated (see Section 4.2.5 of Chapter 2). It was concluded that the frequency and consequences of the aircraft crash are no greater than and likely less than the frequency and consequences associated with the MRF earthquake. Therefore, an accidental aircraft crash was not analyzed in detail.

11.4.5 Transportation Analysis

Pathogen samples will be shipped both to and from NEIDL throughout its operating lifetime. Those samples will be packaged and shipped in accordance with the U.S. Department of Transportation (DOT) Hazardous Material Regulations (49 CFR Parts 171-180). The DOT regulations require triple-packaging of infectious substances. NEIDL policy goes beyond the DOT regulations and requires that the DOT-compliant triple packaging be placed in a large, foam-lined plastic case for an added layer of safety. The over-pack will be secured to the bed away from the exterior walls of an exclusive use (i.e., no other cargo) large truck. While some shipments will be mixed mode (i.e., air and ground), all shipments will arrive or depart from NEIDL in trucks (Murphy 2011). The analysis (Chapter 5) considered crash-related injuries, crash-related fatalities, and pathogen releases due to truck and aircraft crashes.

11.4.6 Threat Assessment (Malevolent Acts)

The TA (Chapter 6) evaluates the potential of 11 malevolent scenarios, but it does not include a quantitative estimate of the frequency or consequences of these scenarios. DOE NEPA Guidance (DOE 2002) acknowledges the difficulty of analyzing malevolent acts and suggests that the consequences could be compared to consequences of severe accidents because the forces resulting in releases of hazardous materials could be similar. An evaluation determined that the consequences of the MRF earthquake are equal to or exceed the consequences of malevolent acts that result in pathogen releases from the facility.

11.4.7 Potential For Released Pathogens To Become Established In The Environment

On the basis of the available evidence, it is concluded that five of the pathogens that are likely to be studied at the NEIDL, namely, *F. tularensis*, *Y. pestis*, 1918 H1N1V, RVFV, and TBEV-FE, have potential, at least theoretically, to become established in the environments in the vicinity of the three proposed NEIDL sites (see Tables 8-1 and 8-2 of Chapter 8). The means by which that might occur involve animals (including arthropods) that could be present in those environments. On the basis of the available data, it is concluded that one of those pathogens, *F. tularensis*, might already be present in some areas in the vicinity of proposed NEIDL sites. Also, it is noted that although released *B. anthracis* spores have potential for long term persistence in soil under particular environmental conditions (microenvironments), the evidence indicates that these conditions do not exist in New England. As a result, there is no indication that released spores could cause *B. anthracis* to become established in the local environments (see Section 7.3.1 of Chapter 7 for details).

11.4.8 Environmental Justice

The environmental justice analysis (see Chapter 10) addresses Executive Order 12898, *Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations*, and the Massachusetts EEA Environmental Justice Policy. The environmental justice analysis addressed the question of operational impacts of NEIDL resulting in disproportionately high and adverse human health effects on minority and low-income populations at the urban, suburban, or rural sites. This analysis examined two types of impacts: (1) those that could directly expose environmental justice communities as a result of a release of pathogen from the facility, and (2) those that expose people in environmental justice communities indirectly through secondary transmission of pathogens.

11.5 Risk to Workers

This section focuses on the events that pose the greatest risk to workers, i.e., centrifuge release and needlestick events. Those events could also pose risks to the public; the public risk from the events is addressed in Section 11.6.

11.5.1 What Could Go Wrong?

Equipment failures and personnel errors can result in worker exposures to infectious pathogens, but biocontainment features used in NEIDL reduce the likelihood and extent of exposure. The CDC and NIH have published *Biosafety in Microbiological and Biomedical Laboratories* (referred to as BMBL) (CDC

and NIH 2007), which provides biosafety practice and policy recommendations. Protocols identified by BU go beyond the recommendations of BMBL and provide additional protection of workers and the public. A few of the BSL-3 and BSL-4 preventive and mitigative features to be used at NEIDL are:

- BSCs used for all activities involving open pathogen containers
- Aerosol seals on rotors/cups and containers
- Use of non-breakable labware wherever possible
- PPE requirements that include double gloves, gowns, shoe covers, boots, mesh gloves when changing blades, hooded PAPRs for all BSL-3 activities, and positive pressure suits for BSL-4 activities.
- Vaccinations when available
- Procedures and training to report all incidents and medical response in the event of incidents

Even with the implementation of those protocols, there remains risk of worker exposures to BSL-3 or BSL-4 pathogens. Numerous equipment failures and personnel errors have the potential of causing a partial loss of biocontainment, more than 30 of which were considered for analysis in this RA (see Chapter 7). This RA focused on two of the larger risks to the laboratory worker, namely, centrifuge release and needlesticks. Because this RA concentrates primarily on the risk to the public, only centrifuge release and needlestick events that go undetected or unreported were analyzed because they have the potential to expose the public to pathogens via infected laboratory workers.

11.5.2 What are the Frequencies and Consequences?

Experience at other BSL-3 and BSL-4 laboratories has shown that laboratory workers may be exposed to pathogens and that LAIs are a real possibility. The following sections provide a comparison by event and by pathogen.

Centrifuge release and needlestick events were analyzed in this RA because they are two of the more common incidents in laboratories, and they involve different routes of exposure. Tables 11-4a and 11-4b

Operating experience:

- BSL-3 or equivalent laboratories NIH intramural (1982-2003):
 - ~3.2 million worker hours
 - 1 symptomatic infection
 - 4 asymptomatic infections
- BSL-4 laboratories worldwide (1972-2009):
 - ~0.69 million worker hours
 - 0 infections
 - The rate of laboratory-associated infections have decreased by more than an order of magnitude over the past decades.

Details and references are found in Tables D-1 and D-4, and Section D.1.1 of Appendix D.

show the frequency of laboratory worker infections and fatalities resulting from centrifuge release and needlestick events, both of which are assumed to be undetected or unreported. The number of potential worker infections from a needlestick event is limited to one worker, while the potential exists for multiple infections from a centrifuge release occurring in a room with multiple laboratory workers. Tables 11-4a and 11-4b provide a comparison of the two events in a format similar to *Consumer Reports* tables. Each of the 13 pathogens is listed in the left column and the two sets of columns present the frequency category for the number of infections and fatalities specified in the lower header row. Table 11-4a provides the results of the analyses for the centrifuge release event and Table 11-4b provides the results for the analyses for the needlestick event.

(Note: There is a range of potential consequences associated with each event (e.g., 0, 1, 2, 3, 4, or more laboratory worker infections) and Table 11-4 presents the results for each level of consequence. Because there is variability and uncertainty associated with the estimates, there is a range of frequencies for each level of consequence and these estimates may cover more than one frequency category. In order to simplify the presentation of results in Table 11-4 and similar tables, the frequency is assigned on the basis of the highest category that contains more than 25 percent of the range of results.)

Table 11-4a. Risk of laboratory worker infections and fatalities as a result of a centrifuge release event

MARV	⊙	×	⊙	×
LASV	⊙	×	○	×
JUNV	⊙	×	○	×
TBEV-FE	⊙	×	⊙	×
NIPV	⊙	×	⊙	×

Frequency categories:

- = A (1 in 1 to 100 years)
- ⊙ = B (1 in 100 to 10,000 years)
- = C (1 in 10,000 to 1,000,000 years)
- = D (1 in >1 million years)
- × = not applicable (a needlestick can infect only one worker at a time)

The results in Tables 11-4a and b suggest that the risk of a single infection in a laboratory worker as a result of a needlestick is greater than the risk of a single infection from a centrifuge release for most pathogens; however, this is largely because of a simplifying assumption that all needlestick events result in infections. In reality, it is known that not all needlestick events occurring in laboratories have resulted in infection, but the simplifying assumption was made because (a) accidental needlestick exposure data are not available for the 13 pathogens and (b) the extent of exposure from a needlestick is highly variable and difficult to quantify for a dose-response analysis. Use of a less conservative assumption could result in a reduction in the frequency of needlestick infections and fatalities for NEIDL and alter this comparison.

As shown in Table 11-4a for a centrifuge release, RVFV poses the greatest risk to the laboratory worker because its concentration in the work stock is greater than the concentration of other pathogens, which result in greater exposures, and the dose-response analysis for RVFV suggests that the amount of those exposures could be highly infective.

11.6 Risks to the Public

11.6.1 What Could Go Wrong?

There are two potential ways that NEIDL operations can expose the public to pathogens:

- Indirect public exposure: Undetected or unreported LAIs, such as the centrifuge release and needlestick events analyzed in this RA, have the potential to expose the public indirectly via secondary transmission of pathogen from an infected laboratory worker.
- Direct exposure: Pathogen releases from the facility, such as those that might result from an earthquake, can directly expose the public to pathogens.

Both the indirect and the direct exposures were considered. The needlestick is used as the basis for indirect public risk because it includes both BSL-3 and BSL-4 pathogens, and the estimated likelihood of an infection is higher than for the centrifuge event for the most transmissible pathogens. The MRF earthquake is used as the basis for direct public risk because it is an extremely severe event that includes the loss of all biocontainment features and it results in the maximum credible direct exposure levels to pathogens.

There are multiple layers of biocontainment that limit the likelihood of indirect and direct exposure. The first layer is the standard operating protocols of NEIDL that advocate safe laboratory practices and other mitigative features such as offering FDA-approved vaccinations to laboratory workers. Biocontainment features include use of sealed unbreakable containers; use of biological safety cabinets; seismic design and construction that exceeds requirements; and a ventilation system with high-efficiency air particulate (HEPA) filtration on the discharge (single filtration for BSL-3 and double for BSL-4). In order for either indirect or direct public exposures to result, failure of biocontainment features must occur.

11.6.2 What are the Frequencies and Consequences?

Operating Experience on Secondary Transmission from LAIs:

Operating experience from five facilities shows that LAIs from BSL-4 pathogens have not been a threat to the public. No LAIs involving BSL-4 pathogens have been reported from these facilities. (Johnson 2009)

LAI from BSL-3 pathogens that have resulted in secondary transmission to the public include one LAI that resulted in seven infections with SARS-associated corona virus in China (one of which was fatal) (World Health Organization 2004). Experience at the CDC between 1947 and 1973 showed that, for 109 LAIs diagnosed among its personnel, no secondary infections occurred among family or community members (Centers for Disease Control and Prevention 1999). The National Animal Disease Center (Ames, Iowa) similarly found no secondary infections associated with 18 LAIs at their institution between 1960 and 1975.

Recent published reviews of LAIs linked to BSL-3 or BSL-4 laboratory operations reported no infections in the community at large since those of the 2004 SARS incident in China (Kimman, Smit, and Klein 2008; Harding 2006) (Johnson 2009)

The public risk of infections and fatalities due to the needlestick and MRF earthquake are presented in Tables 11-6a and 11-6b. The risk of public infections and fatalities from a needlestick has been analyzed for four of the pathogens (*Y. pestis*, 1918H1N1V, SARS-CoV, EBOV) for which there are sufficient epidemiological data and published secondary transmission models available, with results summarized in Table 11-6a. In that table, the frequency of one or more public infections or fatalities is placed in category B (1 in 100 to 10,000 years) for all four pathogens. Outbreaks leading to 100 or more fatalities are placed in frequency category C (1 in 10,000 to 1 million years) for 1918 H1N1V and SARS-CoV and in frequency category D (1 in more than 1 million years) for *Y. pestis* and EBOV. 1918 H1N1V and SARS-CoV pose a higher risk of large outbreaks because they are able to spread more quickly and easily from person-to-person and can cause outbreaks that are more difficult to control than do the other pathogens.

For the earthquake event, RVFV is the only pathogen placed in category C (1 in 10,000 to 1 million years) in Table 11-6b for the frequency of one or more infections or fatalities. RVFV poses the greatest risk because its concentration in the work stock is greater than the concentration of other pathogens, which result in greater exposure estimates, and the dose-response analysis for RVFV suggests that those exposure amounts could be infective to a large enough portion of individuals to cause one or more infections.

***Y. pestis* transmission estimates – historical context**

Information from outbreaks of pneumonic plague (caused by *Y. pestis*) that have been documented in the 20th century was used as the basis for the quantitative transmission estimates in this RA. The outbreaks occurred in various countries (including the United States) and ranged from 3–42 cases per outbreak. Those observations are reflected in the results for this RA, which show that an outbreak of 100 or more total cases would be much less likely than outbreaks with lower numbers of total infections. The reason that larger outbreaks are less feasible is that, in most cases, standard control measures were observed to be highly effective in ending transmission once hospitals and communities were aware of the outbreak. For more details about the historical outbreaks, see Chapter 9 and Appendix L.

1918 H1N1V transmission estimates – historical context

Transmission estimates for 1918 H1N1V were generated using information from both the 1918–1919 influenza pandemic, which was caused by the 1918 H1N1V strain, and the 2009 H1N1 influenza pandemic, which provides insights into how influenza pandemics unfold in the modern world. Studies of the pandemics reveal that influenza can spread very rapidly in a population partly because the generation interval, or time between the onset of symptoms of successive cases, is thought to be relatively short (possibly two days or less) compared to other pathogens. That makes transmission difficult to control through strategies such as isolation of infected patients, because it is difficult to isolate patients fast enough before they transmit to others. Those observations explain why the results for this RA show that the frequency for very large outbreaks involving 1918 H1N1V are potentially higher than for the other pathogens. On the other hand, the average number of transmissions from a single infected case that occurred in the 1918 and 2009 pandemics is thought to be relatively low, possibly less than two. That means that there could be a good chance that a small outbreak would die out by random chance, or that control measures that encourage social distancing would have a good chance of bringing a local outbreak under control before it grows large. That possibility is also reflected in the results for this RA, which shows that there could be a very low frequency for outbreaks resulting in 10 fatalities in the public.

Tables 11-6a and 11-6b demonstrate that the public risk is greater from the indirect route of exposure via an undetected or unreported initial infection resulting from a needlestick event when compared to the direct exposure due to an earthquake. The earthquake results in fewer infections because of the small quantities of pathogen in the laboratory, the limited potential for release of that inventory, and the dilution of any release in the atmosphere.

The uncertainty associated with the needlestick results are shown in Table 11-6c and 11-6d, which provide the range of results for each outcome (95 percent of estimates fall within each range). The results demonstrate that the risk of one or more infections among the public resulting from an undetected and unreported initial infection in a laboratory worker following a needlestick event is in the range of 1 in 510 to 1 in 27,000 years for the four pathogens analyzed. The risk decreases further for 10 or more infections. The risk for outbreaks greater than 100 infections among the public are also presented. A similar analysis of fatalities among the public as a result of the pathogens is presented in Table 11-6d.

Table 11-6c. 95% estimate ranges from uncertainty analysis, of the risk of infections among the public resulting from an undetected and unreported initial infection in a laboratory worker following a needlestick event

Number of infections among the public	BSL-3 Pathogens			BSL-4 Pathogens
	<i>Y. pestis</i>	1918 H1N1V	SARS-CoV	EBOV

EBOV transmission estimates—historical context

The EBOV transmission estimates are based on information from outbreaks that have occurred in Africa. As discussed in Chapter 9, the setting and population in which these outbreaks occurred are in many ways quite different than the United States, and some have suggested that the extent of transmission seen in Africa can be explained by local cultural practices that amplified transmission. However, others have concluded that these locally specific practices accounted for only a small portion of transmission and that many transmissions occurred within families and the community. Given the lack of evidence to suggest otherwise, it was assumed that transmission estimates derived from the Africa outbreaks would be applicable to a potential outbreak in the United States.

At least 14 outbreaks have occurred in Africa since 1976, which ranged from a total of 12–425 cases per outbreak. Most (9 of 14) outbreaks involved fewer than 100 cases. That range of outcomes is reflected in the results for this RA, which show that greater than 100 infections are possible following a single laboratory worker infection, although smaller numbers of infections are more likely. The reason that EBOV outbreaks of more than 100 cases are rarer and more than 1,000 cases have not occurred is that standard, hospital-level control measures were effective once put in place.

SARS-CoV transmission estimates: historical context

Information from outbreaks of SARS that have occurred since it first emerged in 2002 was incorporated into the quantitative estimates shown here. Observations of transmission patterns that occurred revealed that infected cases transmitted to about two to four others, on average, during the early stages of outbreaks before public health control measures were implemented. However, the variation in the number of transmissions that occurred from case-to-case was wider than what has been observed for other transmissible pathogens. More than half of people infected with SARS-CoV did not transmit infection to anyone, while a small portion of cases transmitted to large numbers of others in isolated *superspreading* events. That variation can partly explain why some cities (Hong Kong, Singapore, Toronto) experienced explosive outbreaks of SARS in 2003, while other places (such as the United States) did not, even though infected cases traveled there several times. For more details, see Chapter 9 and Appendix L.

Those observations have important implications for considering possible consequences of a single infected laboratory worker entering a community. There has been one observed case of an infected laboratory worker in China causing seven secondary infections and one death. However, given the variation in transmission described above, much different consequences could occur under similar circumstances—from no transmission at all, to a large number of infections and fatalities. The entire worldwide outbreak of SARS in 2002–2003 resulted in about 8,000 infections and 800 deaths. For the analysis in this RA, extreme outcomes on par with those numbers or higher were observed only if it was assumed that control measures would remain relatively ineffective for a long period. If control measure effectiveness was on par with what was observed in most locations in 2003, those extreme consequences were found to be much less likely.

11.7 Site Differences

11.7.1 What Are the Differences in What Could Go Wrong?

There are differences among the urban, suburban and rural sites; those consist of the following:

- Differences in population densities and characteristics.
- Natural phenomena hazards (such as earthquakes) could have different frequencies and severities among the three sites; however, there are no hazards unique to one site.
- Meteorological conditions differ among the three sites; however, that affects only the concentration of potential aerosol from potential pathogen releases.
- The environs surrounding the three sites could affect the potential for environmental persistence of pathogens if there was a release of pathogens to the environment.

Those factors contribute to differences among the three sites; however, those and other factors do not affect the operations of NEIDL. Because it is assumed that the facilities, operations and potential events are independent of the site, there are no discernable differences in what can go wrong among the three sites.

11.7.2 What Are the Differences in Frequencies and Consequences?

The sites were compared on the basis of the risk of infections and fatalities in the general public, medically vulnerable subpopulations (MVSP), and environmental justice communities. In addition, potential differences among the sites were considered for transportation, malevolent acts, and environmental persistence. The potential differences are addressed in the following subsections.

11.7.3 General Public

There are differences among the three sites, including differences in population, meteorological conditions, and commuting patterns. While some of the differences might be large (e.g., differences in population density), they do not necessarily translate to large differences in the risk to the general public. Appendix L provides a comparison of the estimated likelihood of infections and fatalities resulting from secondary transmission among the public at the three sites as a result of an undetected or unreported initial infection in a laboratory worker. The estimated likelihoods for a given total number of infections or fatalities are generally slightly greater at the urban site than at the suburban and rural sites because of the following assumptions.

- It is assumed that residents in the towns adjacent to the suburban and rural sites have about 15 percent and 50 percent fewer contacts on average, respectively, than residents near the urban site, which results in correspondingly fewer numbers of transmissions. Those assumptions are derived from data-based estimates from each local area.
- The populations at the suburban and rural sites are much lower than urban site population. These lower populations are a limit on the maximum size of outbreaks among locals at the suburban and rural sites.

Despite the above differences, the differences in secondary transmission results across the three sites are not substantial, as uncertainty ranges overlap considerably. This is the case because not all infected

individuals are likely to be local residents. Commuting data were used to estimate the portion of transmissions that would occur among individuals who are nonresidents, and for those individuals, the above assumptions are no longer valid. Therefore, a significant portion of infections and fatalities could occur outside the local area, so local population differences have a diminished effect on overall differences among the three sites.

A similar comparison was performed for fatalities among the public as a result of exposure and infections resulting from a direct exposure of pathogen to the public following an MRF earthquake event. The results of the uncertainty analysis indicate that the risk of one or more fatalities from RVFV as a result of the event is higher at the urban site (1 in 340,000 years to 1 in greater than 10 million years) as compared to the suburban and rural sites (1 in greater than 10 million years for all estimates across the uncertainty range). That is because of the higher population density at the urban site. For this event, RVFV is chosen as the representative pathogen because it was shown to pose a greater direct exposure risk to the public than the other 12 pathogens.

11.7.4 Medically Vulnerable Subpopulations

This RA considered five categories of MVSP; those are those under 5 years of age; those over 65 years of age; those with diabetes, those with HIV/AIDS, and pregnant women. Local, regional and national data sources were used to estimate the proportion of each category of MVSP among the populations at the three sites (Appendix I). There are differences among the proportions of the different MVSP among the three sites. Differences in vulnerability among MVSP to the 13 pathogens were estimated from the literature and from expert opinion (Appendix H).

The risk of infections and fatalities from secondary spread of SARS-CoV among members of MVSP at the three sites resulting from an undetected and unreported initial infection in a laboratory worker following a needlestick event was used to assess the potential risk to MVSP. SARS-CoV was chosen as the representative pathogen because that pathogen was considered to pose a relatively high risk to the public as a result of the event. First, the overall MVSP profile across all five categories at each site was assessed to estimate an overall population susceptibility adjustment as compared to a typical U.S. population. It was estimated that the overall population susceptibility to SARS-CoV at each site was not substantially different than a typical U.S. population. In addition, the risk of infections and fatalities to each individual MVSP was assessed, and again it was found that the differences in risk were not substantially different across the sites. For full details, see Appendix L.

11.7.5 Environmental Justice

The goals of the environmental justice (EJ) analysis (see Chapter 10) are to address Executive Order 12898, *Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations*, and the Massachusetts EEA Environmental Justice Policy; identify potential environmental justice areas at the urban, suburban and rural sites and assess the effects of exposure to pathogens on environmental justice communities. The exposure scenarios are a direct release of pathogen from the facility resulting in exposure of members of EJ communities to that pathogen and spread of pathogen through EJ communities as a result of secondary person to person transmission.

Demographic Data

The area within a 10-km (6-mile) radius from the center of the NEIDL at each of the three potential sites (urban, suburban and rural) is considered the area of off-site impacts. Using US Census data, EJ communities were identified near the urban site. At the suburban site, EJ communities were identified within 10 km but not within 4 km of the suburban site. No environmental justice communities are present within 10 km of the rural site.

Effects of Exposure to Pathogen on EJ Communities

Pathogens exert an effect at the individual level. This RA recognizes, through available literature that a large proportion of EJ communities suffer from health disparities. Differences in life expectancy, morbidity, risk factors, and quality of life are noted among segments of the population by race/ethnicity, sex, education, income, geographic location, and disability status. Those disparities are believed to be the results of the complex interaction among genetic variations, environmental factors, and specific health behaviors. Furthermore, those who are medically compromised among EJ communities are likely to be at higher risk of infection and experience adverse outcomes as a result of those infections. Health disparities along with chronic diseases have the potential to contribute to increased susceptibility to any of the pathogens being studied in this RA. Published reports based on the experience with the recent 2009 H1N1 influenza pandemic have begun to address these issues. There are, however, limited published data on this topic with respect to the pathogens addressed in this RA. Similarly, there are limited data to enable a detailed quantitative analysis on the spread of infections based on contact networks among individuals in EJ communities.

At the community level, several factors affect the response to pathogen exposure. Health disparities have the potential to contribute to differences in how communities respond to exposure and infection with any

of the pathogens. Environmental justice communities most often are comprised of individuals that have lack of access to services. With regard to access to medical care, the findings are unique for the State of Massachusetts as this State has a very different health care system than most states in the Union. The Massachusetts Health Care Insurance Reform Law of 2006 established a state regulated health care insurance coverage system. The law mandates that nearly every resident of Massachusetts obtain a state-government-regulated minimum level of healthcare insurance coverage. It is important to acknowledge that equal accessibility to health services and medical care is not necessarily the same as equal utilization of health services and medical care.

Direct Exposure to Pathogen and EJ Communities

Event sequences such as earthquakes could lead to release of pathogen from NEIDL and directly expose members of the surrounding community. At the urban site, this would result in exposure of EJ communities that are in the vicinity of NEIDL.

If an MRF earthquake occurred, members of the public adjacent to the facility within a 1 km radius would receive an average exposure that is unlikely to cause infection for 12 of the 13 pathogens. The possible exception is RVFV, for which a release leading to one to five infections and one fatality at the *urban site* is estimated to occur with an average frequency of once in 10,000 to 1 million years (category C). Infections with other pathogens are mostly estimated to occur with an average frequency less than once in one million years (category D). Initial infections from all 13 pathogens are estimated to be in the D frequency category at the *suburban and rural sites*. Since no environmental justice communities are present at the rural and suburban site within the 1-km radius of exposure, the impact is *not* considered *significant* to environmental justice communities at either of those sites.

Secondary Exposure to Pathogen and EJ Communities

The risk of secondary exposure to pathogen from work done at NEIDL is based on the scenario that an infected worker leaves the facility and potentially transmits the pathogen to social contacts. If there are secondary exposures due to an infected worker leaving the facility, initially, those at greatest risk will be the worker's close social contacts. It is to be noted that the workers and their contacts may or may not live in the communities in closest proximity to the NEIDL location. In situations where secondary exposures continue, several persons could be infected one after the other. For example, the lab worker could infect person A, who in turn infects person B, who in turn infects person C and so on; such that after a certain period of time, people getting infected are no longer close social contacts of the original lab worker.

An analysis of the extent to which local individuals at the three NEIDL sites would bear the risk of secondary exposure was estimated using commuting data from the US Census Bureau.

For the urban site, the estimated risk to local residents is relevant for the environmental justice analysis as EJ communities have been identified within the city of Boston. Depending on the pathogen being considered, estimates for the frequency of 10 or more fatalities among Boston residents range from once in 5,300 years to once in more than 10 million years. For the frequency of 100 or more fatalities among Boston residents, estimates range from once in 50,000 years to once in more than 10 million years. It is also noted that outbreaks spreading outside of the city might pose a risk to environmental justice communities in the surrounding area as well.

For the suburban site, no environmental justice communities were found in the town of Tyngsborough, Massachusetts. Nonetheless, the estimated effects of commuting into and out of Tyngsborough result in a substantial portion of the risk for large outbreaks being potentially borne by non-locals, a result which suggests that the environmental justice communities identified in nearby Lowell, Massachusetts, could be at risk during a potential outbreak started in Tyngsborough. However, the extent to which there might be a specific risk to residents of Lowell due to observed travel patterns in that area has not been assessed.

For the rural site, no environmental justice communities were found in the towns of Hancock and Peterborough or in towns within a 10-km (6-mi) radius of the site. The estimated effect of commuting into and out of the local area may result in a substantial portion of the risk for large outbreaks being potentially borne by non-locals, and it is possible that large outbreaks would extend beyond the 10-km (6-mi) radius applied in this environmental justice analysis. Therefore, the possibility that a large outbreak starting at the rural site would pose a risk to one or more environmental justice communities in a wider radius cannot be ruled out.

11.7.6 Transportation

The transportation analysis estimates the likelihood of truck crash-related injuries, truck crash-related fatalities, pathogen releases due to truck crashes, and pathogen releases due to aircraft crashes. The likelihood of pathogen releases due to truck crashes was estimated using two approaches:

1. Because of the robustness of the NEIDL packaging, the NEIDL packages are expected to survive crashes that truck-occupants would not survive; therefore, the occupant-fatal crash rate was used as one estimate of the likelihood for a pathogen release.

2. The NEIDL packages are not expected to fail as a result of impact loads and are most likely to be breached as a result of crushing loads. Occupant-fatal rollovers and train collisions are the types of collisions most likely to produce crushing loads and they were used to estimate the likelihood of a pathogen release.

Table 11-7 presents the frequency categories associated with each event for BSL-3 and BSL-4 shipments. The frequency category for injuries and fatalities from BSL-3 shipments is higher than for BSL-4 shipments because there are expected to be approximately ten times more BSL-3 shipments.

Table 11-7. Frequency category for transportation impacts within 10 km of the laboratory.

Event	Frequency category	
	BSL-3	BSL-4
Crash-related injuries(including the public and the driver of the truck)	⊙	○
Crash-related fatalities(including the public and the driver of the truck)	○	·
Public infections due to the crash of a truck carrying NEIDL pathogens	·	·
Public infections due to the crash of an aircraft carrying NEIDL pathogens	·	·

Frequency categories: ● = A (1 in 1 to 100 years)

○ = C (1 in 10,000 to 1,000,000 years)

⊙ = B (1 in 100 to 10,000 years)

· = D (1 in >1 million years)

The conclusions of the NEIDL transportation analysis are summarized as follows:

- Crash-related injuries and fatalities from NEIDL shipments are more likely than pathogen-related infections or fatalities in the public. A crash-related injury due to truck or air transport of NEIDL pathogens has an estimated frequency of one in 100 to 10,000 years and a crash-related fatality has an estimated frequency of one in 10,000 to 1 million years. An infectious pathogen release from a truck or aircraft crash resulting in an infection has an estimated frequency of 1 in more than 1 million years, which is considered beyond reasonably foreseeable..
- In the event of an infectious pathogen release from a transportation crash, the exposure levels are expected to be no greater than 5% of the exposures resulting from the MRF earthquake. The probability of one or more infections from a pathogen release due to a transportation crash is also smaller than the probability for the MRF earthquake.

These conclusions are valid for all three sites being evaluated (i.e., urban, suburban, and rural) as it is assumed the protocols followed for pathogen shipments would be similar for all sites.

11.7.7 Malevolent Acts

The security systems (e.g., electronic systems, personnel, policy, procedure, etc.) are assumed to be the same at each of the three sites, so the threat from any malevolent action(s) was the same at all three sites. Therefore, the analysis (Chapter 6) provides no basis for discerning any differences in the frequency among the three sites.

The consequences may be slightly different among the sites for malevolent acts that involve release of pathogens from the facility; however, the analysis determined that any exposures resulting from such releases would be no greater than the exposures from the MRF earthquake.

11.7.8 Environmental Persistence

The means by which the five pathogens (namely, *F.tularensis*, *Y. pestis*, 1918 H1N1V, RVFV, and TBEV-FE) theoretically could become established in the environments in the vicinity of the three proposed NEIDL sites involve animals (including arthropods) that could be present in those environments. It can be surmised that the intensively urbanized nature of the BioSquare Research Park site supports smaller populations of such animals and, as a result, would be expected to present a less favorable immediate environment for any such potential to be realized. Although a quantitative difference regarding this potential can be surmised, no qualitative difference is noted between the urban, suburban, and rural sites.

11.8 Conclusions

This section provides the major conclusions drawn from this RA.

11.8.1 Conclusions Related to Laboratory Worker Risk

1. NEIDL protocols would reduce and mitigate the risks of laboratory worker exposures and infections. However, the potential for NEIDL laboratory workers to be exposed to and become infected by the pathogens with which they are working remains a risk.
2. An undetected or unreported exposure from a needlestick leading to a laboratory worker infection is estimated to occur with a frequency between 1 in 100 years to 1 in 10,000 years for any of the BSL-3 or BSL-4 pathogens evaluated.
3. An undetected or unreported exposure from a centrifuge release leading to a laboratory worker infection for BSL-3 pathogens is estimated to occur with lower frequency than from a

needlestick, with the possible exception of RVFV. The analysis determined that RVFV poses the greatest risk to the worker, followed by *F. tularensis* and 1918 H1N1V. An undetected exposure from a centrifuge release in a BSL-4 laboratory is not considered credible.

11.8.2 Conclusions Related to Risk to the Public

1. One or more infections or fatalities in the public resulting from an MRF (total collapse) earthquake is expected to occur with a frequency of less than 1 in 1 million years for all pathogens except RVFV. The estimated average frequency of 1 or more infections for RVFV is between 1 in 10,000 years and 1 in million years, while the average frequency of 1 or more fatalities resulting from RVFV infection is between 1 in 340,000 years and 1 in more than 10 million years.
2. The analyses show risk to members of the public from secondary transmission of pathogens from an infected worker leaving the laboratory is significantly greater than the risk of direct exposure to a pathogen from a release due to an earthquake. That is relevant for pathogens that are transmissible directly from one person to another.
3. There does not appear to be any evidence of risk of direct person-to-person secondary transmission of anthrax to the public from a case of inhalational or gastrointestinal anthrax in a laboratory worker. There is a potential for person-to-person secondary transmission of anthrax to the public from a case of cutaneous anthrax in a laboratory worker. There does not appear to be a risk of direct person-to-person secondary transmission to the public from initial infections in laboratory workers of *F. tularensis* or TBEV-FE.. Risk to the public from initial infections in laboratory workers with RVFV is unlikely because that pathogen requires a vector or contact with infected animals for transmission to other humans. There is a potential for secondary transmission of the following pathogens to the public from initial infections in the laboratory worker: *Y. pestis*, 1918 H1N1V, SARS-CoV, ANDV, EBOV, MARV, LASV, JUNV, or NIPV.
4. For all four transmissible pathogens analyzed quantitatively (*Y. pestis*, 1918 H1N1V, SARS-CoV, and EBOV), the estimated average frequency with which one or more secondary transmissions is expected to occur after an undetected or unreported needlestick infection is between about 1 in 500 years and 1 in 30,000 years.

5. Of the four pathogens analyzed quantitatively, SARS-CoV and 1918 H1N1V pose the greatest risk of a large outbreak consisting of 100 or more infections among the public. For example, a SARS-CoV outbreak consisting of 100 or more infections is estimated to occur with an average frequency between 1 in 2,500 years and 1 in 440,000 years.

11.8.3 Conclusions Related to Difference among Sites

1. No site differences were found in risk to laboratory workers because it is assumed that NEIDL operations would be identical at the urban, suburban and rural sites.
2. For 12 of the 13 pathogens, most estimates of the frequency of one or more infections from an earthquake release are estimated to be less than 1 in 1 million years at all three sites. The frequency of one or more fatalities from RVFV as a result of the MRF earthquake event is higher at the urban site (1 in 340,000 years to 1 in greater than 10 million years) as compared to the suburban and rural sites (1 in greater than 10 million years for all estimates). That difference is because of the higher population density at the urban site.
3. Estimates for social contact rates based on data from the urban, suburban, and rural sites suggest that residents at the suburban and rural sites might have about 15 percent and 50 percent fewer average daily contacts, respectively, compared to the urban site, which could result in lower likelihoods of transmissions from those residents. However, on the basis of commuting estimates from each area (including the likelihood that an initially infected laboratory worker is not a local resident), it was determined that a significant portion of infections and fatalities could occur among individuals who are not local residents. As a result, those differences between the local resident populations did not cause the overall estimates of secondary transmissions of pathogens among the public to be substantially different across sites.

11.8.4 Limits of the RA

1. This RA used operational information regarding incidents at other BSL-3 and BSL-4 laboratories to the extent appropriate (see Appendix D). The operational data were an important input to the qualitative analyses, but they were of limited suitability for quantitative analysis of potential frequencies or exposures for NEIDL events. As a result of the data limitations, frequency categories spanning wide ranges were employed and conservative assumptions (i.e., assumptions

that tend to overestimate the frequency or consequences) were made. The results reflect that uncertainty but are generally considered to be conservative (i.e., overstate the true risk).

2. Data regarding the consequences of human exposure (via inhalation or needlestick) were limited for many pathogens and nonexistent for other pathogens. To compensate for incomplete data, expert opinion, information from experimental animal exposures, and conservative assumptions (i.e., assumptions that tend to overestimate the consequences of exposure) were used to inform the analyses. A wide range of initial infection frequency estimates was obtained, and the estimates of overall risk are sensitive to those estimates.
3. This RA focused on scenarios involving potential worker infections from undetected or unreported exposures as those events also pose a risk to the public. As such, the results of the RA are not intended to be an assessment of risk to laboratory workers in general.
4. Changes in the operation of the NEIDL relative to the bases used for this RA will affect the outcomes accordingly and could invalidate the conclusions of this RA if such changes were substantial.

12.2 List of Contributors

- Bozzette Sam, MD, PhD
Professor of Medicine (Infectious Diseases) and International Relations, University of California San Diego
Physician Executive, Cerner Corporation
Principle, Interdisciplinary Health Science Advisors
BS, Georgetown University 1976
MD, University of Rochester 1982
PhD, Policy, Economics, and Quantitative Methods, RAND Pardee Graduate School, 1995
20+ years of relevant experience
- Gibson, Mark C., Senior Environmental Scientist/Technical Editor, Tetra Tech, Inc.
M.S., Environmental Science and Policy, 1996, George Mason University, Fairfax, VA
B.S., Biology, 1989, Virginia Polytechnic Institute and State University, Blacksburg, VA
20 years of experience
- Johnson Karl, MD,
Program Director, Hazardous Viruses, USAMRIID
Chief, Special Pathogens Branch, CDC
Head, Virus Diseases Section, Middle America Research Unit Chair, Scientific Peer Review Group for BSL-4 facility, Hamilton, Montana
Member Scientific Peer Review Group for BSL-4 facility, Galveston, Texas
Biocontainment laboratory practical experience: 36 years
- McLaughlin Heath E., Events Sequence Analyst
B.S. Nuclear Engineering, 1997, Purdue University
M.S. Nuclear Engineering and Engineering Physics, 1998, University of Wisconsin
13 years of experience
- Strong, Jeffery L., Senior Technical Editor, Tetra Tech, Inc.
M.S., Technical and Scientific Communication, 2000, James Madison University, Harrisonburg, VA
B.A., Computer Information Systems, 1988, Eastern Mennonite University, Harrisonburg, VA
Years of Experience: 22

Wood Joseph CHMM, PE, Threat Analysis
MS, Environmental Engineering, University of Florida, 1986
BS, Environmental Engineering, University of Florida, 1984
Certified Hazardous Materials Manager
Years of Experience: 20

Public Comment Responses

Note to electronic readers: Appendix O is intended to be viewed in a two-page view. In order to access the two-page view, place your cursor over “View” in the taskbar. Then, scroll down to “Page Display” and select “Two-Page View.” The comments received by NIH will now appear on the left side of the screen, while the NIH response will appear on the right.

National Institutes of Health
 Attn: NEIDL Risk Assessment
 6705 Rockledge Drive, Suite 750
 Bethesda, MD 20892-7985

From Dr. Roy Lisker:

Hello to the NIH: I received the complete (Draft) Supplementary Risk Assessment report of 1,756 pages sometime last week. As it is impossible to work through the report in detail I've been focusing on specific sections, those in which I feel I might know something or have something to say. As I go through these sections I will be sending in my commentary, on a weekly or bi-weekly basis.

I also hope to be able to attend the hearing at Roxbury Community College on April 19. I would appreciate it if I were notified about a change of date before that time, as I have to make arrangements to stay in Boston over that time.

Today I am sending you my comments on Chapter 1 (1.0 to 1.7)

However, before I begin there is a general issue that I'd like to address. I have not yet examined the table of contents of every chapter and appendix in the DSRAR, but I have the impression that what you are concerned with are the physical aspects of the situation: the security concerns, safety records, accessibility of hospitals, possibilities of natural disasters. All of these are of course relevant and I certainly do not doubt your thoroughness. **However, although you are deeply concerned with the physical and environmental impact of the operations of the NEIDL, I don't see anything(yet) in this report which amounts to what one might call a "Psychological" Impact Assessment, that is to say, issues revolving around the stigmatization of a neighborhood that is already feared and shunned by a majority of the population!**

1.1

Certainly, no neighborhoods in Boston have so negative a reputation as the South End, Dorchester and Roxbury. People (both black and white) stay away unless they absolutely have to go there: women are afraid of being raped, businesses of being vandalized, visitors of being mugged, school-children of being killed by stray bullets shot off by the drug gangs.

To this high level of adverse reaction to this neighborhood, you intend to (gratuitously) load on a whole new level of stigma: the fear, whether justified or not (although you are going out of your way to

Letter 1
Roy Lisker

- 1.1** Executive Order 12898, *Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations*, directs federal agencies to develop environmental justice strategies to address disproportionately high and adverse human health or environmental effects of their programs on minority and low-income populations, and to focus federal attention on the environmental and human health conditions of minority and low-income populations with the goal of achieving environmental protection for all communities. Executive Order 12898 does not specifically address psychological and or political stigmas.

show us that it is not justified), of being felled by one or more of the 13 most horrible diseases known to mankind! How much more sinister does one have to make the district, already suffering from rejection through fears of violence and the potential for serious injury?

Will this help businesses considering the wisdom of opening up there? Prospective-owners, landlords, renters? School children who are already cautious about attending classes? Will people who (perhaps unjustly) shudder when they hear the name of “Roxbury”, be more reassured when they learn that a kind of Frankenstein laboratory is being set up, not far from where (for example) a fatal shoot-out occurred the month before?

These psychological issues, and their attendant economic consequences, are every bit as serious as the actual threats to health. I certainly expect that they will be addressed at the meeting in Roxbury Community College, where I hope to be able to add my voice.

Chapter 1: Introduction

- 1.2 { **1-1** There is some confusion about the date of the completion of the NEIDL plant. Newspaper articles state that it was completed 4 years ago, around 2008. However on Page 1 of the RA it is stated that the plant was completed in the 4th quarter of 2011
- 1.3 { **1-4** There is a certain amount of familiar rhetoric on this page, which I would like to correct. Here it is stated that the “wake up call” for more BSL-3 and BSL-4 labs was a function of two events (1) The terrorist attacks of 9/11 and (2) The anthrax crisis . However, in the catastrophe of 9/11 no weapons of biological or chemical warfare were employed. As for the anthrax scare, research on anthrax is done in BSL-3 labs, not BSL-4, and it is stated somewhere there are over 1,300 laboratories in the US equipped to do research from BSL-1 to BSL-3 levels. So these arguments for the need for a new pair of BSL-4 laboratories are not valid.
- 1.4 { **1-5** . Here one learns that the other BSL-4 lab in the initial proposals of 2004 is in Galveston ,Texas. It is hard for me to understand how one can build such a lab in the “Hurricane Alley” of the US. Two major hurricanes, Rita and Ike, occurred during construction, and the fact that the lab was unharmed does not guarantee that it will not be so from the next major hurricane.

Letter 1
Roy Lisker

- 1.2** Substantial completion of the construction phase of the NEIDL occurred in October, 2008. Section 1.0 has been updated and this information is reflected in the Final Supplementary Risk Assessment.
- 1.3** In early 2002, NIAID, the lead NIH institute for infectious disease research, developed the *NIAID Strategic Plan for Biodefense Research* which outlines plans for addressing research needs in the broad area of bioterrorism and emerging infectious diseases. In February 2002, NIAID convened a Blue Ribbon Panel on Bioterrorism and its Implications for Biomedical Research which provided an objective assessment of the *NIAID Strategic Plan for Biodefense Research*. The Panel's findings became the *Biodefense Research Agenda for CDC Category A Agents* and the *Biodefense Research Agenda for Category B and C Priority Pathogens*. These research agendas identified a need for research resources to facilitate basic and applied BL3 and BL4 research towards development of: tests to rapidly diagnose, vaccines and immunotherapies to prevent, and drugs and biologics to treat diseases caused by agents of bioterror and other emerging infectious diseases that pose a potential threat to public health. Overall, the NIAID biodefense strategic plan and research agendas reflect a broad vision not only to conduct innovative and critically needed biodefense and emerging infectious disease research, but also to develop a research infrastructure with the breadth and flexibility to respond to ever changing infectious diseases research needs, including those that could be posed by public health emergencies such as a bioterror event or infectious disease epidemic or pandemic. One of the critical resource needs identified in the planning process was biocontainment laboratory space in which high-priority government-supported research on biological agents could be safely conducted.
- 1.4** This comment is outside the scope of the Draft Supplementary Risk Assessment.

- 1.5 { 1-6. Bioweapons are prohibited by international law. Thank goodness for that. Where, then, are the international inspection teams. Surely we are not supposed to believe that, alone among nations, we can simply take the word of the government that no secret designer bioweaponry research will be done in these plants. The US is actively demanding inspection teams in countries all over the world when it comes to nuclear plants. Why isn't it equally willing to allow inspection teams to periodically visit the Galveston site and the projected NEIDL site. My real question is, why doesn't the DSRAR address this issue. I hope it will be brought up in Roxbury, and at the other meetings scheduled around the city.
- 1.6 { 1-9 On this page this misleading impression is given that everything that needs to be known about safe workplace practices is already known, and it's only a question of implementing them properly. One knows however, that research, which perennially sets new goals and new guidelines, will forever be presenting new security and safety challenges. What one would therefore like to see is a discussion of how much leeway, either in terms of usable space or equipment, is being set aside for the inevitable development of directions in research that raise the specter of new dangers that have not yet been considered.
- 1.7 { 1-10 In the list of "principal hazardous characteristics of a biological pathogen, used to determine the appropriate BSL", there is no mention of iatrogenic complications, vaccines for example, with serious side effects; more generally, dangers presented to the staff, researchers and public by the research itself.
- 1.8 { 1-13. This page is concerned with "bio-containment" I haven't (yet) found the sections of this report that deal with the issues of toxic waste storage and disposal. The irresponsible activities of some hospitals that have dumped their toxic wastes in landfills and rivers are well known. How will the waste be stored? How will it be decontaminated? How will it be disposed of? I hope to find these issues treated in the other chapters of the Risk Assessment Report.
- 1.9 { 1-14. Are there additional potential dangers from radioactive releases (isotopes)? Toxic chemicals which are not "biological" pathogens?

Letter 1
Roy Lisker

- 1.5** No bioweapons research will take place at the NEIDL. The production of bioweapons is prohibited by Article 1 of the *Biological Weapons Convention* of 1972. Research at the NEIDL will be performed for scientific research and biodefense purposes (i.e. developing effective vaccines, therapeutics, and diagnostics). All research at the NEIDL will be conducted in accordance with applicable federal, state and local regulations. Information on the purpose of the NEIDL was provided in Chapter 1.1 and Chapter 1.3 of the Draft Supplementary Risk Assessment.
- 1.6** Safety and security requirements for work with agents such as pathogens are based on their properties. For example, the NIH/ CDC *Biosafety in Microbiological and Biomedical Laboratories* (5th edition) guidance details the precautions recommended for BL1, BL2, BL3, and BL4 research in terms of facility design, personnel protective equipment, control of aerosol production, etc. These fundamental protection principles are then customized and applied to any specific research being conducted. Any new pathogens that are identified will be classified by relevant regulatory agencies such as the World Health Organization, Centers for Disease Control (CDC) and Prevention, and the Boston Public Health Commission before they can be the subject of research in laboratories such as the NEIDL. The Risk Group classification of the new agent and the assigned biosafety level will determine the precautionary measures and facilities. The current facilities at the NEIDL are designed to facilitate research at all four biosafety levels. The space and equipment present in the NEIDL are designed and intended to accommodate new pathogens and new directions in biosafety research.
- 1.7** Principal hazardous characteristics are used in determining biosafety levels as well as risk groups for pathogens. Risk groups correlate with, but do not equate to, biosafety levels. The risk assessment passage in question addresses principal hazardous characteristics as they pertain to the assignment of pathogens to biosafety levels.

1.10

1-19 A diagram of the “hazard identification process overview” is presented on this page. The progression of stages from the “identification of candidate events” through to the characterization of the risk is presented as thoroughly linear, a 7-step process that leads, through a solitary chain of causation, to the desired result:

1. Identify candidate events →
2. Select events →
3. Analyze events →
4. Estimate initial infections →
5. Assess transmission potential →
6. Model secondary transmission →
7. Characterize risk

One knows however, that catastrophes are rarely, indeed I would say that they are never linear. In fact they are always the result of multiple causes that mutually interact. Rene Thom and EC Zeeman, the authors of so-called “Catastrophe Theory” knew this very well. Thus, step 6 “Model Secondary Transmissions” is bound to affect step 4 “Estimate initial infections”; step 2 “Select events”, must be reviewed and recast after the final characterization of risk. This chart gives a false picture of what really happens in a disaster, and is hardly reassuring to anyone who bothers to take a second look.

Within a short time, I will send you my comments on Appendix B.

Appendix B: Site Characteristics

Letter 1
Roy Lisker

- 1.8** The Draft Supplementary Risk Assessment provided extensive discussion of the management of waste. For example, Section 2.1.5 of the Draft Supplementary Risk Assessment concerns waste management and describes the process of sterilization of biological waste and the shipment of such waste off-site for incineration using a licensed third-party contractor. Section 2.1.5 also discusses radioactive and hazardous waste management. Additional details on waste management were provided in Appendix A.5: “Waste Management” as well as Appendix A.6 under “Decontamination Waste Treatment.”
- 1.9** Potential radiation sources at the NEIDL include an irradiator which uses sealed sources (i.e. encapsulated) of radiation as a means of sterilizing samples. The irradiator does not create a contamination hazard or a risk of spills. Research laboratories are expected to use very small quantities of radioactive materials such as Hydrogen-3, Carbon-14, Phosphorous-32, and Sulfur-35; typically in micro-curie to low milli-curie quantities. Research laboratories typically use a variety of chemicals (e.g. reagents, cryogens, acids, corrosives) which are stored in small quantities (typically in a few grams to liters). The probability of a release of these compounds is very low and, given the very small quantities, the risk posed by any potential release is also very low. Boston University will follow all applicable federal, state and local regulations for the storage and use of radioactive materials.
- 1.10** There are feedbacks to the analytical process, as explained in the methodology presentation to the National Research Council. The following sentence is being added to page 1-19, of the Final Supplementary Risk Assessment to provide clarification:
- “...process shown in Figure 1-9. There are potential feedback loops among the various steps in the analyses that are not shown in this diagram. The final step...”

1.11 { **B-1 In the RA description of the human geography of the South End, I would have expected to see street by street population and population density figures for the areas surrounding the BUMC complex**

1.12 { **B.1.3 You say there are no livestock in this Suffolk County inventory. I am very surprised that you don't list pets and their estimated numbers. An animal does not have to be livestock to be a potential victim or carrier of disease.**

1.13 { **B.1.3 Apart from a vague reference to a BWSC sanitary sewer line, one would expect a more detailed treatment of waste water disposal**

1.14 { **B-3 : One does not doubt that there are more than enough Emergency Response agencies in the neighborhood. But recall Three Mile Island: how many of these systems collapsed when the real emergency hit?**

1.15 { **B-5: This discusses the "synergy" between BUMC and the projected NEIDL laboratories. Is this synergy always a good thing? After all, diseases, particularly iatrogenic conditions could be transported back and forth between the two institutions.**

B-6 Tyngsborough, Massachusetts

1.16 { **An animal census for 2002 is presented.
(1) Animals are organic and proliferating creatures. Census figures change yearly, monthly, even daily. What is even more relevant is the animal to human ratio. Once again, no mention of pets, though there is a description of the wild life (no figures or estimates). No mention also of insects, microorganisms or archaea (fungi).**

(2) I quote from the report itself:

1.17 { **a. Municipal sewer service is not available from Tyngsborough
b. It might be possible to tie into municipal sewer service from the adjacent town of Chelmsford
c. The Merrimack River Valley ... was shaped by the history of the region as a major site of American industrial development in the 19th century. *Question :How much industrial sewage was left behind when the factories moved to China (Mexico, the Philippines?)***

Letter 1
Roy Lisker

- 1.11** Per the Council on Environmental Quality (CEQ), available demographic data from the U.S. Census Bureau census tracts and block numbers were used to identify the composition of the potentially affected population. Census tracts are small, relatively permanent statistical subdivisions of a county. Block Numbering Areas are small statistical subdivisions of a county for grouping and numbering blocks in non-metropolitan counties where local census statistical committees have not established census tracts. A Block Group is a combination of a census blocks that is a subdivision of a census tract or Block Numbering Area. Census blocks are the smallest geographic area for which the U.S. Census Bureau collects and tabulates decennial census data. Both census tracts and Block Numbering Areas provide the geographic framework for delineating block groups, assigning census block numbers, and tabulating data (U.S. Census Bureau 2000a). It is important to note that the unit of analysis for determining environmental justice communities by the federal criteria is the census tract; whereas for the determination by Massachusetts criteria, the unit of analysis is the census block.
- 1.12** Consideration of potential impacts to pets is beyond the scope of this document as agreed upon by both the Blue Ribbon Panel and the National Research Council. However, pets and insects were included in the Draft Supplementary Risk Assessment with consideration to pathogens becoming established in the environment (see Chapter 7).
- 1.13** The Draft Supplementary Risk Assessment discussed waste management extensively. Appendix A.5.1 of the Draft Supplementary Risk Assessment discussed biological waste treatment, including treatment of liquid effluent. Appendix A.5.3 addressed the disposal of chemical waste.

**B.3 Boston University Sargent Center for Outdoor Education
(Peterborough)**

The famous MacDowell Colony for the Creative Arts is to the south. I was there for the summer of 1962. The artists may turn out to be very vocal in opposing the siting of a BSL-4 lab nearby, with the north winds coming down on them from Canada.

B-11. As stated in the RA itself, access by roads is very poor. There would have to be considerable road construction in the area before NEIDL could be sited there.

B-12 Quoting from the RA:

“Peterborough is one of the most flood-prone areas in the state and has been included in three disaster declarations since 1987. It is subject to a variety of natural hazards including riverine flooding, wildfires, ice storms and river ice jams. The town has more than 40 dams, two of which have been classified as high-hazard dams. Specifically, the rural site property is encompassed by a Special Flood Hazard Area designation as Zone A, a 100-year floodplain. “

I suspect that one can translate the information given about the alternative sites in the following way: “We want to convince you that Roxbury is the only option!” However, you have not convinced many of us that a new BSL-4 laboratory is even necessary!

Chapter 10: Environmental Justice

1.18

10-1 The environmental justice chapter does not discuss the psychological, political and other stigmas presented by the public perception of a laboratory like NEIDL in a neighborhood like Roxbury: see the first page of my previous commentary. As with the rest of this report (as I've understood it so far) it only deals with safety and security issues.

1.19

10-2 The "federal environmental justice criteria" are badly flawed. A "minority" is a small population against a larger population: ethnicity is only one of the various categories in this equation: "college students" would be a minority in a blue collar town; "alcoholics" are an important minority on New York's Bowery; the "elderly" would be a minority in a town where most of the young people have moved away: paradoxically they become the "minority" because they are now the "majority", but they are underserved! By contrast, Afro-Americans are really too large a group to be classified as a "minority" To continue to call them a minority is merely a reinforcement of the notion of second-class citizenship. Afro-Americans constitute an *economically disadvantaged sub-population* in a multi-ethnic society. Alaskans and Native Hawaiians may be "minorities", but are they more so than Vietnamese or Kosovars? Jews are not classified as a minority (Thanks!) because they've been well-integrated into American society. However there is clearly a glaring omission when you don't treat Moslems and peoples from the Middle East as a minority. Not only are they one, they are an "oppressed minority", (which is what we really mean when we use the word "minority".) Once again, in citing poverty statistics (from widely different years!) you are missing the point: the real issue is infrastructure development. To take an obvious example relevant to this report: *public health* . It doesn't matter all that much how low the median salary is, if the standards of public health are high. On page 10-3 you do in fact discuss public health but do not relate it to infrastructure. In other words, *the degradation of the neighborhood* , quite apart from the median income, or educational level, or language proficiency, or ethnic profile, is the real issue, and it is a gross oversimplification to assume that all these things are closely correlated. The drug related problems of affluent teen-agers in the suburbs are just as bad, relative their own context, as the drug related problems in the poor inner city

Letter 1
Roy Lisker

1.18 See response to comment 1.1.

1.19 See response to comment 1.1.

.

1.19

neighborhoods. Prejudice knows no boundaries: if there were less prejudice in rural and suburban municipalities than in downtown Boston, there would be more “oppressed minorities” moving out to them. Ultimately “environmental justice” has to encompass the entire society”

10-5 There appears to be an excessive flexibility in drawing the lines of the target area. A draft EIS, Supplemental Draft EIS and Final EIS are all discussed. In only one of them, the Final EIS, is there any attempt to draw the boundaries of the area under discussion. The way these boundaries are defined sounds suspiciously like Gerry-mandering to get the results you want. Thus

- a. The population is 25% minority (circa 2005)**
- b. The median of household income in the South End (the whole South End or just the portion designated in the EIS) is greater than the median household income of the City of Boston. (How should that influence the placing of a BSL-4 infectious lab disease in the middle of the neighborhood?)**
- c. Less than 25 percent are foreign-born.**
- d. Less than 25% lack English language proficiency**
- e. The final comment is, excuse me, outrageous: “It is unlikely that the Proposed Action would have proportionately greater impact on the disadvantaged (e.g. minority) population than any other population in the area (NIH 2005)**

1.20

1. Does one gauge the “proportion” on the degree of disadvantage already present?

1.21

2. If all populations are stricken with anthrax, is there any comfort in knowing that the rich suffered as much as the poor?

3. The vague buzz-words are in “disproportionate” number: ‘unlikely that’...’proportionately greater’ ...’disadvantaged’ ...”other populations in the area...”

Letter 1
Roy Lisker

- 1.20** A 10-kilometer (km) radius was defined around the proposed NIH Boston University Medical Campus NEIDL site. A guideline of 1-km radius study area within the city limits and a 2.4-km radius outside city limits is provided by the U.S. Nuclear Regulatory Commission as generally sufficient for assessing potential environmental justice impacts associated with activities other than nuclear power plants (NUREG 2003). For the NEIDL, environmental justice data were collected for a radius of 10 km of each of the three sites, which is 10 times the city recommendation of the U.S. Nuclear Regulatory Commission. The larger radius is used to ensure that all potentially affected areas are considered. Demographic data were collected from the U.S. Census Bureau's 2000 decennial census for each census tract within the 10-km area; that is the most recent year for which data are available at the census tract geographic level.
- 1.21** This comment is outside the scope of the Draft Supplementary Risk Assessment.

1.22

Is this statement really saying that it's all right to go ahead with the creation of NEIDL because the amount of misery is already so high, that "proportionately", even more won't make all that much difference?

Finally, at the bottom of this page, you do discuss the degradation of basic physical health due to being a member of an oppressed minority: infant mortality, heart disease, diabetes, cancer, infectious diseases. HIV, tuberculosis ... The figures are dated 2011, that is to say, up to date. The conclusion is not that this population is far more susceptible to biolab induced infections, but are "the results of the complex interaction among genetic variations, environmental factors, and specific health behaviors"

1.23

10-7 This paragraph is followed by a statement of the laws which, in theory, entitle everyone in Massachusetts to adequate health care. This side-steps the fundamental issue of how much health care are persons in the target population actually receiving and is it adequate. The proximity of the BMC and BUMC are mentioned; as I've said, the "synergy" between the BMC and NEIDL might increase the iatrogenic toxicity of both environments.

10-9. On this page there is a frank admission of lack of essential knowledge and information. Quotes:

"OSHA...publishes and permits Permissible Exposure Levels to protect workers against the health effects of exposure to hazardous substances ... PELs do not include biological agents"...

..."Unlike the chemical and nuclear industry, no government agency regulates or enforces worker or public exposure to biological agents. Nor is there legislation that has set occupational or public exposure limit values for biological agents."

Letter 1

Roy Lisker

1.22 This comment is outside the scope of the Draft Supplementary Risk Assessment.

1.23 This comment is outside the scope of the Draft Supplementary Risk Assessment.

...” A small amount of a micro-organism can grow considerably in a very short time under favorable conditions....”

...”Biohazards do not show a proportional answer of the human body to the exposure of risk, which makes it very difficult to determine universally valid evaluation criteria (Gorny 2007)”

1.24

Those “proportions” again! One can use, as is done here in this report, “proportions arguments” to reach any conclusion.

This chapter has to be read in conjunction with Appendix F. However, as I will be away for two weeks and will not return to this examination until after March 27, I’m sending this along in advance.

1.25

4-1. On this page a selection of “candidate events” for accidents and mishaps is presented. These have been chosen to “represent” the full spectrum of possible dangers, either because they are typical or because they “bound” other accidents in the same category, that is, all other accidents in that category would be less destructive, dangerous or containable.

The choice of the 5 candidate events is very controversial and in some cases debatable: These are

(1) Aerosol Release (2) Needlestick (3) Earthquake (4) Aircraft Crash (5) Malevolent Acts.

The “aerosol releases” are assumed to be due entirely to centrifuge malfunction; likewise the “needlestick” incidents are taken to cover any kind of wound or injury caused by broken glassware, pre-existent bruises, knives, etc.

The very unlikely disasters produced by severe or moderate earthquakes, and aircraft accidents of the 9/11 type were selected over the very much more likely damages caused by hurricanes, tornados and floods. This makes no sense to me. Why not gauge the safety of the installation on the basis of things that are likely to occur? The huge damage caused by a very rare earthquake should not take preference over the severe, if not totally disabling, damages of a major flood? This is particularly relevant when considering the Peterborough alternative, which is a major disaster area for floods.

Letter 1
Roy Lisker

1.24 This comment is outside the scope of the Draft Supplementary Risk Assessment.

1.25 As described in Table 4-4 of the Draft Supplementary Risk Assessment, numerous candidate events that resulted in aerosol releases were considered. The centrifuge release event was selected for analysis not because the “aerosol releases are assumed to be due entirely to centrifuge malfunction,” but rather because it is at least as frequent and its releases are generally greater than other events (see Table 4-7). Therefore, the centrifuge release was selected as representative of other aerosol release events.

As discussed in Section 4.1.1 of the Draft Supplementary Risk Assessment, National Environmental Policy Act (NEPA) analyses should consider the spectrum of events including low probability/high consequence accidents and higher probability/ (usually) lower consequence accidents. The spectrum of events was considered for this analysis as explained in Section 4.1.1. Special attention was given to the maximum reasonably foreseeable event because of the court’s interest in a “worst-case” scenario in Section 4.1 of the Draft Supplementary Risk Assessment.

As described in Section 4.1.3.3 of the Draft Supplementary Risk Assessment, flooding was considered and determined to be in the same similar frequency category and have consequences that are at least as great as a severe earthquake. The laboratory was designed in consideration of floods so flooding within the design basis should be a minor concern. Severe external flooding beyond the design basis may cause operational problems. However, the BSL-3 and BSL-4 laboratories would not be threatened by flooding because they are not located on ground level.

With respect to malevolent acts, these are listed, but it is explained that discussion of them is reserved for another section of the report. The following comment however on page 4-12 is highly revealing:

“Malevolent acts were not considered in the selection of the MRF (Maximum Reasonably Foreseeable event. ‘because the potential number of scenarios is limitless and the likelihood of attack is unknowable (DOE 2002)’”

1.26 { I would respectfully submit that among the potentially malevolent events, one must include *the very siting of a BSL-4 biodefense laboratory in the heart of a densely populated poor urban neighborhood !*

1.27 { 4-2 Maximal Reasonably Foreseeable (MRF) incidents are defined here. This comment is made:
“For this RA, the MRF event was defined solely in terms of the accident with the maximum pathogen release from the facility”
 The definition is fatally hampered by the lack of statistics quantities of pathogens and durations of exposures to biological agents, in constrast to what one finds in the nuclear and chemical industries. Furthermore they proliferate: The release of even a minute quantity of a virus (most notably RVFV) could provoke a full scale epidemic.

4-3 The RA report does admit its own limitations : “Therefore, past BSL-3 and BSL-4 experience was used to support the RA whenever appropriate, but they are not suitable for quantitative use.”

1.28 { 4-4 There is a strong emphasis on “biocontainment” throughout the report. However, this must depreciate and certainly cannot last forever. I have not yet found any discussion of the decommissioning which must occur after 50 years

4-5 In this report we are often reminded that the exposure and impact criteria are based on the DOE NEPA Guidelines (DOE 2002). One must keep in mind that

- (a) Energy is a different subject with its own concerns
- (b) 10 years have passed since then

Letter 1
Roy Lisker

- 1.26** This comment is outside the scope of the Draft Supplementary Risk Assessment.
- 1.27** The definition of maximum reasonably foreseeable was adapted from the definition provided in the Department of Energy (DOE) NEPA Guidance. The pathogen quantities presented in Appendix F.3 of the Draft Supplementary Risk Assessment are the best available prediction of future inventories and they were reviewed and agreed upon with the Blue Ribbon Panel and accepted by the National Research Council. Regarding the duration of exposure, each receptor is assumed to be present for the time it takes for the plume to travel past them. As discussed in Section 4.2.4.2.1 of the Draft Supplementary Risk Assessment, “This is an extremely severe scenario that is extremely unlikely to occur and whose airborne releases are highly unlikely to be exceeded.” Smaller releases are expected to result in correspondingly fewer direct impacts. In terms of pathogen propagation, persistence in the environment is addressed in Chapter 7 and person-to-person secondary transmission is addressed in Chapter 9.
- 1.28** Decontamination of the facility was discussed in Appendix A.6 of the Draft Supplementary Risk Assessment. Biocontainment facilities are routinely taken out of commission for preventive maintenance, equipment re-certification, and upgrades. Decontamination, performed by authorized individuals, uses validated processes to effectively sterilize and/or disinfect the laboratory space, rendering its occupancy status biologically safe without personal protective equipment. These actions are taken by fully decontaminating the spaces and equipment prior to allowing entry to such spaces. All surfaces in the high-biocontainment laboratories were designed and constructed to be easily cleaned and decontaminated, with seams, floors, walls, and ceiling surfaces all sealed to facilitate fumigation and to be resistant to liquids and chemical used for cleaning and decontamination. When the facility has reached a point in future where it is no longer necessary, it will be decontaminated and returned to other uses. The Boston Public Health Commission reviews and approves the removal of space from use as high-biocontainment facility.

4-7 The assignment of statistical categories is very controversial. These are

A: Events one should assume will occur within the 50 years of the laboratories operation

B. Groups of those events which are likely to occur, with the occurrence of any specific event being less (100 to 10,000 years) This is impossibly vague.

C. Combinations of events which it is not reasonable to assume would occur, but which are reasonably foreseeable, though one cannot say which ones (10,000 to 1 million) Statistical double-talk

D. Not reasonable foreseeable (more than 1 million years). My objection here is to wonder if we really know enough, given the short amount of time such laboratories have been in operation, to confidently make the prediction that some events would not occur even once in a million years

4-9 Here the tables begin. As one must assume good faith on the part of the people who have prepared this report, I will not enter in a minute criticism of each category and each entry. This can, and should be done by more specialized monitors. I do wonder, however that, for example, in the category of "liquid waste release", the cell for animal wastes is left blank.

4-21 *With respect to exposure levels for facility workers, to centrifuge aerosol releases, it is stated*

Facility worker: No reasonable mechanism for exposure of facility worker was identified and the facility worker exposure category for a centrifuge aerosol release event is NONE

Objection : Who cleans up after the "event"? Isn't it the janitors and cleaning staff?

Letter 1
Roy Lisker

This includes a review of results of the decontamination to prove that the space and equipment have been properly decontaminated.

1.29 Data limitations are discussed in Section 4.1.2.2.4 and in Sections F-2 through F-4 of Appendix F of the Draft Supplementary Risk Assessment. As explained in these sections, these limitations are addressed by using comparisons with events in other industries, use of judgment, and use of the higher frequency category when there is a question regarding which of two categories should be selected. Additionally, the Variability and Uncertainty discussion at the end of the section for each event in Appendix F addresses these and other factors for an overall assessment. The general conclusion for each event is that the analysis tends to be more conservative.

1.30 It is assumed that the commenter meant “animal-related” rather than “animal waste.” The “animal-related” route of exposure was considered to be directly related to the animal, such as bites or scratches. The liquid waste system includes wastes from various sources so it is not directly associated with animals. As shown in Tables 4-5 and 4-6 of the Draft Supplementary Risk Assessment, this candidate event group would not have been selected for analysis even if the indirect animal effects were included here.

To clarify, Section 4.1.2.2.1 of the Final Supplementary Risk Assessment has been revised to read “*Animal-related exposures are those exposures resulting from contact with infectious animals. These exposures could occur via animal bite, scratch, or airborne dispersal of infectious particles.*”

1.31 All spill clean-up at Boston University laboratories is conducted either by the trained researchers with appropriate personal protection, Environmental Health and Safety (EHS) Staff or trained contractors supervised by EHS. No janitorial or housekeeping staff is allowed to perform such tasks.

1.32

Page 4-27 It seems to me that the discussion of the possible consequences of a major earthquake is very inadequate. Such an event of necessity triggers multiple secondary disasters, which can be even more severe than the event itself. For example:

- a. Collapse of neighboring buildings
- b. Fires
- c. Public panic
- d. Panic within the facility that could seriously delay the time for laboratory and facility workers to escape the building
- e. Break-down of evacuation plans
- f. Traffic jams
- g. “Needlesticks” and other wounds, bruises and injuries caused by the sudden impact of the earthquake
- h. The fact that, given the potential seriousness of outbreaks of disease from this laboratory, fire trucks, ambulances, rescue squads, National guard and police will be diverted from the rest of Boston to concentrate on this area, thus causing severe deprivation of these services to other neighborhoods.
- i. No one imagined that the World Trade Center would collapse until it was actually attacked.
- j. Tsunamis coming in from Boston harbor
- k. Aftershocks

4-34 to 4-40 Tables of data. I assume these are accurate, but they should be checked by specialists and experts

General observation: There appears to be a lack of imagination in these scenarios and their associated estimates. Even disaster movies show more of a sense of the unforeseen possibilities than one finds in this report. The line of demarcation between “reasonable” and “unreasonable” is important, but it is a very fuzzy grey area, not a sharp boundary.

Letter 1
Roy Lisker

- 1.32** The earthquake events were defined to result in the maximum direct public consequences as a direct result of the NEIDL facility (see Appendix F.8.3.1.1). The analyses were performed consistent with accepted guidance and practice (see Section 4.2.4.2.1) and included numerous conservatisms (see Appendix F.8.3.6).

The specific comments are addressed below.

Items a-c: These impacts are likely to be more severe than the impacts due to pathogen releases. However, these impacts would occur independent of the presence of NEIDL and, therefore, should not be included in the assessment of the impacts of the NEIDL. To clarify this, page 4-27, has been revised to read "...earthquake. *While there may be many earthquake-related impacts such as building collapse and fires associated with neighboring buildings, this analysis only addresses NEIDL-related consequences because the non-NEIDL impacts are not directly related to the action being evaluated herein.* The initial conditions..."

Item d: This scenario was defined to result in the maximum direct public consequences (see Appendix F.8.3.1.1), which is the primary focus of this risk assessment. Pathogens are assumed to be released from the facility promptly because retention inside the facility would result in lower public impacts due to biological decay and the reduced exposure levels resulting from a gradual release.

Item e-f: In this analysis, no credit is taken for evacuation, so delays in evacuation will not affect the results.

Item g: There are numerous potentially severe impacts to workers as a result of the earthquake, but as discussed for Item d above, this analysis focused primarily on direct public exposure.

Item h: DOE NEPA Guidance (DOE 2002) cautions against consideration of impacts that are speculative. Consideration of how emergency resources might be allocated and the resulting incremental

Installment 4: Appendix F, part 1 (pages 1-44)

1.33

General remarks. In reading the various chapters of this report, certain things stand out

To begin with, there is no mention of costs. This may not appear to be directly relevant to safety, but it becomes very important when one considers how pointless it is to talk about alternative sites for the NEIDL in Tyngsboro and Peterborough, when the government has already invested \$200,000,000 in building the laboratory in Roxbury. The probability that there would be any recommendation after the hearings on April 19 that the plant which has already been built be demolished, and that another \$200,000,000 be invested in a new plant in Peterborough, is less than the probability that there would be an exposure incident involving Ebola virus in a million years.

This being the case, the whole procedure begins to take on the characteristics of a farce. Why has so much money and labor been invested in working up the statistics for safety precautions in Tynborough and Peterborough, while no effort is being made in finding out where to find the hundreds of millions of dollars needed to build laboratories in these places? It's just nonsense. I have therefore decided to ignore all of the impact assessments and calculations of risk and feasibility connected with these locations.

1.34

The purpose of the April 19th hearing then reduces to a simple all-or-nothing proposal: either the BUMC laboratory will become available for research at the BSL-3 and BSL-4 levels, or such plans will be abandoned and the building converted to other uses. Since I feel that there is no need for another BLS-4 laboratory, particularly in the Greater Boston area, I personally would applaud this outcome as a good thing.

However what I have discussed is only one dimension of the whole issue of costs. There are many indirect costs which would affect the population of the district around the plant that must also be looked at

Letter 1
Roy Lisker

consequences is considered speculative and, therefore, is not included in the scope of this analysis.

Item i: Appendix F.9 analyzes aircraft crash. The Maximum Reasonably Foreseeable (MRF) earthquake includes total building collapse, which envelopes any impact from an aircraft crash.

Item j: Other natural phenomena were considered and the basis for not analyzing them in detail was presented in Table 4-6 of the Draft Supplementary Risk Assessment. Tsunamis (which are part of the “Other Natural Phenomena Hazards”) were placed in the same frequency category but their consequences are considered comparable to or less than those of an earthquake. Therefore the earthquake was selected for analysis.

Item k: The MRF earthquake is an extremely severe event and aftershocks would not result in greater consequences.

- 1.33** This comment is outside the scope of the Draft Supplementary Risk Assessment.
- 1.34** This comment is outside the scope of the Draft Supplementary Risk Assessment.
- 1.35** Boston University Public Safety and Environmental Health & Safety offices have staff that is trained to respond to emergency incidents including staff assigned exclusively to the NEIDL. Additionally, the Boston University Police Department (BUPD) has approximately 50 police officers dedicated to the campus. BUPD’s 50 police officers have primary jurisdiction over the campus, including the NEIDL facility. The BUPD is supplemented by armed public safety officers and non-sworn security officers. The BUPD officers are also trained to operate within health care and biomedical research facilities. The operation of the laboratory does not require the deployment of any routine security resources from the City and Boston University continues to work with the City on emergency response coordination issues for those occasions, campus wide, that require city resources.

- 1.35 { (1) The deployment of major security resources in and around the neighborhood of the plant is bound to deplete the current resources (police, fire, medical, military, etc.) available to the city of Boston
- 1.36 { (2) Quite apart from any real dangers, the neighborhood will become further stigmatized as a dangerous one, beyond the current impressions maintained by the general public
- 1.37 { (3) Further infrastructure will have to be built to guarantee the safe transportation of pathogens to the laboratory, and the safe disposal of wastes. This money could be better spent in building up the human infrastructure of the neighborhood
- 1.38 { (4) The area comprised by Cambridge, Boston and surrounding suburbs contains the highest density of top scientific minds in the country. It also has a huge student population, idealistic, intelligent and willing to take on difficult political struggles.
This means that lawsuits, challenges, protests and opposition will always be fierce in this particular region, costing huge amounts in legal proceedings, hearings, reconstruction, re-siting, etc. Would it not have been more sensible to have located the NEIDL in a backward area filled with poorly educated people who would not be likely to realize the negative impact of its presence? This is perhaps a bit tongue-in-cheek, because I am very happy that there is such resistance. But it is difficult for me to understand why Boston University should have made such an unwise decision from their point of view.
- 1.39 { (5) At the present moment it is difficult to imagine why any terrorist organization would want to launch an attack on Roxbury. Once this plant is fully operational however, it will immediately become high on the list of possible targets for terrorist initiatives. Today the neighborhood is poor, but it is not under the cloud of any threat from the outside. This will change if BLS-3 and BSL-4 research is being pursued at NEIDL.

Letter 1
Roy Lisker

- 1.36** This comment is outside the scope of the Draft Supplementary Risk Assessment.
- 1.37** The transportation of pathogens is currently being conducted routinely across the country and internationally. There are strict regulatory requirements imposed by the US Department of Transportation as well as Boston Public Health Commission amongst many agencies. The transportation of pathogens will not require any additional infrastructure.
- 1.38** This comment is outside the scope of the Draft Supplementary Risk Assessment.
- 1.39** A threat assessment was developed as a separate component of the Draft Supplementary Risk Assessment in response to concerns raised by the public regarding the capability of the facility's security systems inclusive of security/law enforcement personnel, electronic systems, policies, and procedures in place to prevent, withstand, or respond to a malevolent action (e.g., disgruntled or unbalanced lab worker, insider threats, terrorist action) against critical systems and assets at NEIDL that could result in the exposure of personnel or release of a pathogen into the community. (Chapter 6, Section 6.1.1) Because the analysis contains sensitive information, the threat assessment is a confidential/official use only document. Additionally, a threat assessment for select agents requires the plan to be reviewed annually and revised as necessary. Drills or exercises must be conducted at least annually to test and evaluate the effectiveness of the plan. Both Boston University and NIH security personnel have reviewed the analysis and conclusions of the threat assessment.

1.40 { **In conclusion, I am quite surprised that a huge document of 1,756 does not devote any of its pages to the direct and indirect financial costs, to the people of Roxbury, Boston or the United States.**

Page F-1 Event Sequence Analysis. The list of topics to be covered include:

1.41 { **-Airbourne dispersion analysis . No mention of waterbourne dispersion analysis or dust dispersion analysis**

-Population estimates. Because, in biological disasters such as epidemics, one must take into account infection, propagation and transmission, these are of necessity fuzzy boundaries rather than precise statistical margins

1.42 { **-The candidate events resulting in a potential loss of bio containment. "Earthquake" has been chosen, though the Boston area is not noted as being earthquake-prone. Violent weather events, such as hurricanes and floods are very much more likely, but not once considered. It is true that Peterborough is described as the greatest flood disaster area in New England. But since the very consideration of alternative sites is fatuous, this has little bearing**

1.43 { **-Airplane crash. A crash into the building is essentially one form of "bombardment". Would it not have made more sense then just to consider "bombardments"?**

1.44 { **F-2 It is admitted that DOE recommendations for analyzing human health effects are limited to exposure to radiation and chemicals. Why then it is stated, without supporting evidence, that these are also relevant to pathogen exposures?**

F-3. This page is to be commended for its honesty. Five serious limitations to identifying the frequency of critical events are listed and acknowledged:

- (1) historical data don't reflect features in place at the NEIDL**
- (2) Fear of reprisal inhibits the reporting of incidents**
- (3) Source of exposure for the majority of laboratory related incidents (82%) is not known**
- (4) The number of operational hours associated with reported incidents is not known**
- (5) Descriptions are not given in sufficient detail**

Letter 1
Roy Lisker

- 1.40** The economic impact of the operation of the NEIDL on the surrounding community is outside the scope of this document. However, these impacts were described in detail in the NIH Final Environmental Impact Statement for the Boston University NEIDL. That analysis showed that there would be no significant adverse economic impacts to the surrounding community as a result of the construction and operation of the NEIDL.
- 1.41** Prompt public exposure due to waterborne dispersion is much less likely than airborne dispersion because people will not be ingesting raw water but they will be inhaling air. Therefore, airborne dispersion analyses were performed but waterborne dispersion analyses were not performed. Exposure due to long-term pathogen persistence in water is addressed in Chapter 7.

The airborne dispersion addresses dispersion of particulates, including dispersion of “dust.” Re-suspension of particulates is addressed by conservatively excluding depletion of the plume by deposition.

- 1.42** Appendix F.8.3.1.1 of Appendix F of the Draft Supplementary Risk Assessment explains the reason that an earthquake was selected over other natural phenomena events. Violent weather is included in the "Natural Phenomena Hazard-tornado and strong wind" and "Natural Phenomena Hazard-Other (flooding, snow, etc.)". These Natural Phenomena Hazard events are in the same frequency category as the as Natural Phenomena Hazard-earthquake, but their consequences are less than or equal to the consequence of an earthquake. Violent weather, including hurricanes, results in much greater mixing of the air, which results in much lower exposure levels. Therefore, an earthquake was analyzed because the frequency categories are similar but the consequences are greater.

- 1.45 { **F-6. Among the administrative controls “training” is listed. No mention of the average period between re-trainings**
- 1.46 { **In the catalog of items of safety equipment, there is no mention of waste disposal**
- 1.47 { **F-9 Item 14 of the list of biocontainment features mentions alarms and communication systems inside the laboratory. No mention of alarms and communication systems in the surrounding neighborhood, or on the large super-highways of the “Massachusetts Connector”**
- 1.48 { **F-15 Working Stock. There is a tendency here to quote “average concentrations”. For example, there is this quote: “Active research is likely to be collected on only a fraction of the viruses at any given time..... the instances at which a working stock exceeds 150 ml are roughly offset by the times when the working stock is less than 150; therefore the average volume is about 150ml**
- (a) **How could such a statistic be derived for research that has not begun?**
- (b) **Crises and disasters do not happen under average conditions but under singular conditions. Thus, it does not restore ones confidence to know that conditions “on the average” are safe. That’s true almost every at most times.**
- 1.49 { **F -17 Infected Animals.**
- Here there is no mentions of the means by which animals could infect human beings:**
- (1) **Scratches**
- (2) **Bites**
- (3) **Wastes**
- (4) **Diseases which do not come from the research**
- (5) **Hostility**

Letter 1
Roy Lisker

- 1.43** The most likely reasonably foreseeable unintentional “bombardments” capable of compromising the facility are aircrafts.
- 1.44** There is a supporting evidence for this assertion. Page F-2 of the Draft Supplementary Risk Assessment contains a direct quotation from the National Research Council, and reads in full: “*U.S. Department of Energy’s (DOE) recommendations for the preparation of EISs contain some of the most detailed explanations and guidelines for discussing human health impacts in an EIS. Although DOE’s recommendations for analyzing human health effects are limited to exposure to radiation and chemicals, they also are relevant to pathogen exposures.*”

The major difference between chemical, nuclear, and biological laboratory accident analyses is the potential replication of pathogens. This difference is taken into account in the secondary transmission analyses (see Chapter 9) and in Chapter 7 for persistence in the environment.

- 1.45** The Draft Supplementary Risk Assessment provides information on the training program for the NEIDL. For example, section 2.1.4.3 states that “Boston University Medical Campus provides annual laboratory training as a minimum standard and increases training frequencies depending on the type of work being done and materials used in each laboratory”. The OSHA Bloodborne Pathogen Standard and CDC Select Agent and Toxin regulations, as well as those of Boston Public Health Commission, also require refresher training annually, or when there is a change in the risks associated (e.g. deployment of new procedures, equipment, and/or agents) with the operation of the laboratory. Appendix F.2 states that “[t]he training requirements for NEIDL laboratory workers are outlined in the BUMC Biosafety Manual Appendix F for BSL-3 and Appendix G for BSL-4. This training program educates employees about the hazards to which they might be exposed and instructs them on the proper protocols to be used for safe operation of the NEIDL.” Section 2.1.4 of Chapter 2 provides additional details on administrative controls.

1.50 { **F-24 Vehicle Occupants. I see no discussion in this part of the report, on the population density of the vehicular flows along the large highways that bound the southern rim of the NEIDL. These figures are bound to be much higher than the “national average occupancy ranges” (1.12 for trucks, 2.35 for vans)**

1.51 { **F-28. There is a site map on this page, with legends that are virtually unreadable. However the Massachusetts Avenue Connector is clearly shown as *going directly south* of the NEIDL! In addition to the potential harm to the occupants of the vehicles, they could continue on Interstate 695 and carry disease all across the city and state.**

1.52 { **Figure F.4-2 appears to be missing from the text**

F-30 to 44 For reasons stated above, I am not examining the data on the rural or suburban sites. They serve as an embarrassingly transparent smokescreen.

General Observations

In the course of selecting and studying various sections of the 1,756 page Risk Assessment report, I’ve built up a picture of how Boston University has proceeded in this project, and how it intends to continue. In a few words I find its method of proceeding totally incomprehensible.

1.53 { **(1) The need for a new BSL-4 laboratory in the United States is debatable. Granted that, after 2003, federal money became available for the construction of 6 new facilities, the big universities would compete for their part of the share. A more astute administration might have perceived that, once the hysteria surrounding the 9/11 attacks had died down, the demand for these facilities would have also diminished, leaving Boston University with a white elephant that would, for the most part, sit idle until it was time to be demolished. The projected lifetime for the laboratory is only 50 years**

Letter 1
Roy Lisker

- 1.46** As stated in Appendix F.2 of the Draft Supplementary Risk Assessment, this list identifies the “biocontainment features that play a key role in these analyses...” The waste disposal systems do perform a biocontainment function.
- 1.47** The alarms and communication systems described in the risk assessment are requirements of the laboratory design and are intended to allow for communication and notification of events within the facility. In the event of an incident at the NEIDL, the Boston Public Health Commission, as the lead agency, will be notified and they will coordinate any notification through the mayor’s Office of Emergency Preparedness, which is responsible for administering the emergency management activities for the City of Boston.
- 1.48** The pathogen quantities presented in Appendix F.3 of the Draft Supplementary Risk Assessment are the best available prediction of inventories and they were reviewed and agreed upon with the Blue Ribbon Panel and accepted by the National Research Council.

The rationale for use of the 150 mL typical volume is presented in Appendix F.3.3.3 of the Draft Supplementary Risk Assessment. The suggestion of using the maximum volume is not consistent with guidance, which recommends using a bounding scenario (e.g., the most severe earthquake) with median factors (Appendix F.8.3.4). Use of a bounding scenario in conjunction with bounding values would result in an unrealistic analysis that would result in misleading results.

- 1.49** Appendix F.3.3.4 of the Draft Supplementary Risk Assessment presents the inventory of animals. Appendix J.2.2 provides the definition of animal-related exposures and lists some of these conditions.

1.54

- (2) **Once Boston University had received its grant to build the NEIDL, it is very difficult for me to understand why it would then choose to locate the plant right in the downtown of a major American city. Clearly, no matter how slight the risk of a serious pathogen release, locating the laboratories in Boston would so magnify the dangers to a very large population as to turn a serious emergency (for example, the release of poison gas in the Dugway sheep kill of 1968) into a world level catastrophe. The consideration of convenience of placing the NEIDL on the grounds of the Boston University Medical Center could scarcely overshadow the risks to the populations of a major city, the cloverleaf Massachusetts Avenue Connector highways and the immediately adjacent neighborhoods of Roxbury and the South End.**
- (3) **Beyond that, Boston is not only a major city. It is the center of a hub of scientific research centers and educational institutions without parallel in the world. How could the administrators at BU have imagined that there would be no organized resistance to this plan, nor that it would swell to the level it has reached today?**

Letter 1
Roy Lisker

- 1.50** No road-specific occupancy rates are available, so national average values were used. As discussed in Appendix F.4.3.5 of the Draft Supplementary Risk Assessment, uncertainty associated with the vehicle occupancy value will have a minor impact because: 1) there are large conservatisms in the vehicle count estimates (based on busiest highways) which would compensate for any potential non-conservatism and 2) the population in vehicles is a small fraction of the total population (see Table 4-16).
- 1.51** The potential for infection of vehicle occupants is addressed directly (see Section 4.3.3.4 of the Draft Supplementary Risk Assessment for population estimates). Appendix L.2.5 (Effect of Commuting) of the Draft Supplementary Risk Assessment addresses the potential effects of infected individuals traveling outside the city.
- 1.52** The Figure labeled F.4-1 in Appendix F.4.3.3.1 of the Draft Supplementary Risk Assessment has been changed to Figure F.4-2. This change is reflected in the Final Supplementary Risk Assessment.
- 1.53** Please see response to comment 1.3.
- 1.54** NIH provided partial funding for the construction of the NEIDL based on the project's scientific and technical merits. The decision to fund this project was made after a rigorous scientific peer review that evaluated several factors. These factors included the technical merit of the Boston University Medical Campus's application; the scientific expertise of the proposed NEIDL staff; and the Boston University Medical Campus commitment to regional research collaborations. A key strength of the Boston University Medical Campus application was that the NEIDL would be close to a large and renowned community of infectious disease researchers. Prior to construction, NIH and Boston University Medical Campus conducted several studies on the safety and siting of this facility. NIH began by preparing a report evaluating the potential environmental impacts of the NEIDL. The report was prepared in accord with the National Environmental Policy Act (NEPA).

1.55

(4) It is also very difficult to understand how the comparative examination of 2 alternate sites (clearly a requirement for a federally-funded project of this magnitude) was not made at the beginning, that is, before spending \$200,000 on the current laboratory! Holding a hearing to examine the comparative merits of these sites is so patently ridiculous that it amazes me that it has been proposed with a straight face, and that the NIH has compiled a 1,756 page draft report to address this proposal!

1.56

(5) Summarizing, one comes away with the impression that Boston University has, right from the beginning, blundered and bungled every aspect of this project. It first tried, in 2004, to foist the laboratory onto the city without consulting anyone. They were caught by, among other agencies, the Committee for Responsible Genetics at Tufts University, the ACE and other grassroots organizations.

It then followed up this essentially illegal action by making all sorts of promises that it had no intention of fulfilling, such as additional jobs for the residents of Roxbury, clinics to treat victims of serious epidemics (strictly ruled out by the terms of the NIH grant) and so on.

Letter 1
Roy Lisker

Public input was sought and considered multiple times before the report was finalized in the Final Environmental Impact Statement. This analysis determined that the facility posed a negligible risk to the surrounding community.

- 1.55** NEPA and the implementing Council on Environment Quality regulations require Federal agencies to analyze reasonable alternatives to a proposed action, including the no-action alternative. The NIH's Final Environmental Impact Statement for the Boston University NEIDL analyzed fully the potential impacts of the NEIDL at the current location in Boston and the no-action alternative. The Final EIS also identified two additional alternative sites. These sites were identified as potential alternatives to the proposed action but, upon further study, were found to be unsuitable and were eliminated from further study.
- 1.56** This comment is outside the scope of the Draft Supplementary Risk Assessment.

1.56

Then it proceeded to build the laboratory without bothering to make the comparative assessment that is to be “debated” on April 19th. Every single thing it has done indicates a policy of continually pushing its intentions, plans and building activities onto the city in the hope that it won’t be caught, with little attention to following procedural guidelines prescribed by law.

The result seems to have been a catastrophe for BU, but perhaps a good thing for the country. By stumbling over itself time and again, BU has strengthened the hand of the growing opposition to such an extent that there is a good chance that the NEIDL will never be used for BSL-4 research, or even for BSL-3 research. Let’s breather a sign of relief: what is the waste of \$200 million taxpayer dollars relative to the potential extermination of Greater Boston by epidemics of Biblical proportions?

Chapter 6: Threat Assessment

1.57

This is the slimmest chapter of all in the 1756 page report, a mere 19 pages. This is consistent with the general tone of the RA, which is focused on Biosafety, with relatively little on Biosecurity, and nothing at all about cost effectiveness.

1.58

Page 6-1 There are numerous reasons why people might be inspired to commit malevolent actions, but the RA lists only 3: disgruntled lab worker, unbalanced lab worker, terrorist action. The words “terrorist action” for example, covers a wide range of motives, resources and strategies. A member of PETA might decide to free the lab animals; or simply conceal cameras to film activities that could disgust the general public; an angry driver on the highway might ram a truck delivering pathogens to the lab, without realizing that his “road rage” could ignite a biomedical disaster; a paramilitary operation could surround the entire 7 story building, holding everyone hostage and causing a shootout that could, in theory, shatter glassware holding infectious germs.

Letter 1
Roy Lisker

1.57 Please see response to comment 1.39.

1.58 Please see response to comment 1.39.

- 1.59 { Some of these scenarios are fanciful, others less so. The point is that, in a document of 1756 pages, biosecurity deserves more than a barren 19 page sketch.
- 1.60 { Page 6-3 Equation: $Risk = Px C$. Are we expected to take this seriously?
- 1.61 { 6-5: The CAP Index Analysis measures the “criminality” (whatever that is), of a particular context, neighborhood, municipality, etc. I suppose that one ought to consider the “statistics of street crime” in Roxbury, in comparison to the same things in Tyngsboro and Peterborough, but it is hard to see how this has much to do with the real issues of biosecurity at the NEIDL plant. We certainly appreciate the anxieties of the senior researchers who may be afraid of being mugged on the way home at night!
- 1.62 { The rest of Chapter 6 is basically routine, consisting largely of technical definitions, explications of the “philosophy of security”, technical meanings of the words “threat”, “vulnerability” and “security”. The tables merely continue this listing of scenarios, adversaries and so on. What is notable is a lack of concrete applications to the specific situation at the NEIDL or anywhere else.

All of this is consistent with the intention of deflecting attention from “biosecurity” onto “biosafety” as if they were the same thing, which they are not.

Letter 1
Roy Lisker

- 1.59** Please see response to comment 1.39.
- 1.60** *Risk = PxC* is a standard, accepted definition used to express risk as a product of frequency (or probability) and consequence. This definition is used by NASA and DOE amongst other federal agencies.
- 1.61** CAP Index reporting was one of several variables used by the risk assessment threat analysis team to define the threat at each of the three sites.
- 1.62** Please see response to comment 1.39.

Subject: PUBLIC comment ON FEDERAL REGISTER - THE INSANITY AT MANAGEMENT OF NIH - THEY ARE OUT OF THEIR MINDS TO BUILD IN BOSTON WHEN PLUM ISLAND THE IDEAL SITE

2.1

THIS IS A DISPROPORTIONATE RISK FOR LOW INCOME PEOPLE IN BOSTON. I DO NOT FAVOR THIS BUILDING IN BOSTON. NOR DO I FAVOR PUTTING THESE LABS ALL OVER THE USA. THERE IS NOTHING MORE LIKELY TO HAPPEN THAN A PROBLEM CAUSED BY LABS LIKE THIS. USE PLUMB ISLAND SITE. THAT IS A WONDERFUL SITE WITH THE CHARACTERISTICS THAT THESE LABS SHOULD HAVE. BUILD ON THAT ISLAND. STOP THIS CONSTRUCTION ALL OVER AMERICA. THIS AGENCY SEEMS CONSUMED WITH STUPID POLCIES THAT HURT AMERICA. WHEN YOU GO TO OTHER GOVT AGENCIES THEY WILL ALWAYS PRAISE YOUR WORK BECAUSE THEY LOOK FOR QUID PRO QUO FROM YOUR AGENCY. THEY ARE NOT HELPING AMERICA. I AM SURE THE ENTIRE US PUBLIC THINKS THIS IDEA IN BOSTON IS TOTALLY INSANE. OF COURSE, THERE SHOULD BE NO CONSTRUCTION IN BOSTON. PLUM ISLAND IS THERE ALREADY USE IT.

To: Adel A. Mahmoud; Patterson, Amy (NIH/OD) [E]; Shipp, Allan (NIH/OD) [E]
Subject: comment 1 on the draft of the Draft Risk Assessment Report and the Reader's Guide

Adel, Amy, and Allan

I must say that I am greatly disappointed by what I have found during my initial reading of the documents.

- 4.1 { First, the risk assessment, itself, does not appear to contain a summary that is accessible to members of the general public.
- 4.2 { Perhaps, you will argue that the Reader's Guide is intended to provide such a summary, but it was not labeled as such and it is clear that "the NIH is not seeking comments on this guide" (as stated on the Note to the Reader that appears on the first page of this Guide). If the Reader's Guide is intended to provide a summary of the risk assessment, then the NIH should have explicitly requested comments on this Guide.

Perhaps, you will argue Chapter 11 is intended to provide a summary, but it, too, was not labeled as such. In addition, this summary is not written in a style that is more accessible than the remainder of the risk assessment and it is buried at the end of a 1.700 page document where it is unlikely to be seen.

- 4.3 { Second, the substance of the Reader's Guide is presented in a biased manner, to say the least. For example, in the review of the history of the risk assessment process (pages 1-3 of the Guide) there is no mention of the inadequacies of the prior risk assessments. Furthermore, the "Overall Conclusions" reported on page 17 of the Reader's Guide are not supported by the text of Chapter 11 (e.g., the text highlighted in blue on the first page of Chapter 11)

I would appreciate your help in finding the summary of the document, if one is included and subject to comment.

thank you

David

Subject: Boston NEIDL bio-lab

My family lives in the Boston area.

5.1 { I am opposed to the proposed opening of a BSL-4 lab in a densely populated area in a city which has no evacuation plan in case of an accident.

I believe they have yet to submit an acceptable risk assessment study.

5.2 { Why the need for yet another BSL-4 lab when there already is one in Maryland, Georgia and Texas?

5.3 { No one has talked (to my knowledge) about the "need" for more BSL-4 labs. Why can't they just expand the ones they already have?

I stand opposed to the opening of yet another BSL-4 lab, and especially in a densely populated neighborhood.

Sincerely,

A. W

Letter 5

A. W.

- 5.1** The containment of an infectious disease relies on early diagnosis and treatment and reducing the spread of the infection by preventing contact between the infected individuals and the community. This is accomplished by asking those with an infection to stay in their homes (sometimes referred to as quarantine or shelter-in-place). Evacuation is not part of a typical public health response to an infectious disease. Boston Public Health Commission's Infectious Disease Bureau is the public agency that makes decisions about management of infectious diseases. Their mission in part is to "reduce the impact of infectious diseases, prevent the morbidity associated with these diseases, and create healthier lives for the residents of Boston". The Office of Emergency Management is responsible for coordinating all emergency management and homeland security programs for the City of Boston.
- 5.2** In early 2002, NIAID, the lead NIH institute for infectious disease research, developed the *NIAID Strategic Plan for Biodefense Research* which outlines plans for addressing research needs in the broad area of bioterrorism and emerging infectious diseases. In February 2002, NIAID convened a Blue Ribbon Panel on Bioterrorism and its Implications for Biomedical Research which provided an objective assessment of the *NIAID Strategic Plan for Biodefense Research*. The Panel's findings became the *Biodefense Research Agenda for CDC Category A Agents* and the *Biodefense Research Agenda for Category B and C Priority Pathogens*. These research agendas identified a need for research resources to facilitate basic and applied BL3 and BL4 research towards development of: tests to rapidly diagnose, vaccines and immunotherapies to prevent, and drugs and biologics to treat diseases caused by agents of bioterror and other emerging infectious diseases that pose a potential threat to public health. Overall, the NIAID biodefense strategic plan and research agendas reflect a broad vision not only to conduct innovative and critically needed biodefense and emerging infectious disease research, but also to develop a research infrastructure with the breadth and

Letter 5

A. W.

flexibility to respond to ever changing infectious diseases research needs, including those that could be posed by public health emergencies such as a bioterror event or infectious disease epidemic or pandemic. One of the critical resource needs identified in the planning process was biocontainment laboratory space in which high-priority government-supported research on biological agents could be safely conducted.

Subject: Boston NIDL public comment meeting 4/19/12

Dear NIH Blue Ribbon Panel,
I'm writing to provide what input I can for the public comment period.

First, please let the NIH rep who moderated the 4/19 meeting know he did a very good job. I'm sorry he was subjected to so much ire, but he handled it with grace.

1. I am very much in favor of the NIDL facility opening for BSL 4 work. I believe the facility creates opportunities for tangible and important work in public health with pathogens that stand to impact large populations, including in the US.

6.1

2. I'm disappointed with the poor job Boston University did in communicating what the NIDL is and what sort of research will be conducted there, however. The majority of the people at the meeting who expressed their views had significant misunderstandings about what research would be performed there and what risks this might pose to them. Several seemed not to understand where the facility was actually located (not in Roxbury)! Unfortunately still others came away with perceptions based entirely on hyperbole shared by the more imaginative participants. A one on one conversation with any of the researchers working there would most likely have assuaged the concerns of many participants, but such a format is not likely to happen.

6.2

3. I know the NIH is trying to clean up the mess, but some participants correctly noted that BU no longer seems to be interacting with the community. It is worth pointing out that many students and researchers affiliated with the NIDL have attended these meetings, including tonight's, but have been extremely reluctant to comment. This is understandable given the very high level of aggression directed at anyone who identifies themselves as being in favor of the NIDL fully opening, and especially affiliated with BU Microbiology. I am not affiliated with BU, but felt extremely unsafe after the group of BU grad students I was sitting next to was 'outed' by a community organizer (Claire). Because I was sitting next to them I was verbally attacked and felt threatened on my walk home (within 2 miles of the NIDL, by the way). Given the great anger and extreme misperceptions held by some anti-NIDL participants and their calls for escalation, I think it is very reasonable to feel ill at ease about commenting favorably. I can only imagine how other proponents feel at these events, but suspect that any "pro" voices are very underrepresented for this reason. I'm not sure what the solution to this issue is, but hopefully more comments received my mail or phone help represent this group.

Thanks for taking the time to read all this.

Cheers, Evan Howard

April 13, 2012

To Whom It May Concern:

I am writing to you on behalf of the Kenmore Association in support of the National Emerging Infectious Diseases Laboratories (NEIDL) at Boston University, and in support of the Draft Supplementary Risk Assessment findings. We are convinced that the NEIDL can safely conduct research that will not only be vital to the state's biomedical and life science research sector, but also provide significant public health benefits locally, nationally, and across the globe.

We have found the Draft Supplementary Risk Assessment to be a thorough, comprehensive review of the risks associated with the operation of the NEIDL. It is important to note that very conservative assumptions were used to analyze the likelihood of an incident. The scenarios modeled are realistic, and the analyses and conclusions presented show that the potential risk posed to researchers or local residents as a result of the NEIDL's operation is extremely low to beyond reasonably foreseeable; for example, the likelihood of infections from a release of 1918 H1N1 influenza or SARS might occur perhaps over 500–5,000 years of operation, but that range is far beyond the facility lifetime of 50 years. The Risk Assessment's detailed explanation of the facility's safeguards, including its state-of-the-art air filtration systems and redundant operating systems, security systems, and safety procedures, provide adequate evidence to support this claim.

It is clear that the NIH has been very thorough in its evaluation of the potential risks associated with this facility. We were encouraged by the NRC's determination that this draft Risk Assessment is scientifically sound and credible and a substantial improvement over the previous documents.

After an unprecedented amount of review and years of delay, it is now time for the NIH to approve the NEIDL and for the lab to commence full operations. The Kenmore Association supports the findings of the Draft Supplementary Risk Assessment, and hopes that the NEIDL will soon be able to embark on its mission to conduct cutting-edge scientific research.

Sincerely,

Pamela G. Beale

Attn: NEIDL Risk Assessment

To Whom It May Concern:

I am writing in support of Boston University's (BU) National Emerging Infectious Diseases Laboratories (NEIDL) in Boston's South End. I believe the National Institute of Health's Draft Supplementary Risk Assessment verifies that BU has the expertise and proper security measures currently in place to safely conduct valuable scientific research at this facility.

To assure a comprehensive study, the NIH's Draft Supplementary Risk Assessment uses very conservative assumptions to analyze the likelihood of an incident, and consequently the risk to the community, from conducting biosafety research in the NEIDL. As a resident of the city of Boston, I believe the potential scenarios outlined are credible and realistic and that the NIH incorporated the concerns and input of the community in this report.

The South End of Boston is an appropriate location for the NEIDL as the infrastructure for research is already well established on the BU Medical Campus. The Risk Assessment shows that there are no differences in the risks of infections or fatalities to lab workers at the three different sites analyzed (South End, Peterborough and Tyngboro) and that the potential risk to the community is very small and not significantly different when comparing the locations.

The Risk Assessment also finds that greatest level of risk is to the researchers that would be working in the NEIDL. Given the state-of-the-art safeguards built into the design of the facility as well as the appropriate level of precautions that would be used by researchers, this risk is significantly minimized. I believe that the NIH has provided a detailed and thorough evaluation of the design of the facility and its safety and security systems. I am also reassured by the National Research Council's panel of expert scientists, who conducted a review of Risk Assessment this past December and found its analysis to be scientifically and technically credible.

The research that the NEIDL is hoping to conduct has the potential to discover cures for deadly infectious diseases that can save lives. I am satisfied by the findings of the NIH's Draft Supplementary Risk Assessment and support the full opening of the NEIDL.

Sincerely,

Subject: I challenge the BU Biolab risk-assessment

Dear Friends at NIH,

There are several fundamental flaws in the BU Biolab risk assessment presented April 19th at the Roxbury Community College

- 9.1 { 1. Probabilities are normally based on past experience (the number of hits out of the number of attempts). We have no data or experience of a Level 3 and Level 4 biolab operating in a densely populated area in the United States, because there has not ever been such in place. Therefore, there is no statistical basis for the probabilities given in the report.
- 9.2 { 2. The experience has shown that in the last twenty years there have been notable numbers of life-threatening incidents involving bio-labs. These incidents show that the probabilities are possibly much higher than reported in the NIH study. The ones cited at the hearing, including the anthrax incident, suggest that there is ample room for concern.
- 9.3 { 3. There has been no replication of the modeling by other scientists because the relevant formulas are not given for how the model has been constructed. Probabilities are additive across many possible scenarios, each discrete adverse outcome within the realm of possibility (terrorist attack, deranged employee, equipment malfunction, fire, traffic tie-up and accident, and sabotage to name just a few) should be cumulatively added to form an assessment of risk of a catastrophic event.
- 9.4 { 4. There are other intangible risks not strictly related to catastrophe, but are palpable. Loss of trust in government and educational institutions because of the decision not to hear and respond to community residents is dangerous for the political process. Residents expressed anger and frustration at their apparent powerlessness. These sentiments are part of the risk of arbitrary decision-making.
- 9.5 { 5. There is a risk to inflicting more suffering and environmental degradation in low income neighborhoods adjacent to the biolab. And what does this say about our efforts to do away with environmental racism? Victims are not unaware of the implications of such decisions, given our nation's current deploing of other racist travesties: Native Americans and smallpox, experiments at Tuskegee, sterilization, for example
- 9.6 { 6. Considerable numbers of BU alumni oppose the bio lab, as do a wide network of Greater Boston residents who have petitioned city and town councils against the biolab. The Massachusetts Nursing Association is also opposed to the lab. All of these voices should also be heard.

Thank you for letting us comment. I appreciate the opportunity.

Best wishes,

Alice E. Kiddler, Ph.D. Economics, MIT, 1967

Letter 9

Alice Kidder

- 9.1** As discussed in several locations, including the text box in Section 4.1 of the Draft Supplementary Risk Assessment, the operating experience presented in Appendix D and expert judgment are used for the development of the initiating event frequency estimates and the conditional probability of subsequent events. The frequency estimates for events internal to the facility and for events that result in a release from the facility are only dependent upon the specific operational protocol of the facility and are independent of the surrounding population density. However, the population is taken into account in the evaluation of initial and secondary infections.
- 9.2** Available operating experience was presented in Appendix D of the Draft Supplementary Risk Assessment and was used in the frequency estimates.
- 9.3** The inclusion of cumulative risk was discussed with the Blue Ribbon Panel and excluded from the Draft Supplementary Risk Assessment because analyses were not performed on every potential scenario. Summation of the frequency for those events that were analyzed would present a misleading perspective that we believe would not serve the public interest.
- 9.4** This comment is outside the scope of the Draft Supplementary Risk Assessment.
- 9.5** This comment is outside the scope of the Draft Supplementary Risk Assessment.
- 9.6** Throughout the course of the project NIH has held extensive consultations with the Boston community. During the drafting of the Environmental Impact Statement (EIS) for the NEIDL, public input was sought and considered multiple times before the report was finalized. For the Supplementary Risk Assessment, the NIH Blue Ribbon Panel has held several public meetings to hear the concerns of the community and to solicit feedback on what scenarios and agents the community wished to see analyzed in the document.

Subject: Risk Assessment of the NEIDL at BUMC

To whom it may concern:

I was deeply disappointed in the review of the Risk Assessment presented at the Public Meeting at Roxbury Community College on April 19, 2012. These are some of my concerns:

The fact that there is even a tiny fraction of risk in hundreds or thousands or millions of years is not acceptable if it should happen at all and if it should happen to me.

- 10.1 { I am not satisfied that a malevolent action would not have greater consequences than an earthquake. It is difficult to predict an earthquake, but it is even more difficult to know what might go on in someone's mind if that person is intent on causing harm to an urban population.
- 10.2 { The statement "The inner packaging is expected to withstand any credible vehicle crash" is not at all reassuring. Has it been demonstrated that it is impossible for the packaging to be damaged or destroyed in a credible crash?
- 10.3 { And what about an incredible crash? And what about the theft of the package if it does withstand the crash?
- 10.4 { Locating the Lab in an urban environment means that many people are coming and going in the neighborhood--people living nearby, people visiting, people working--so many people. It makes it harder to notice someone who might have malevolent intent, someone who could blend in with the crowd, making plans, watching for just the right moment to carry out an incredible plan.

I have many more concerns, but I would like to point out in closing that I do not believe you have done your job until you have really gotten to know the neighborhood in which a dangerous infectious lab is to be located. In short, what is really going on here?

Sincerely,

Phyllis J. Miller
427 Marlborough St. #4
Boston, MA 02115-1205

Letter 10

Phyllis J. Miller

- 10.1** As discussed in Section 6.8 of the Draft Supplementary Risk Assessment, the consequences due to malevolent acts that attempt to release pathogens from the building are compared to the potential consequences of accidents; however, malevolent acts that attempt to remove pathogens from the building before exposing the public could not be evaluated. As discussed in Section 6.8, the malevolent act releases are expected to be less than the Maximum Reasonably Foreseeable (MRF) Earthquake releases because the inventory is less, the release fraction is less, and the release is likely to be discharged out the stack.
- 10.2** Section 5.3.2.2 of the Draft Supplementary Risk Assessment does not attempt to “demonstrate that it is impossible for the packaging to be damaged or destroyed in a credible crash.” Instead it states that it is beyond reasonably foreseeable for a crash to occur within the vicinity of NEIDL that results in a pathogen release. This estimate was calculated with two separate techniques and substantiated with historic data.
- 10.3** Theft of a package is a malevolent act and malevolent acts are addressed in Chapter 6 of the Draft Supplementary Risk Assessment, but this postulated scenario was not analyzed. It is beyond reasonably foreseeable that someone inclined to steal and release a pathogen would happen upon a severe crash in the small window of time before the crash scene is secured.
- 10.4** A threat assessment was developed as a separate component of the Draft Supplementary Risk Assessment in response to concerns raised by the public regarding the capability of the facility’s security systems inclusive of security/law enforcement personnel, electronic systems, policies, and procedures in place to prevent, withstand, or respond to a malevolent action (e.g., disgruntled or unbalanced lab worker, insider threats, terrorist action) against critical systems and assets at NEIDL that could result in the exposure of personnel or release of a pathogen into the community. (Chapter 6, Section 6.1.1) Because the analysis contains sensitive information, the threat assessment is a confidential/official use only document. Additionally, a

Letter 10**Phyllis J. Miller**

threat assessment for select agents requires the plan to be reviewed annually and revised as necessary. Additionally, drills or exercises must be conducted at least annually to test and evaluate the effectiveness of the plan. Both Boston University and NIH security personnel have reviewed the analysis and conclusions of the threat assessment.

Comments on the Tetra Tech 2012 risk assessment for the BU NEIDL

Submitted by:
Lynn C. Klotz, PhD

Submitted to:
NIH Blue Ribbon Panel
National Institutes of Health
6705 Rockledge Drive, Suite 750
Bethesda, Maryland 20892
Email: NIH_BRP@od.nih.gov

Dear Blue Ribbon Panel,

I am here submitting my comments on the 90% Tetra Tech 2012 risk assessment (RA90) for the BU NEIDL.

But before I begin, I want to tell you why many of us are frustrated with the process. For years, we have been asking questions and making comments to BU/NIH and, more recently, Tetra Tech. They never answer our questions and they ignore our comments. It is like talking to a brick wall.

11.1

My main comment on the RA90 is that despite the scathing criticism by the NRC of the 2010 Tetra Tech risk assessment, Tetra Tech still does not explicitly take into account the three SARS escapes in its calculations. The RA90 continues to base its risk assessment for SARS and other pathogens on hypothetical scenarios. In my mind, the RA90 is not responsive to the NRC's criticism that Tetra Tech take into account the actual SARS escapes. To be sure, the RA90 does provide a scholarly and thorough discussion of SARS along with the SARS escapes, but ends up dismissing the threat to the public and the pandemic potential of a lab escape.

11.2

My risk analysis for SARS (attached) entitled A More Meaningful SARS Risk Assessment is based on the three escapes and the number of lab-years live SARS has been researched in BSL3 labs; that is, the analysis is based on "real" data. I then calculate the probability of escape over the 50-year lifetime of the BU NEIDL, which is not negligible; and I document the pandemic potential of a SARS escape. I conclude that even a small pandemic risk is too much risk to allow SARS research except under very strict biosafety guidelines that go beyond BSL3 or BSL4. The BU NEIDL cannot hope to meet these biosafety guidelines because of its urban setting, and I expect because of other measures it will not or is unable to agree to.

11.3

Letter 11

Lynn Klotz

- 11.1** NIH has consulted with the community extensively from the beginning of this project. At important milestones, the community was briefed on the progress of the project and community input was sought. The NIH Blue Ribbon Panel also actively engaged the community during this project by holding several public meetings in order to solicit feedback from the public on what scenarios and agents should be analyzed in the Draft Supplemental Risk Assessment.
- 11.2** The three historic SARS incidents referenced in the comment were considered in the Draft Supplementary Risk Assessment (see Table D-6 of Appendix D); however, these foreign incidents were not used to estimate the laboratory-acquired infection (LAI) rates for the NEIDL because they are not directly applicable for SARS research at the NEIDL. The Beijing incident is not applicable because it did not occur in a BSL-3 or 4 laboratory, which would be the case at the NEIDL. The Singapore incident involved a worker with “minimal training,” which is not consistent with the training and certification requirements at the NEIDL. There is insufficient information on the Taipei incident to determine whether their protocols were similar to those of the NEIDL. It should be noted that the recent CDC study of LAI rates (NRC 2011) also excluded these and all other foreign data from its evaluation.

The risk assessment analyses were performed on the basis of NEIDL-specific biocontainment features (see Section F.2), while considering the potential for equipment failures and personnel errors. These NEIDL-specific protocol (e.g., use of hooded PAPR for all BSL-3 activities) dramatically affect the outcome of mishaps and must be considered for a relevant analysis. Use of data that are based on different biocontainment features would result in different results that are not predictive for the NEIDL. The NEIDL-specific results are summarized in Table 11-6c, which reports the frequency of public infections due to an undetected/unreported needlestick (urban site) for the relevant pathogens, for example 1 in 760 to 27,000 years for SARS.

.”

I list briefly below two other shortcomings of the RA90:

- 11.4 { ➤. LAIs are the most frequent route for escapes of pathogens from labs (e.g. the three SARS escapes). The RA90 does not consider LAIs followed by lab escapes for any pathogen as one of its Candidate Events in its Table 4-4. How could they avoid analyzing the most frequent cause of lab escapes?
- 11.5 { ➤. While Table 4-4 does list “punctures” and “pathogen not inactivated” as candidate events, the table explicitly claims the public is not an exposed group. Again, punctures and not deactivating pathogens have led to LAIs with infected workers leaving the laboratory and potentially exposing the public (e.g., failure to inactivate is the reason for the secondary infections in the SARS lab escape in Beijing).
- 11.6 { What exactly is Tetra Tech’s role? They appear not to be neutral risk analysts. Biosafety risk analysis is an activity where neutrality is vital because lives are at risk.

Sincerely yours,
Lynn C. Klotz, PhD

Letter 11
Lynn Klotz

- 11.3** Please see response to comment 11.2
- 11.4** The centrifuge event described in Section 4.2.2) and the needlestick event described in Section 4.2.3 both involve laboratory acquired infections that are undetected or unreported (i.e., “escapes”).
- 11.5** As stated in section 4.1.3.1 and in the reference to Table 4-4 of the Draft Supplementary Risk Assessment, these are “candidate initiating event groups.” The “puncture” and “pathogen not inactivated” events can only expose the public via a laboratory acquired infection, which makes the exposure a secondary event. Since public exposure is not a result of the initiating event, it is not included in this table. However, the potential for public exposure is included in the analysis of events selected for analysis (e.g., the needlestick).
- 11.6** Tetra Tech is an independent consulting company that was hired by NIH to perform a supplementary risk assessment for the NEIDL. Tetra Tech has no personal or financial interest in the outcome of the supplementary risk assessment.

A More Meaningful SARS Pandemic Risk Assessment

E-mail: lynnklotz@live.com

Submitted to:

NIH Blue Ribbon Panel

National Institutes of Health

6705 Rockledge Drive, Suite 750

Bethesda, Maryland 20892

Email: NIH_BRP@od.nih.gov

During the 2010 presentation by Tetra Tech at Roxbury Community College, I brought to the attention of the Blue Ribbon Panel (BRP) that Tetra Tech's draft risk assessment for the BU NEIDL¹ completely ignored the three escapes of SARS from laboratories. Tetra Tech 2010 RA concluded that an escape from a lab with secondary infections among the public might not occur for thousands to a million years. How can that be? There had already been three escapes.

Shortly after the 2010 Roxbury College presentation, the NRC committee charged with overseeing the risk assessment issued a scathing criticism of the draft RA. The NRC criticism carried an account of the Beijing SARS laboratory escape through a laboratory acquired infection (LAI) in which 9 persons were infected and one died.² It appears that the RA90 continues to base its risk assessment for SARS and other pathogens on hypothetical scenarios, such as needle sticks and centrifuge accidents.

The RA90 does not take into account explicitly LAIs, which are the most frequent route for escapes of pathogens from labs (e.g. the three SARS escapes). While Table 4-4 in the RA90 does list "punctures" and "pathogen not inactivated" as candidate events, the table explicitly claims the public is not an exposed group. Again, punctures and not deactivating pathogens have led to LAIs with infected workers leaving the laboratory and potentially exposing the public; for instance, failure to inactivate is the reason for the secondary infections in the SARS lab escape in Beijing.

¹ National Emerging Infectious Disease Laboratory at Boston University

² "Continuing Assistance to the National Institutes of Health on Preparation of Additional Risk Assessments for the Boston University NEIDL, Phase 2," National Research Council, p14-15 (November 5, 2010)
http://www.nap.edu/catalog.php?record_id=13310

Letter 11
Lynn Klotz

In my mind, the RA90 is not fully responsive to the NRC's criticism that Tetra Tech did not take the "real world" SARS escapes into account.

More importantly, the current, 90% deliverable RA³ (which I will refer to as RA90) does not explicitly take into account the pandemic potential of the three SARS escapes in its calculations by calculating likelihood-weighted infections and fatalities resulting from a pandemic over the 50-year facility lifetime.

To be sure, the RA90 does provide a scholarly and thorough discussion of SARS along with the SARS escapes; and it provides data (Table 3-5-3a) for the likelihood of secondary infections leading to one-or-more to 10,000-or-more deaths. But they end up dismissing the threat to the public from a pandemic (perhaps 10 million deaths; see below) of a lab escape.

"Those extreme, higher risk results depend on the assumption that control measures attempting to curb transmission would not be effective at ending an outbreak that becomes large. That scenario is not supported by past experience, given that the entire worldwide outbreak of SARS in 2002–2003 resulted in about 8,000 infections and 800 deaths."

This statement fails to recognize that the areas where the 2003 outbreak occurred had adequate public-health surveillance and had the ability to quarantine. What if an infected person flew to a crowded city in a poor nation or to a war zone where surveillance and quarantine would be minimal? During the outbreak, a Hong-Kong-infected woman flew not to a poor nation, but instead to Toronto with modern public health capabilities. Despite Toronto's capabilities and their knowledge of the Hong Kong outbreak, she still seeded 438 probable and suspect SARS cases in Canada, including 44 fatalities.⁴

Lynn Klotz

Probability of SARS escape from the BU NEIDL over the facility's lifetime

There is a way to take into account explicitly the limited “real world” data on SARS escapes to carry out a risk analysis that delivers very different results regarding a pandemic from the RA90. This is how Tetra Tech could have proceeded to be responsive to the NRC’s criticisms. To begin, Figure 1 shows a flow chart for my analysis along with key results.

Figure 1. Flow chart for the risk and consequences of a pandemic resulting from a SARS escape from the BU NEIDL over the facility’s 50-year lifetime.

The Beijing lab escape, the Toronto outbreak, and the total outbreak are in the diagram simply to illustrate some high probability consequences of a BU NEIDL escape. p_{LT} is the probability of at least one escape. s_{LT} is the probability of at least one escape with secondary infections. The probability of a pandemic resulting from escape is chosen, very conservatively, to be 0.001, or 1 in 1,000 escapes that are accompanied by secondary infections will then lead to a pandemic with 10 million deaths.

I calculate a 21.2% likelihood of at least one SARS escape with secondary infections over the assumed 50-year lifetime of the BU NEIDL. The detailed calculations are presented in Appendix I, and also available on a spreadsheet, which may be an easier way for you to follow the analysis.

Can a SARS lab escape cause a pandemic?

What data do we have to support the notion that SARS can seed a pandemic? First, we have three pieces of evidence that escapes can cause a number of infections and fatalities.

(1) In 2004 in Beijing, after the only natural SARS outbreak in humans was contained, two BSL3 lab infected workers infected seven others outside the lab. One lab worker infected her mother who then died. A nurse caring for one of the lab workers infected the others.⁵

⁵ <http://www.cdc.gov/sars/media/2004-05-19.html>

Letter 11
Lynn Klotz

(2) In 2003 in Asia, during the first and only human outbreak of SARS, one victim flew from Hong Kong to Toronto, where she seeded 438 probable and suspect SARS cases in Canada, including 44 deaths. A global pandemic likely was averted only because public health officials in Asia and Canada took rapid preventative action, including quarantine.

(3) “During November 2002--July 2003, a total of 8,098 probable SARS cases were reported to the World Health Organization... [causing] 774 SARS-related deaths (case-fatality rate: 9.6%).”⁶ It is presumed the outbreak began when an unknown, but likely small, number of people contracted it from horseshoe bats or palm civets harboring the bat virus.

These are all data points on a probability distribution of victims (or fatalities) vs. probability of occurrence from a lab escape. While we do not know the exact probabilities for each of the three infected/fatality numbers, the probabilities are not near zero, because they have happened.

While the numbers of victims and fatalities from the 2002-2003 outbreak are large, they are nowhere near pandemic numbers. The most convincing evidence that a lab escape could cause a pandemic is a comparison of the virus features relating to pandemic potential for SARS and the 1918 pandemic flu. The 1918 virus caused a world-wide pandemic with about 50 million deaths, with a fatality rate of about 2.5% of those infected.⁷

In Table 1, pandemic-related features of the two viruses are compared.

<u>Virus Features Relating to Pandemic Potential^a and Fatalities</u>			
<u>Infectiousness or Contagiousness Feature</u>	<u>Value for</u>		<u>Comments</u>
	<u>1918 Flu</u>	<u>SARS</u>	
<u>R₀ (reproductive number)^b</u>	1.5 to 3.5	~3	R ₀ is the average number of secondary cases caused by an index human case
<u>ID₅₀ (infectious dose 50%)</u>	700	2,900	The number of viruses needed to infect 50% of persons harboring that dose
<u>Fatality rate</u>	~2%	9.6%	
<u>Atmospheric stability (aerosol, cool humid night)</u>	55	125	Table reports half-life in minutes
<u>Atmospheric stability (warm, dry, sunny day)</u>	20	25	Table reports half-life in minutes

a. All data from RA90, Appendix H, p13-15; except for fatality rate data.
b. Estimates are for populations that has not yet instituted control measures.

Table 1. Features of the 1918 pandemic flu virus and the SARS virus that relate to their pandemic potential and to fatalities. The RA90 data is the average of opinions from a number of experts (the Delphi method).

⁶ “Revised U.S. Surveillance Case Definition for Severe Acute Respiratory Syndrome (SARS) and Update on SARS Cases --- United States and Worldwide, December 2003”

Letter 11
Lynn Klotz

The most important data in Table 1 are the so-called reproductive numbers, which are the average number of secondary infections seeded by an infected individual. For SARS and the 1918 flu, these numbers are similar. While the estimated number of virus particles needed to infect a person harboring that number of particles (ID_{50}) is 4-fold higher for SARS, it does not seem to affect R_0 , the most important number regarding pandemic potential. The aerosol stability numbers tell us only that both viruses are stable enough in the air for transmission through coughing and sneezing.

I conclude that SARS has high pandemic potential.

Likelihood-weighted SARS infections and fatalities from a “rare” SARS pandemic.

By a “rare” pandemic, I mean a one-in-one hundred to one-in-a-thousand chance (probability= 0.01 to 0.001) that a SARS escape with secondary infections leads to a pandemic. While we do not know what this probability really is, my intuition tells me that once in a hundred to once in a thousand times a victim of a secondary infection will travel to a poor or war-torn country infecting others, where victims are not identified as SARS victims until it is too late to stop a world-wide pandemic. It is difficult to argue that the rare pandemic probability is smaller.

I assume 10 million fatalities resulting from about 100 million infections for such a pandemic. The fatality rate is not unreasonable given that the 1918 flu caused about 50 million fatalities, and SARS has three to four times the fatality rate as the 1918 flu (Table 1).

It is now a simple matter to calculate likelihood-weighted SARS infections and fatalities for this rare pandemic. Starting with the probability, $s_{LT}=0.212$, of at least one SARS escape with secondary infections over the assumed 50-year lifetime of the BU NEIDL, the likelihood-weighted number of infections using the conservative 0.001 pandemic probability, LWI, is

$$LWI = 0.001 \times 0.212 \times 100 \text{ million} = 21,200$$

And the likelihood-weighted number of fatalities, LWF, is

$$LWF = 0.001 \times 0.212 \times 10 \text{ million} = 2,120$$

For the 0.01 probability, still within the range of my intuition as the likelihood that a pandemic is seeded,

$$LWI = 0.01 \times 0.212 \times 100 \text{ million} = 212,000$$

And the likelihood-weighted number of fatalities, LWF, is

Letter 11
Lynn Klotz

$$\text{LWF} = 0.01 \times 0.212 \times 10 \text{ million} = 21,200$$

21,000 to 210,000 expected infections and 2,100 or 21,000 expected fatalities from SARS over the BU NEIDL facility lifetime are many too many to be tolerated. I note that there are about 30 labs working with live SARS virus throughout the world. Collectively, they are playing Russian roulette with our lives.

In Table 3-5-3a of the RA90, Tetra Tech does calculate a probability of 0.0002% for 100,000 or more public infections and 10,000 fatalities. Compare this to our much larger intuitive estimate of 1% to 0.1% for a pandemic of 100 million infections and 10 million fatalities. Interestingly, Tetra Tech puts a wide range ~0% to 2.8% on its best estimate of 0.0002%. The 2.8% number is larger than our largest 1%. Of course, we are both guessing at all these numbers.

I am not a big fan of the “precautionary principle,” because strict application of that idea would stand in the way of accomplishing many things. But for research on potential pandemic pathogens, the potential consequences of a lab escape are so horrific, the precautionary principle should apply.

Would moving SARS research to a BSL4 facility solve the risk problem?

The answer is “No,” as the following will show.

Since 1988, there have been three documented dangerous pathogen escapes from BSL4 containment:

(1) In December 2003, “a senior research scientist working with SARS in a Class III biosafety cabinet (BSC)⁸ cleaned up waste fluid that leaked from a tightly docked transfer chamber connected to the main cabinet...The next day, after he was infected, he attended a SARS meeting in Singapore”⁹. This is a clear example of escape from BSL4 containment through an LAI.

(2) In August of 2007, “An outbreak of foot and mouth disease was confirmed at a farm in Surrey, U.K... It was concluded that the FMDV likely originated from the nearby Pirbright Research and manufacturing site in Surrey because of construction activities surrounding a leaking drainage pipe.”¹⁰ While the NBAF report says “likely,” the FMDV outbreak almost certainly came from the Pirbright BSL4 laboratory. This is a clear example of escape from a BSL4 facility through a containment failure

⁸ Note: A Class III biosafety cabinet has a BSL4 rating, but was likely resident in a laboratory of lower biosafety rating. For a description of biosafety cabinet levels see <http://escoglobal.com/resources/pdf/BSC-Types-Classes.pdf>

http://www.dhs.gov/files/labs/gc_1187734676776.shtm

¹⁰ *Ibid*, Appendix B, pB-14

Letter 11
Lynn Klotz

(3) In 1990, a 35-year-old junior scientist from the Vektor Laboratory of the Novosibirsk Scientific Center contracted a Marburg virus infection. "[I]n violation of safety regulations, he worked with blood serum of laboratory animals infected with that virus, considering the material to have lost its infectivity in view of its storage at a temperature of 4°C for about 6 months...[F]eeling unwell on April 13th, he went home from work without alerting the laboratory's medical service, and on April 14th he entertained 10 guests at home. In fact, up until the time he was hospitalized, the patient was in close contact with 12 relatives (his wife and daughter – every day of illness up until hospitalization, and 10 people as guests...)"¹¹ He ultimately survived, and it is very lucky no one else was infected.

I estimate that there are a total of 39 operational BSL4 labs as of April 2012. How numbers relating to BSL4 labs for this analysis were obtained is presented in Appendix II. And over the 23 years from 1988 through 2011, the period I take for my analysis, the average number of BSL4 labs is estimated at 20.4. This average number is a crude estimate that Tetra Tech and NIH with their considerable resources should be able to pin down. Thus, the number of lab-years for BSL4 containment is $20.4 \times 23 = 468.6$.

Given there have been three pathogen escapes, the probability of escape for a single lab in a single year is $p_{1,BSL4} = 3/468.6 = 0.0064$. I need only to note that this probability is only 2.2-fold less the probability of escape of SARS from a single lab BSL3 in a single year, which is 0.014. So, based on historical data, moving to BSL4 containment does not provide a significant reduction of pandemic risk.

As a measure of the safety of BSL4 labs, BU NEIDL representatives point to the millions of person-hours of safe operation. Person-hour statistics are highly misleading. A typical lab worker spends about 2,000 hours at work each year. If each of 10 BSL4 facilities has 10 lab workers working for 10 years, that calculates to $2,000 \times 10 \times 10 \times 10 = 2$ million person-hours. You can see that this statistic becomes large quickly, mainly because of the 2,000 hours at work each year. I prefer probability of escape for a single lab for a single year as more meaningful statistic, because it is basic number from which numbers for all sorts of scenarios can be calculated.

How can risk be reduced to a tolerable level?

¹¹ Personal communication with an expert on the disbanded Soviet bioweapons program. The published source is Никифоров В. В., Түровский Ю. И., Калинин П. П., Акинфеева Л. А., Каткова Л. Р., Бармин В. Letter 11
Lynn Klotz

For research on deadly, highly contagious potential pandemic pathogens (PPPs), something safer than BSL4 containment is needed. Today, I see only four pathogens in that category: smallpox, SARS, the 1918 flu, and potentially human contagious H5N1 bird flu. By international agreement, smallpox is researched only in two facilities worldwide where lab workers have been vaccinated.

What to do about the other three PPPs? A path to increased biosafety has been outlined in a Huffington Post article.¹² The measures suggested in that article, with additional measures added here, are presented below:

- Institute an international system for deciding whether an experiment should be done at all and for continuing monitoring of experiments (prior and continuing monitoring).
- Carry out PPP experiments only in BSL4 labs in remote locations, where an escape would pose the least risk to populated areas.
- The number of labs should be limited to two or three worldwide.
- A team of international inspectors should have complete access to the labs at any time on short notice.
- Transparency regarding experiments should be available to inspectors and to other authorized international bodies. (Ground rules regarding what must be kept confidential to keep it from falling into the wrong hands would need to be worked out.)
- Train a full-time technical staff dedicated to work with highly dangerous pathogens to carry out experiments directed by research scientists who will not ever need to be present in the BSL4 laboratory. With modern audio/video technology, research scientists can hover over the lab work as if they were there.
- To assure that no PPP escapes from the BSL4 lab through an LAI, require the lab staff to follow up extended work shifts with periods of quarantine before they head home to families, friends and neighbors.

One conclusion is clear, no work on potential pandemic pathogens should be allowed in Boston, regardless of biocontainment level.

Letter 11
Lynn Klotz

Appendix I. Detailed Calculations

To determine p_{LT} , I started with PubMed searches using two search terms: "SARS virus animal challenge" and "SARS BSL3". The search yielded 30 labs worldwide working with live SARS virus. The number may be an underestimate since only a few keywords in the PubMed search were used and since some labs may not have yet published their research. The actual number is likely less than 50, which is close enough to 30 to support my general conclusions.

For SARS, assume laboratories have been working with live virus since perhaps a year after the natural outbreak, that is, since 2004. Then, as of the end of 2011, the labs have been working with live SARS for 7 years, and the number of lab years for researching live SARS is $7 \times 30 = 210$. Some labs may have started later, reducing the number of lab years.

For 3 escapes in 210 lab-years, the probability of escape from a single lab (the BU NEIDL for example) in a single year is $p_1 = 3/210 = 0.0143$ or 1.43%

p_{LT} , the probability of at least one escape over the $LT=50$ years facility lifetime, is calculated from the equation

$$p_{LT} = 1 - (1 - p_1)^{LT} = 1 - (1 - 0.0143)^{50} = 0.513$$
 or 51.3% chance of at least one escape, likely through an LAI.

And since only one of the three SARS escapes resulted in secondary infections, SLT is less

$$s_{LT} = 1 - (1 - p_1/3)^{LT} = 0.212$$
 or 21.2% chance of at least one escape with secondary infections, likely through an LAI.

Letter 11
Lynn Klotz

Appendix II. Key Numbers for BSL4 facility Risk Calculations

In May 2007, the BSL4 labs operating worldwide were cataloged at a MIT Biosecurity Program seminar entitled "Maximum Containment Facilities –Sense and Nonsense, Risks and Benefits." From the MIT talk, the BioWeapons Monitors 2010 & 2011, and other research, my count of operating BSL4 facilities is presented in Table A II-1:

<u>Country</u>	<u>Number of BSL4 Facilities</u>
<u>Active as of May 2007</u>	
Australia	3
Belarus	1
Canada	1
Egypt	0
France	1
Gabon	1
Germany	2
Hungary	1
India	2
Italy	1
Russia	5
Singapore	1
South Africa	1
Sweden	1
Switzerland	1
Taiwan	1
UK	5
US	9
<u>Active after May 2007</u>	
China	?
US	1
US	1
TOTAL:	39

Table A II-1. An estimate of operating BSL4 labs worldwide. Russia is listed as having 5 facilities. This number is highly uncertain. Vector, SergievPosad, and Irkutsk are definite. There may be two or more labs that can't be positively identified. There are about 13 labs, not listed here, either under construction, not yet active, or may never be active.

Letter 11
Lynn Klotz

Over the 23 years from 1988 through 2011, the period taken for risk analysis, the average number of BSL4 labs was estimated to be 20.4. This crude estimate was arrived at as follows: 1988 was the year of the first recorded Marburg LAI, where the researcher died. Subsequently there was another Marburg LAI in 1990, and an Ebola LAI in 1994. So, 1988 seems like a fair starting place for our accounting of lab-years. Another assumption is that two labs per year became operational between 2002 and 2011, after the anthrax attacks. Before that, it is assumed that one lab per year became operational.

Table A II-2 lists for each year between 1988 through 2011 the estimate of numbers of operational BSL4 labs worldwide.

<u>Year</u>	<u>No. of operational BSL4 labs</u>
2011	39
2010	37
2009	35
2008	33
2007	31
2006	29
2005	27
2004	25
2003	23
2002	21
2001	20
2000	19
1999	18
1998	17
1997	16
1996	15
1995	14
1994	13
1993	12
1992	11
1991	10
1990	9
1989	8
1988	7
Average:	20.4

Table A II-2. An estimate of the number of operational BSL4 labs worldwide between 1988 and 2012.

Attn: NEIDL Risk Assessment

To Whom It May Concern:

Associated Industries of Massachusetts (AIM) is the largest employer association in Massachusetts. Our mission is to promote the well being of our thousands of members and their employees and the prosperity of the Commonwealth by improving the economic climate, proactively advocating fair and equitable public policy and providing relevant, reliable information and excellent services.

AIM would like to affirm the findings of the National Institute of Health's Draft Supplementary Risk Assessment and to express our support for Boston University's National Emerging Infectious Diseases Laboratories (NEIDL).

On January 26th, I had the opportunity to tour the NEIDL and meet with lead researchers and security personnel who will be working in the laboratory. I also viewed the systems and learned of the policies that will make the research in the facility safe. From the background checks to the retina scan security systems to the special air filters and protective equipment, Boston University has incorporated state-of-the-art equipment into the NEIDL to ensure the safety of the researcher and the public.

Given these safeguards and the NIH's detailed and thorough evaluation of the design and location of the facility, there is sufficient evidence to support the NIH's conclusion that the potential risk that researchers or local residents will get infected from agents is extremely unlikely during the facility's anticipated life time of 50 years. I am reassured that this conclusion is valid because the National Research Council's panel of expert scientists, who conducted a review of the Risk Assessment this past December, found the NIH's analysis to be scientifically and technically credible.

The City of Boston also has strict operating requirements for research laboratories. I am confident that, under the oversight of the Boston Public Health Commission and our public safety departments, the NEIDL will conduct research safely and securely.

Boston | Bridgewater | Burlington | Holyoke | Marlborough | Washington, D.C.

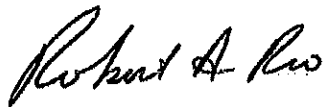

Letter 12
Robert Rio
Associated Industries of Massachusetts

Research that will be conducted in this facility will have an impact on public health locally, nationally, and globally. I am satisfied by the findings of the NIH's Draft Supplementary Risk Assessment and support the full opening of the NEIDL.

For these reasons AIM supports Boston University's waiver application.

Should you have any questions please do not hesitate to contact me.

Sincerely yours,

Subject: Northeast Emerging Infectious Diseases Laboratory

Dear Director Collins and Director Fauci,

Two things are true. The mission of the NEIDL is both critical and increasingly urgent, and human nature is both beautiful and flawed.

No matter how rigorous the safeguards, circumstances beyond prediction or control will always occur. Ample evidence of this exists in the comparably regulated nuclear power industry. Even our military has lost nuclear weapons. The chance of human misjudgment with regard to the controllability of risk, and the public health and socio-economic consequences of a release of Biosafety Level IV pathogens in the heart of downtown Boston, should be sufficient for any thinking person to realize that an expensive mistake has been made and must be corrected.

13.1 { The NEIDL facility will not go to waste if it is restricted to Biosafety Level III work. A separate Biosafety Level IV facility, away from population centers, should be constructed as soon as possible.

Respectfully,

Gary Johnson, MPA

To Whom It May Concern:

I'm taking this opportunity to write to you regarding the NEIDL. I believe that the National Emerging Infectious Diseases Laboratory at Boston University emphasizes both the need for scientific research and safety precautions.

The location of the NEIDL, here in Boston, to me makes perfect sense as is it in the center of the hub of scientific and medical knowledge. I believe that if such a facility as NEIDL were to be sited in a remote location such as the Tyngsborough, as some have suggested the potential for accidental release of infection agents would be greatly increased due to the long transportation distances required.

I also think that it is the major transportation hubs, such as an international airport such as Logan, that will likely be either an inadvertent or deliberate entry points into the general populace for dangerous infectious agents, and the sooner these agents can be isolated, the shorter the distances to the facilities for their study, the lower the overall risk they pose and the more successful they can be controlled and eliminated.

I have the highest confidence that the staff of the Boston University's NEIDL facility and its partners. That confidence includes my personal endorsement of its full licensing and operation in Boston.

Thanks you for this opportunity,

Sincerely,

A handwritten signature in dark ink, appearing to read "Christine Harris-Idiokitas". The signature is fluid and cursive, with a large loop at the end.

To whom it may concern:

I'm taking this opportunity to write regarding my impressions of and concerns for the NEIDL lab currently undergoing the review process there at the NIH. Let me say from the outset that it is my firm belief that the New Emerging Infectious Disease Laboratory at Boston University represents an important and critically vital component in the ongoing struggle against the worldwide threat posed by emerging and rapidly evolving pathogens, and that I fully support its startup and full operation. I have the confidence that the designers and administrators of the lab have taken the necessary precautions to prevent the laboratory itself from becoming a vector allowing these pathogens to migrate into the general populace. In fact, it is my opinion that without such a facility, the risk to the health of the general public is greater.

My wife and myself had been given an opportunity to tour the Boston NEIDL facility under the direction of Dr. John Murphy in March of this year. I found the presentations and the tour to be very informative and illuminating. The emphasis on both the scientific and security considerations are impressive and went quite far in building our own confidence that the designers, staff and cooperating government entities have taken safety as a primary driving motivation in the NEIDL facility. My understanding, prior to our introduction to the NEIDL facility, is that there is an increasing risk of the spread of serious and potentially lethal pathogens that is only made worse by the fact that these pathogens are easily and swiftly transported by their human hosts across the globe in mere hours, and that no where in the world does anyone any longer enjoy the safety of physical isolation as protection against infection.

Having the NEIDL located as it is does not, in our view, pose a significant risk to the general populace. Ironically, it is places like Logan Airport or South Station that pose a far higher risk of introducing serious infectious agents into our region. The location of the NEIDL, here in Boston, to us, makes perfect sense as is it in the center of the hub of scientific and medical knowledge. I believe that if such a facility as NEIDL were to be sited in a remote location such as the New Mexico desert, as some have suggested, the potential for accidental release of infectious agents would be greatly increased due to the long transportation distances required. I also think that it is the major transportation hubs, such Logan International Airport, that will likely be the point of either inadvertent or deliberate entry into the general populace for dangerous infectious agents, and the sooner they can be isolated, the shorter the distances to the facilities for their study, the lower the overall risk they pose and the more rapidly and successfully they can be controlled and eliminated.

Letter 16

Richard D. Pierce

I have, in the past, had the opportunity to tour a variety of secure locations, such as nuclear facilities, scientific laboratories, military installations and more. In my humble opinion, none have impressed me as "secure" as NEIDL has. But, honestly, I think it's important to realize that for a pathogen to be studied at NEIDL, it's already likely been let out of the bag, so to speak. If anyone is looking for absolute security against infection, my only recommendation, and certainly an impractical one at that, is to live in the vacuum of outer space.

Let me conclude by stating, again, that I have the highest confidence that the staff of the Boston University NEIDL facility and its partners are an essential weapon in the ongoing struggle to protect the general populace against the onslaught of emerging diseases and pathogens, and that confidence includes my personal endorsement of its full licensing and operation in Boston.

Thanks you for this opportunity to make my views known. Please feel free to contact me should you have any questions.

April 24, 2012

National Institutes of Health
Attn: NEIDL Risk Assessment
6705 Rockledge Drive, Suite 750
Bethesda, MD 20892-7985

To Whom It May Concern:

I am writing in support of Boston University's National Emerging Infectious Diseases Laboratories (NEIDL) in Boston. I believe the NIH's Draft Supplementary Risk Assessment verifies that BU has the expertise and proper security measures currently in place to safely conduct valuable scientific research at this facility.

To assure a comprehensive study, the NIH's Draft Supplementary Risk Assessment uses very conservative assumptions to analyze the likelihood of an incident, and consequently the risk to the community, from conducting Biosafety research in the NEIDL. As a resident of the South End, I believe the potential scenarios outlined are credible, realistic and that the NIH incorporated the concerns and input of the community in this report.

The South End of Boston is an appropriate location for the NEIDL as the infrastructure for research is already well established on the BU Medical Campus. The Risk Assessment shows that there are no differences in the risks of infections or fatalities to lab workers at the three sites analyzed (South End, Peterborough and Tyngsboro) and that the potential risk to the community is very small and not significantly different when comparing the locations, because the range of values in the estimates for the three sites overlaps considerably.

The Risk Assessment also finds that greatest level of risk is to the researchers who would be working in the NEIDL. Given the state-of-the-art safeguards built into the design of the facility as well as the appropriate level of precautions that would be used by researchers, this risk is significantly minimized. For example, in the 1918 H1N1 scenario, the estimate for one or more infections is between 1 in 100-10,000 years.

I believe that the NIH has provided a detailed and thorough evaluation of the design of the facility and its safety and security systems. I am also reassured by the National Research Council's panel of expert scientists, who conducted a review of Risk Assessment this past December and found its analysis to be scientifically and technically credible.

The research that the NEIDL is looking to conduct has the potential to discover cures for deadly infectious diseases that can save lives. I am satisfied by the findings of the NIH's Draft Supplementary Risk Assessment and support the full opening of the NEIDL.

Sincerely,

Christopher Brayton

To Whom It May Concern:

I am writing in support of Boston University's National Emerging Infectious Diseases Laboratories (NEIDL) in Boston's South End. As a Registered Nurse in the City of Boston, I believe the scenarios outlined in the Risk Assessment are credible and accurate.

Given the infrastructure already in place at Boston University's Medical Campus, I believe the South End is the appropriate location for the NEIDL. In conjunction with the institution and the medical center, the NEIDL will create a positive boost in economic value in the area. The location will also allow my fellow nurses to be better educated on infectious diseases and the best ways to address them if confronted.

The research that the NEIDL is looking to conduct has the potential to discover cures to deadly infectious diseases that can save lives. I am more than satisfied by the findings of the NIH's Draft Supplementary Risk Assessment and support the full opening of the NEIDL.

Sincerely,

Jasmine Bigby, RN BSN

To Whom It May Concern:

I am writing in support of the NEIDL on Boston University's Medical Campus. I believe the National Institute of Health's Draft Supplementary Risk Assessment verifies that BU has the expertise and proper security measures currently in place to safely conduct valuable scientific research at this facility. As a teacher, it is very important to me that my students are safe and secure each day they travel to and from school.

I have taken it upon myself to research the NEIDL. I have viewed the systems and learned of the policies that will make the research in the facility safe. From the background checks to the retina scan security systems to the special air filters and protective equipment, Boston University has incorporated state-of-the-art equipment into the NEIDL to ensure the safety of the researcher and the public.

Given these safety precautions, there is plenty of evidence to support the NIH's conclusion that the potential risk that researchers or local residents will get infected from agents is extremely unlikely during the facility's anticipated life time of 50 years.

The City of Boston also has strict operating requirements for research laboratories. I am confident that, under the oversight of the Boston Public Health Commission and our public safety departments, the NEIDL will conduct research safely and securely.

Research that will be conducted in this facility will have an impact on public health locally, nationally, and globally. I am satisfied by the findings of the NIH's Draft Supplementary Risk Assessment and support the full opening of the NEIDL.

Sincerely,

Eric Fabb

To Whom It May Concern:

I am writing to you on behalf of The New England Council (the "Council") in support of the National Emerging Infectious Diseases Laboratories ("NEIDL") at Boston University, and in support of the Draft Supplementary Risk Assessment findings. We are convinced that the NEIDL can safely conduct research that will not only be vital to the state's biomedical and life science research sector, but also provide significant public health benefits locally, nationally, and across the globe.

We have found the Draft Supplementary Risk Assessment to be a thorough, comprehensive review of the risks associated with the operation of the NEIDL. It is important to note that very conservative assumptions were used to analyze the likelihood of an incident. The scenarios modeled are realistic, and the analyses and conclusions presented show that the potential risk posed to researchers or local residents as a result of the NEIDL's operation is extremely low to beyond reasonably foreseeable. The Risk Assessment's detailed explanation of the facility's safeguards, including its state-of-the-art air filtration systems and redundant operating systems, security systems, and safety procedures, provide adequate evidence to support this claim.

It is clear that the NIH has been very thorough in its evaluation of the potential risks associated with this facility. We were encouraged by the NRC's determination that this draft Risk Assessment is scientifically sound and credible and a substantial improvement over the previous documents. Moreover, spending by the National Institutes of Health has consistently generated substantial economic benefits over long periods of time. Academic research and industry partners have long noted the strong, symbiotic relationship between NIH basic research funding and subsequent investment and innovation in the private economy. The Council believes that NIH approval of the NEIDL will continue this trend.

After an unprecedented amount of review and years of delay, it is now time for the NIH to approve the NEIDL and for the lab to commence full operations. The Council supports the findings of the

Letter 21

David J. O'Donnell

The New England Council

Draft Supplementary Risk Assessment, and hopes that the NEIDL will soon be able to embark on its mission to conduct cutting-edge scientific research.

If you have any questions, please do not hesitate to contact me.

Very truly yours,

David J. O'Donnell

Subject: Comment NEIDL at BU Meidcal

This is the text of a column I wrote for my Boston Globe blog. Please consider it as my comment on the draft report.

Fatal flaws in the biolab report

“If you build it, they will come,” a much overused expression for just about any kind of venture, originally referred to a “Field of Dreams” ballpark in an isolated Iowa cornfield that would attract the unsettled spirits of disgraced ballplayers. In the case of the Boston University Biosafety Lab on Albany Street, which has stood for several years awaiting resolution of a controversial risk assessment, it is more like “If you open it, they may come.”

The “they” in this instance are a lot more worrisome than a bunch of ghosts with leather gloves. The “they” include nefarious folks, terrorists and saboteurs who would see the facility as a prime target for their malicious schemes.

Despite a healthy dose of resistance from my South End community to a perceived health risk, Boston University has been eager to establish a Level 4 biosafety lab for research on highly dangerous pathogens. The interests of science were delayed, however, when the first risk assessment report, released two years ago, was deemed wholly inadequate, particularly given the high stakes of potentially exposing a densely populated area to Ebola and other deadly viruses.

The recently-released draft supplementary report, no less than 1,750 pages in length, does an exhaustive job of attempting to evaluate the risks (likelihood of occurrence, consequent health effects and emergency response) associated with a wide variety of threatening events, both accidental and intentional. And although it would seem kind of late for such an analysis given the awaiting structure and the green light from local politicians, the assessment compares three potential sites for the lab, one urban (Albany Street in the South End of Boston), one suburban (in Tyngsborough, Mass.), and one rural (near Peterborough, N.H.).

23.1

Risk assessments of incidents like an earthquake or an accidental airplane crash may be reasonable, but the coverage of so-called “malevolent acts” is questionable, at best, having been grounded in unsupported assumptions concerning the likelihood of such misdeeds. While one may calculate the probabilities of certain calamities, the likelihood of a terrorist mission targeting the facility or of a disgruntled employee intent on sabotage is inestimable.

The research team does attempt to gauge the chances of criminal acts, appealing to a measure known as the CAP (Crimes Against Persons/Property) Index. This statistic predicts such things

Letter 23
James Alan Fox

- 23.1** The Draft Supplementary Risk Assessment does not indicate that the probabilities of occurrence for the Maximum Reasonably Foreseeable (MRF) event and a malevolent act are similar. Instead, the risk assessment states that the consequences of malevolent act scenarios are expected to be much less than the consequences of the MRF event.

23.2

as rape, robbery and burglary that might impact on a commercial establishment, such as a restaurant or a retail store, but is silent on the kind of concerns associated with a research laboratory. According to Jon Groussman, President of the company that produces the CAP Index, the measure is definitely not designed to determine probabilities associated with terrorism or employee disgruntlement. The biolab assessment team also interviewed federal, state and local law enforcement officials as well as representatives of the BU police force, but there is little data that would permit the chances to be quantified.

At the end of the day, the assessment team punted, concluding that “It would be speculative to attempt to provide an estimate of the consequences of malevolent scenarios involving the removal of pathogens from the facility.” Instead, the report decided to use another, more tractable threat as a proxy:

23.3

"Because of the importance of the MRF [[Maximum Reasonably Foreseeable] event, an evaluation of an aircraft crash was performed to confirm the expectation that the severe earthquake bounds (i.e., has consequences and frequencies that are not exceeded by) an aircraft crash. Appendix F presents this comparison and demonstrates that the severe earthquake bounds an aircraft crash in terms of both frequency and consequences. Malevolent acts were not considered in the selection of the MRF event, 'because the potential number of scenarios is limitless and the likelihood of attack is unknowable' (DOE 2002). As recommended by the DOE NEPA Guidance, malevolent acts were evaluated by comparison to accidents with similar consequences (see Chapter 6)."

The potentially fatal flaw here is in mixing probabilities and outcomes. While the consequences of a malevolent act and an earthquake may be somewhat comparable, the probabilities are certainly not. One is knowable, the other elusive.

No one can say with any degree of certainty whether “they will come,”-- whether launching Level 4 research activities will be irresistibly attractive to intruders or insiders wishing to create havoc by releasing pathogens into a highly congested area. BU scientists may wish to experiment with dangerous biological agents, but they shouldn’t experiment with the safety and well-being of the millions who live or work in the surrounding area.

A research lab devoted to the most dangerous of viruses does not belong in Boston, or any urban area. Maybe they should move it to that isolated ballpark in Iowa -- a “Field of Nightmares.” After all, the old time ballplayers there are already dead.

James Alan Fox,
The Lipman Family Professor of Criminology, Law, and Public Policy
Northeastern University Boston, MA 02118

Letter 23
James Alan Fox

23.2 CAP Index reporting was one of several variables used by the risk assessment threat assessment team to define the potential threat at each of the three sites.

Re: Comments in support of the draft Supplementary Risk Assessment for
National Emerging Infectious Diseases Laboratory at Boston University

To Whom It May Concern:

The Association of Independent Colleges and Universities in Massachusetts (AICUM) represents the interests of 60 independent colleges and universities throughout Massachusetts, the 250,000 students who attend those institutions and the nearly 100,000 employees who work at those institutions. Our member institutions include large nationally renowned research universities, smaller, highly regarded liberal arts colleges, religiously affiliated institutions, and colleges with special missions focused on business or music or allied health services.

As AICUM's president, I write to express our support for the National Emerging Infectious Diseases Laboratory (NEIDL) at Boston University (BU), and in support of the Draft Supplementary Risk Assessment findings. Construction of the \$200 million NEIDL at BU, which is located on BU's Medical Campus, was completed in 2008. The safeguards built into the design of the NEIDL, including its state-of-the-art air filtration systems and redundant operating systems, and the appropriate level of precautions that is the hallmark of researchers in Massachusetts, will significantly mitigate the possibility of any risk. We are convinced that the NEIDL can safely conduct research that will not only be vital to Massachusetts' biomedical and life sciences research sector, but ultimately provide life-saving public health benefits across the Commonwealth, across the United States, and, indeed, throughout the world.

It is clear the National Institutes of Health has been very thorough in assessing and fully evaluating the potential risks associated with the NEIDL at BU. We were encouraged by the National Research Council's determination that the Draft Supplementary Risk Assessment is scientifically sound and credible.

Letter 26

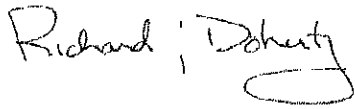

Richard Doherty

Association of Independent Colleges and Universities in Massachusetts

A further delay in the approval of this state-of-the-art facility would delay vital research projects and has the potential to cost the Commonwealth millions of dollars in grants. For these reasons, and because the NEIDL research can save lives and invent cures for deadly infectious diseases, we support the NEIDL at BU as well as the Draft Supplementary Risk Assessment.

I respectfully urge you to allow the NEIDL at BU to start moving forward on cutting-edge research, the benefits of which will accrue to people here in Boston and to people around the world.

Sincerely,

A handwritten signature in cursive script that reads "Richard Doherty". The signature is written in dark ink and is positioned above the typed name.

April 26, 2012

Dear NEIDL Risk Assessment Group,

I am the General Manager of a Medical Office Building at 801 Massachusetts Ave. Boston MA., on the edge of the BU Medical Center campus. I have three staff managers who operate the garage and office space here, and we all toured the NEIDL facility last March 2012. Several of us were concerned to various degrees about what is to go on in NEIDL building. I had seen a short news show on our local PBS station about the facility and I wanted to see the place for myself. We had an hour and a half tour by the Associate Director, Dr. Ronald Corley. We were all very impressed with the building and the program, and any concerns that any of us had were fully addressed. We all feel very comfortable working some two blocks from the building and we all have a better understanding of the need for this type of research to be undertaken.

It is great that this society gives small vocal groups an opportunity to speak up about community issues. However, giving these groups total veto power to stop important work like that which will go on in the NEIDL Building is just not right. Some of these parties wanting to stop this work will never, ever be satisfied with any answers BUMC could give them. I work just down the street and I have no fears or concerns about this building and the work that will be done inside of it. Our country needs this research. BUMC wants to do this work to be a worldwide recognized top medical center that can attract the best medical researchers and practitioners from around the country and the world. It would be a shame if a loud group could shout over the needs of this society.

Please feel free to contact me if it would help this Risk Assessment Group make a decision. I can be reached at 617-427-3307.

Sincerely,

A handwritten signature in black ink, appearing to read "Paul J. Rogan".

Cambridge, MA 02139

To Whom It May Concern:

MassBio affirms the findings in the Draft Supplementary Risk Assessment and supports the National Emerging Infectious Diseases Laboratories (NEIDL) at Boston University. We believe that research can and will be done safely in the NEIDL. Further, the laboratory is an important component of biomedical and life science research in the Commonwealth and will provide significant public health benefits locally, nationally and globally.

The Draft Supplementary Risk Assessment represents a thorough and comprehensive review of the risks associated with the operation of the laboratory. It is important to note that very conservative assumptions were used to analyze the likelihood of an incident. The scenarios modeled in the report are realistic and are based on combined experiences of biosafety laboratories. The analysis and conclusions show that the risk of researchers or local residents getting infected from agents in the NEIDL is generally very low or beyond reasonably foreseeable – using the SARS and Ebola scenario a large outbreak is unlikely even over 1 million years.

Importantly, the safeguards built into the design of the NEIDL, including its state-of-the-art air filtration systems and redundant operating systems, and the appropriate level of precautions that researchers use, will significantly mitigate and lower the possibility of any risk.

The NIH has been very thorough in evaluating the risks of this facility. It is particularly noteworthy that the National Research Council conducted a review of the methodology used in this draft Risk Assessment and noted that it was a substantial improvement over previous documents and that it was scientifically sound and credible.

After an exhaustive review, it is now time for the NIH to approve the NEIDL and for the lab to begin operations. As its mission, MassBio aims to create an environment in which every biotechnology company can grow to reach its utmost potential. Research like the work proposed at NEIDL is a very important piece of the innovation pipeline that will fuel industry growth and, ultimately, treatments and cures for patients in need around the world.

Having toured the NEIDL and viewed the security measures in place, MassBio is very pleased with the findings in this Draft Supplementary Risk Assessment and is hopeful that after much delay and review, Boston University will soon be able to conduct important public health research in the NEIDL.

Sincerely,

Robert K. Coughlin

To Whom It May Concern:

I am writing to you on behalf of Greater Boston Chamber of Commerce in support of the National Emerging Infectious Diseases Laboratories (NEIDL) at Boston University, and in support of the Draft Supplementary Risk Assessment findings. The Chamber believes that the NEIDL can safely conduct research that will not only be vital to the state's biomedical and life science research sector, but also provide significant public health benefits locally, nationally, and across the globe.

The Draft Supplementary Risk Assessment represents a thorough and comprehensive review of the risks associated with the operation of the laboratory. It is our understanding that the following is true of the report and its findings: a) very conservative assumptions were used to analyze the likelihood of an incident; b) scenarios modeled in the report are realistic and are based on combined experiences of biosafety laboratories, and c) analysis and conclusions show that the risk of researchers or local residents getting infected from agents in the NEIDL is generally very low or beyond reasonably foreseeable.

A senior director on my staff recently had the opportunity to tour the NEIDL, meeting with lead researchers and security personnel who will be working in the laboratory. He was very impressed by the systems, policies, and state-of-the-art equipment incorporated into the NEIDL in an effort to ensure the safety of both researchers and the public. It is our understanding that the extensive safeguards built into the design and operation of the NEIDL will significantly mitigate and lower the possibility of any risk.

The NIH has been very thorough in evaluating the risks of this facility. It is particularly noteworthy that the National Research Council conducted a review of the methodology used in this draft Risk Assessment and noted that it was a substantial improvement over previous documents and that it was scientifically sound and credible.

Greater Boston's life science cluster continues to be an important economic engine, directly and indirectly supporting tens of thousands of well-paying jobs, and driving advancements in public

Letter 29

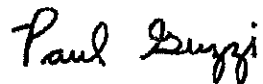

Paul Guzzi

To Whom It May Concern:

As a former resident of the city of Boston, and a leader in the South End community, I am writing to express my support for the National Emerging Infectious Diseases Laboratories (NEIDL) located on the Boston University Medical Campus.

I feel that the Risk Assessment determines that the potential risks associated with the lab are extremely low. The Risk Assessment found that the researchers working within the facility were at the greatest level of risk; however the facility's safeguards and safety procedures significantly mitigate that risk.

Accounting for the design of the building, the safety procedures, the security systems, and other important issues, the evaluation of risk associated with the NEIDL's operation seems to have been very thorough. I am reassured that the National Research Council and its scientific experts conducted a review of the methodology used in this Risk Assessment, and noted that it was a substantial improvement over previous documents and that it was scientifically sound and credible.

After years of review and delay, I would like to see the NEIDL carryout its mission to conduct extremely important and potentially life-saving research. I support the NEIDL's mission and the long-anticipated full opening of this important facility.

Sincerely,

Sophia Thomas

Re: National Emerging Infectious Diseases Laboratories,
Comments on the Draft Supplementary Risk Assessment

To Whom It May Concern:

We write on behalf of Boston University to provide comments on the Draft Supplementary Risk Assessment (RA) for the Boston University National Emerging Infectious Diseases Laboratories (NEIDL). We found that the RA was a careful and thorough analysis of the potential risks posed by the operation of the NEIDL. It addressed issues raised by the courts, the public, the National Research Council, the Blue Ribbon Panel, and the Massachusetts Executive Office of Energy and Environmental Affairs. It clearly constitutes the required “hard look” at the issues.

In preparing the RA, the National Institutes of Health (NIH) and the Blue Ribbon Panel instructed its contractors, whenever there was uncertainty about the risk of a given accident or infection, to use the higher risk estimates in their analyses. This systematic overestimation of risk leads to a final risk estimate that might err on the high side, but cannot be criticized for underestimating or minimizing the risk to the community.

31.1 { We endorse this conservative approach. We only note that, in always choosing higher risk estimates, the RA at times does not take into account many of the safety features of the building, the procedures that will be used there, and the additional oversight that will be provided by the Boston Public Health Commission. In these comments, we would like to point out some of those overestimated risks and the safety features that would reduce them when the lab is operating.

1. Overestimation of the likelihood that accidents, such as needle sticks, will go unreported. To reduce the chance that an accident like a needle stick would go unreported, we will use the “two-person rule.” In short, no work in BSL-4 space or

Letter 31
Thomas J. Moore
Boston University School of Medicine

31.1 As discussed in Section 4.2.1 of the Draft Supplementary Risk Assessment, bounding analyses (i.e., analyses using conservative assumptions that tend to overestimate the risk) were performed in order to streamline the analyses, enhance defensibility, and account for uncertainty. This approach is consistent with the Department of Energy (DOE) NEPA Guidance. As a result, there will be biocontainment features in place that are not included in the analyses or described in the text. Building features, additional procedures, and oversight by the Boston Public Health Commission, will also tend to reduce risks.

.

BSL-3 with select agents may be performed unless two researchers will be present in the space. Additionally video monitoring of the space allows for further viewing of the activities. We believe that these mitigation measures make the likelihood of an unreported accident extremely low. While a researcher might be embarrassed by a needle stick and fail to report it if working alone, the presence of the second researcher will dramatically reduce, the possibility of non-reporting. The second researcher will have an obligation, at the risk of losing his or her laboratory privileges, to report the accident involving the first researcher. The Boston University Research Occupational Health Program (ROHP) is an integral part of the “culture of safety” program at BU and provides medical surveillance and training for the researchers who work with pathogens, including a reporting program.

- 31.2

{

1. Facility Commissioning, Registration, and Operation Process (2.1.7) describes the process employed by the Centers for Disease Control and Prevention (CDC) for registration and oversight of laboratories possessing or using select agents.

However, in Boston, the Boston Public Health Commission (BPHC) must also review, approve, and oversee all laboratories possessing or working with any BSL-3 and BSL-4 agent. This additional commissioning, registration and routine inspection program adds an extra level of safety.
- 31.3

{

2. 5.1.3 Description of NEIDL Shipments (Page 5-8); states “Transfer of infectious BSL-3 and BSL-4 pathogens between the NEIDL and other BUMC facilities will be performed with the same triple-packaging and over-pack case requirements imposed on external shipments; however, BUMC courier services may be used rather than commercial carriers”. Actually, there are no other BSL-4 facilities at BUMC and therefore no BSL-4 shipments will be made between the NEIDL and other BUMC facilities.
- 31.4

{

3. Page 10-9; Lines 20-21 states: “Unlike the chemical and nuclear industry, no governmental agency regulates or enforces worker or public exposure to biological agents”. Operation of NEIDL is subject the BPHC Biological Laboratory Regulations (adopted September 19, 2006) which regulate the use of BSL-3 and BSL-4 agents, and includes requirements for worker safety, incident reporting and medical surveillance program.
- 31.5

{

4. A.4.2 Page-14: it should be added that the BPHC Recombinant DNA Technology: Use Regulations requires that all “All institutions proposing any use of rDNA technology, as defined in and not exempted by the November 21, 1980 NIH Guidelines, must obtain an rDNA use permit. The regulations further require that all projects using rDNA be registered with BPHC and the permit holder must submit an annual report that include copies of Institutional Biosafety Committee (IBC) minutes, certification that the institution is in compliance with the Guidelines and the regulations, and a complete roster of current IBC members. Similar requirements exist for NIH rDNA Guidelines and the Select Agent Rule administered by the CDC.

Letter 31
Thomas J. Moore
Boston University School of Medicine

- 31.2** The 3rd paragraph of Section 2.1.7 of the Draft Supplementary Risk Assessment has been revised to read as follows: “In addition, the operation of the NEIDL must comply with various city (including the Boston Public Health Commission), state, and federal regulations before operations with pathogens begin and throughout facility operations.”
- 31.3** The last paragraph of Section 5.1.3 of the Draft Supplementary Risk Assessment has been revised to read as follows: “Transfer of infectious BSL -3 pathogens between the NEIDL and other BUMC facilities will be performed with the same triple-packaging and over-pack case 2 requirements imposed on external shipments; however, BUMC courier services may be used rather than 3 commercial carriers.”

Additionally, the following will be added to the end of this paragraph: “There are no other BSL-4 facilities at BUMC, so there can be no transfers of BSL-4 pathogens to other BUMC facilities.”

- 31.4** The 3rd paragraph of Section 10.5.4 of the Draft Supplementary Risk Assessment has been revised to read: “Unlike the chemical and nuclear industry, there are no explicit occupational or public exposure limit values for biological agents.”
- 31.5** For use of recombinant DNA, a permit is required from the Boston Public Health Commission Board, as outlined by Section 1.03.a of Recombinant DNA Technology: Use Regulations (City of Boston). Accordingly, Section 1.3 of the Risk Assessment stipulates that Boston University’s research operations would be governed by all applicable federal, state, and local laws, regulations and guidance. This includes the Boston Public Health Commission. Also see response to comments 31.2 and 31.4.

5. In BSL-3 incident scenarios (e.g. aerosol exposure), it is assumed that the potentially exposed individual either does not realize the exposure, or fails to reports the exposure, and walks out of the facility. While theoretically this is possible, the scenario does not account for the fact that workers must remove their “street clothing” and change into scrubs suits and outer Tyvek jump suit that is removed prior to leaving the laboratory. This substantially reduces the potential for carrying any contamination outside the laboratory.

In its comparison of the risk of siting the NEIDL in Boston versus other locations, the RA understates the benefits of locating the NEIDL in Boston and as part of Boston University Medical Center. The RA assumes that, were the NEIDL to be built and operated in one of the alternative locations, control measures in those locations would be comparable to those existing near the NEIDL. Examples of this including the following:

1. We believe that, if an accident were to occur, post-accident control measures would be more effective in Boston than in the alternative locations. For example, there is no emergency response infrastructure in Peterborough, NH or Tyngsborough, MA that is comparable to the City of Boston’s, and there is no likelihood one would be developed. To achieve such an infrastructure would require substantial public spending which has never been committed or even discussed.
2. In addition to the response infrastructure, the Boston site includes a robust utility and services infrastructure that allows for the reliable delivery of electrical, steam, water and other services in primary and backup methods of delivery. While possible to replicate these services in other areas, it would be difficult to create the same level of redundancy and service response expertise that exists in Boston.
3. Third, there is a much more experienced, extensive, and accessible medical infrastructure in Boston than near the alternative sites. This medical expertise makes it far more likely that any infections would be diagnosed and treated more quickly and effectively than at the suburban or rural locations.
4. The expertise among responders at the Boston Public Health Commission and Boston Police and Fire Departments is substantially greater than that available in the alternative locations, and it is difficult to imagine those locations being able to develop such expertise. This expertise cannot guarantee that an infectious disease would not spread in the Boston location. But it does make the Boston site better prepared to handle, control, and mitigate the impact of any accidental release of a pathogen compared to the response that could be mustered in the alternative locations.

We would like to repeat that this risk assessment is extremely thorough and comprehensive. It clearly and definitively answers the questions posed by various stakeholders. It establishes that the risks posed by the facility have been fully and carefully assessed, that those risks are extremely low, and that BUMC will have

Letter 31
Thomas J. Moore
Boston University School of Medicine

31.6 As a result of this comment, item 10 of Section F.2 of Appendix F of the Draft Supplementary Risk Assessment has been revised to read:

“The specific personal protective equipment (PPE) used for centrifuge operation is dependent on the pathogen, and concentrations involved, but will always include protective clothing, eye protection (the respirator could serve this function), and double gloves (BUMC 2009a). PPE are removed prior to exiting the BSL-3 or BSL-4 laboratories to avoid carrying contamination out of the laboratory. While respirators are considered to PPE, they are addressed separately because of their significance for reducing the inhalation hazard and the pathogen-specific requirement to use them.”

appropriate structural and operational controls in place to further mitigate those risks. The Boston location is clearly the appropriate location for the siting of the NEIDL.

We appreciate the extensive effort that NIH has put into the development of this risk assessment, and we appreciate the opportunity to comment.

Sincerely,

A handwritten signature in black ink, reading "Thomas J. Moore". The signature is written in a cursive style with a large, looped initial "T".

Thomas J. Moore, MD
Associate Provost

Letter 31
Thomas J. Moore
Boston University School of Medicine

To The Blue Ribbon Panel of the NIH
cc The Mayor of Boston and City Counselors, President of BU, US Senators and
Representatives from MA and U.S. Secretary of Health and Human Services.

As members of Pax Christi Boston, we promote peace through justice. We have been concerned during most of the last decade about the social justice and possible military/terrorism risks involved with the placement of the National Emerging Infectious Diseases Laboratories at the Boston University Medical Campus, an “environmental justice” area of Boston. These laboratories are slated to include the study of levels III and IV pathogenic microorganisms.

Our concerns are:

- 32.1 {
1. **Biological Terrorism:** The organisms, already being researched in other U.S. Biolabs, are dangerous and deadly to humans. The risk of these organisms accidentally or intentionally entering the human community leads us to ask why research them at all, anywhere? **Since the lab is being funded by the US government/military, the strong possibility exists that it will be used at some time for development of biological weapons.** The large sums of money that accompany this research are very attractive to the local political power elite who support its establishment despite its placement in a locality where very vulnerable citizens live and work.
- 32.2 {
2. **Environmental Justice:** **Since these organisms are so deadly to humans, why grow and research such pathogens in an obviously high risk, densely populated locality?** Anyone with an ounce of common sense and knowledge of the Boston Area would never locate a lab atop the largest land fault on the East Coast, where highly vulnerable people are packed tightly together amidst gridlock traffic, multiple streets and underground subways and waterways. The most recent draft of the “Final Draft Supplementary Risk Assessment” is primarily based on theoretical models, for many of which, “no data is available.” We question the validity of the results contained in the Assessment. Tetra Tech has given the Blue Ribbon Panel a Risk Assessment Report that reinforces decisions already made by the political-governmental power elite coalition, rather than the health and safety of the people of Boston. Under these conditions the living Boston Community can never agree to increase the research in the NEIDL to levels III and IV.

The Compromise of Truth: “No data is available” is repeated so many times in the risk assessment that we cannot believe these labs are safe, secure or necessary here or anywhere else. Given the actual dangers and risks of the Boston location, we must conclude that the national and local leaders charged with the approval of NEIDL have intentionally betrayed the trust given to them by the people of Boston. They have misled especially those minority and low-income communities where the building is located. We ask you to remember Fukushima, the BP oil rig blowout in the Gulf of Mexico and the weapons of mass

Letter 32
Pax Christi

- 32.1 No bioweapons research will take place at the NEIDL. The production of bioweapons is prohibited by Article 1 of the *Biological Weapons Convention* of 1972. Research at the NEIDL will be performed for scientific research and biodefense purposes (i.e. developing effective vaccines, therapeutics, and diagnostics). All research at the NEIDL will be conducted in accordance with applicable federal, state and local regulations. Information on the purpose of the NEIDL was included in Chapter 1.1 and Chapter 1.3 of the Draft Supplementary Risk Assessment.
- 32.2 This comment is outside the scope of the Draft Supplementary Risk Assessment.

3. destruction that were not found in Iraq, situations of deliberate government/industrial deception of the people.

Desmund Tutu says, "There is no justice without truth." And we say, "There is no peace without justice. Therefore, as members of the Blue Ribbon Panel, charged with assessing the true risk of NEIDL in Boston, you must report the truth to the decision-makers and citizens: **the NEIDL is too dangerous to be placed in Boston or anywhere else.** In order to avoid continued conflict, you must restore truth and justice to preserve peace for the Common Good.

Subject: comments on risk assessment for NEIDL

My name is Marc Pelletier, a resident of Boston and molecular biologist with 25 years+ experience in medical research in immunology, infectious disease and cancer. I have reviewed all the previous iterations of risk assessments (RA) since 2004. Below are my comments on the +1700 page report compiled for NIH by TetraTech and Dr. Adi Gundlapalli, presented in Spring 2012.

Data from important & relevant accidents has been omitted from their risk assesement
Chapter 6 is an important one looking at "Threat Assessment". Table 6-5 (p265) "Relationship of the Consequences of Threat Assessment Scenarios and Accident Scenarios" lists several threat scenarios that the RA contractors model and assess in this report. They also list whether there are actual, historic examples of such a scenario that can be used in their assessment.

- 33.1 { TetraTech and Dr. Adi Gundlapalli did not include the anthrax attacks from 2001 attributed to Bruce Ivins as a historical example of 'release of pathogen' in their 'malevolent acts' scenarios. The only mention of the 2001 anthrax attacks in the entire report was as a justification to open the NEIDL and other biodefence labs.
- 33.2 { Here is an actual event that should have been included in the RA but was not. A respected and career scientist who had been working in the US lab for 30 years, decides to smuggle material out of his lab and use it for bioterrorism. Such an act is impossible to model or even guard against. Therefore, it was conveniently left out of their RA. The same treatment is given to the 1979 release of anthrax from a government lab in Russia that killed 70+ people. This was downplayed as 'not relevant' to the NEIDL situation. However, this was an actual event, not a hypothetical. Instead of focusing on an actual event, they focus on hypotheticals. The inconvenient truths were left out of this RA.
- 33.3 { In the same table 6-5, they list "loss of pathogen" as a scenario that TetraTech and Dr. Gundlapalli will model and assess for risk. They also state there are 'no similar events' to use to model this 'loss of pathogen' scenario. They neglect to include the disappearance of 9000 vials of pathogens that were reported "unaccounted for" by Ft. Detrick in 2009.
- 33.4 { The sample table 6-5 states that more information is available about their selection of "threats" and relevant accidents in Section G.10.2.2. However, this section does not exist in the document.
- 33.5 { TetraTech and Dr. Gundlapalli provide no discussion about how the lab-borne tularemia infections came about at BUMC in 2004-2005. In light of a subsequent lab-borne infection of Neisseria meningitidis at BUMC in 2009, it is critical to understand how these infections

Letter 33
Marc Pelletier

- 33.1** A threat assessment was developed as a separate component of the Draft Supplementary Risk Assessment in response to concerns raised by the public regarding the capability of the facility's security systems inclusive of security/law enforcement personnel, electronic systems, policies, and procedures in place to prevent, withstand, or respond to a malevolent action (e.g., disgruntled or unbalanced lab worker, insider threats, terrorist action) against critical systems and assets at NEIDL that could result in the exposure of personnel or release of a pathogen into the community. (Chapter 6, Section 6.1.1) Because the analysis contains sensitive information, the threat assessment is a confidential/official use only document. Additionally, a threat assessment for select agents requires the plan must be reviewed annually and revised as necessary. Additionally, drills or exercises must be conducted at least annually to test and evaluate the effectiveness of the plan. Both Boston University and NIH security personnel have reviewed the analysis and conclusions of the threat assessment.
- 33.2** Please see response to comment 33.1.
- 33.3** Please see response to comment 33.1.
- 33.4** The reference to Appendix G.10.2.2 in the Draft Supplementary Risk Assessment has been replaced in the Final Supplementary Risk Assessment with a reference to Appendix of G.10.1.1

33.5 { happened at BUMC. This is exactly an incident that TetraTech and Dr. Gundlapalli were charged with modeling in the very institution that is the subject to RA. This was deemed irrelevant and left out of their RA.

33.6 { TetraTech & Dr. Gundlapalli did not investigate how proliferation of easily transportable 'virus bomb parts' poses a risk to biosecurity.

33.7 { State of the art research on most viral pathogens (Ebola, Marburg, 1981 influenza, SARS) involves taking the viral genome apart and putting the separate pieces onto plasmids for easier manipulation for the researchers. This also means that these 'parts of a virus bomb' can be used (and are normally made) in BSL-1, labs with much lower security. These 'virus bomb parts' look like a tiny drop of water and can be spotted onto any piece of paper, carried out of the lab, mailed anywhere in the world and then used to rebuild the 'virus bomb' with materials and know-how available in any biological research lab. This would be the **democratization of bioterrorism** capabilities, from nationally funded labs for a wider public. Think about someone having the ability of dispensing SARS or influenza from a spray bottle concealed in a backpack on a subway. As the recent shooter in France and the 2001 anthrax attacks showed, you just need to kill a few people to sow terror and shut down society.

These are such glaring omissions in the analysis and should cause concern in any objective reviewer, in particular scientists looking to understand how these accidents happen and what the likelihood is of a repeat, or worse, with a more deadly pathogen. Due to this failure, the report lacks credibility.

33.8 { TetraTech does not have relevant experience
I went to Tetra Tech's website to read about their previous experience with this type of assessment of risk that a "BioSafety Lab" could pose to a community. Their "knowledge center" has no mention of any biosafety expertise. Neither is there mention of any biosafety work in their "featured projects". Actually, a keyword search of Tetra Tech's site has "0" hits with 'biosafety' and 'BSL'. Judging from their own website, Tetra Tech's experience in biosafety lab risk assessment is 'limited', if it even exists.

33.9 { Dr. Adi Gundlapalli does not have relevant experience
A search for publications by Dr. Gundlapalli shows that he has never published any peer-reviewed paper on relevant topic. His recent publications are focused on medical communications. Based on his publication record, Dr. Gundlapalli is not someone with experience in high-containment labs or any biological research laboratory.

33.10 { Dr. Gundlapalli & TetraTech have a conflict of interest in assessing the NEIDL for NIH
From Dr. Gundlapalli's biography on his University of Utah faculty site:
He is currently an investigator with the NIH-funded Rocky Mountain Center of Excellence for Biodefense and Emerging Infectious Disease Research ...
Dr. Gundlapalli is an employee of NIH who is contracted by NIH to assess if the lab that NIH has already sunk substantial money and pride into and is part of the same system research system

Letter 33
Marc Pelletier

- 33.5** This incident is discussed in Section 3.5.1.2 and in Table D-7 of Appendix D.1.3.6 of the Draft Supplementary Risk Assessment.
- 33.6** Please see response to comment 33.1.
- 33.7** See response to comment 33.1.
- 33.8** Tetra Tech has core competencies in the preparation of environmental analyses and a wide breadth of technical expertise, particularly in the areas of Biosafety/Biocontainment Laboratories. Tetra Tech has prepared hundreds of human health and ecological risk assessments for the Department of Energy (DOE), Department of Defense (DOD), Environmental Protection Agency (EPA), NIH/NIAID, and other federal agencies involving biological, chemical, and radiological materials. Tetra Tech has performed similar analyses for other BL4 laboratories, such as the National Bio and Agrodefense Facility, Rocky Mountain Laboratories, and the Galveston National Laboratory.
- 33.9** Dr. Gundlapalli received his basic medical training at Madras Medical College and graduate training in immunology at the University of Connecticut Health Center. He then completed an internal medicine residency at the University of Connecticut. Dr. Gundlapalli is Board Certified in both Internal Medicine and Infectious Diseases and has over 25 peer-reviewed publications to his credit. Currently, he is an Assistant Professor in the Departments of Internal Medicine at the University of Utah School of Medicine, which is one of ten institutions that comprise the NIH-funded Rocky Mountain Center of Excellence for Biodefense and Emerging Infectious Disease Research. Dr. Gundlapalli has extensive experience in influenza research, public health surveillance, and preparedness for emerging infections/agents of bio-terrorism. His broad range of experience, accomplishments and medical expertise make Dr. Gundlapalli uniquely qualified to take part in the risk assessment process.

33.10

where he is currently employed, would pose any threat to the community and should open. This is a blatant conflict of interest and cannot expect to produce an objective assessment.

The fact that the risk assessment of this NIH lab is being done by contractors paid by NIH is reminiscent of the relationship between the ratings agencies and the investment banks that paid them for AAA ratings on junk securities, leading to the financial meltdown.

A credible risk analysis, free of conflict of interest, needs to be organized by an agency outside of NIH. I have previously suggested the General Accounting Office, which has already compiled two reports on the status of BSL-3 & 4 labs in the U.S. The GAO still remains a much better option than having NIH run a risk assessment for their own project.

As an experienced, professional scientist, I am very familiar with the scientific process of posing a specific question and completing a set of experiments or analysis to arrive at the objective answer. The Risk Assessment presented by TetraTech and Dr. Gundlapalli has instead decided ahead of the analysis what the desired answer is and have tailored their report to arrive at the predetermined answer. This report is not science, this is sales

Letter 33
Marc Pelletier

33.10 Dr. Gundlapalli is not an NIH employee. He is currently a faculty member at the University of Utah, School of Medicine, one of ten institutions that comprise the NIH-funded Rocky Mountain Regional Center of Excellence. Dr. Gundlapalli has no personal or financial interest in the outcome of the supplementary risk assessment.

Boston University's National Emerging Infectious Diseases Laboratories

Comments on the February 2012 BUMC Draft Risk Assessment

April 30, 2011. I live a few miles from the site of the proposed lab, in Egleston Square, a neighborhood of Roxbury. I am opposed to the opening of a level 4 lab in my community, and do not feel the February 2012 Risk Assessment addresses the real risks or allays my trepidation.

Here are my concerns:

- 34.1 { 1. While attempting to address the risk of an intentional criminal act, the report concludes, "It would be speculative to attempt to provide an estimate of the consequences of malevolent scenarios involving the removal of pathogens from the facility." Are you kidding me? After 9/11, the anthrax scare that followed, and all the other thwarted and successful attempts to attack this country, the report is going to punt on this?
- 34.2 { 2. If this lab is approved, does the community lose all input in what happens there for the lifetime of the lab? Will I, as a neighbor and citizen of Boston, be able to know what research is being proposed at the lab? Will I have a chance to weigh in if something seems too dangerous? Or once the lab is approved, is it all up to the "experts," and the community loses all say? Will details about the research be hidden under the guise of "national security" or by proprietary issues?
- 34.3 { 3. How will the diseases be transported? On which streets will they travel? What if there is a car accident involving that vehicle? What if there is an intentional effort to hijack/damage/release the disease from that vehicle? At some point, we learned the diseases will not be transported on Route 93. So where will they go? Through my neighborhood? Through other people's neighborhoods? What protection will be afforded to the transportation of those diseases before they even arrive at the lab? BU has constantly touted the lab as a safe within a vault within a submarine. What about all the time and miles before the diseases get into that safe? Isn't there an incredible risk there?
- 34.4 { 4. What is the line between public health research and department of defense research? Who decides what falls into what category? Why isn't the lab focused on top infectious diseases in the US?
- 34.5 { According to The Summary of Notable Infectious Diseases, a report of the CDC, the most common infectious diseases in the US (in 2008) were, with number of reported infections:

1.	Chlamydia trachomatis	1,210,523
2.	Gonorrhea	336,742
3.	Salmonellosis	51,040
4.	Syphilis (all stages)	46,277
5.	AIDS	39,202
6.	Lyme disease	35,918
7.	Varicella (chickenpox)	30,386
8.	Shigellosis	22,625
9.	Giardiasis	18,908
10.	Pertussis	13,278

Letter 34

Elizabeth Skidmore

- 34.1** A threat assessment was developed as a separate component of the Risk Assessment in response to concerns raised by the public regarding the capability of the facility's security systems inclusive of security/law enforcement personnel, electronic systems, policies, and procedures in place to prevent, withstand, or respond to a malevolent action (e.g., disgruntled or unbalanced lab worker, insider threats, terrorist action) against critical systems and assets at NEIDL that could result in the exposure of personnel or release of a pathogen into the community. (Chapter 6, Section 6.1.1) Because the analysis contains sensitive information, the threat assessment is a confidential/official use only document.

A threat assessment for select agents requires the plan must be reviewed annually and revised as necessary. Additionally, drills or exercises must be conducted at least annually to test and evaluate the effectiveness of the plan. Both Boston University and NIH security personnel have reviewed the analysis and conclusions of the threat assessment.

- 34.2** The community input in the research at the NEIDL will continue in two distinct forums within the processes established by Boston University. The first is the NEIDL Community Liaison Committee (CLC) whose members are representatives of various neighboring community groups and which will continue its advisory role during the operations of the NEIDL. The second is the Institutional Biosafety Committee (IBC), the committee which must approve all research involving pathogens. The IBC has two community members, and neither of them are affiliated with Boston University. The IBC members participate in all regularly scheduled monthly meetings and provide input on the proposed research projects. The minutes of all IBC meetings are posted on their publically available website. These minutes include a description of the proposed research, the pathogens that would be studied, the biosafety level, and the committee's deliberations. (<http://www.bu.edu/orcccommittees/ibc/committee/ibc-minutes/>)

Another venue, external to Boston University, where the information regarding the NEIDL projects are reviewed is the Boston Public Health Commission. Under the Boston Public Health Commission Laboratory Regulations, once a project at BSL-3 or BSL-4 is approved by the Boston University-IBC, it must also be submitted to the Boston Public Health Commission for their approval prior to initiating the study.

- 34.6 { Will these be studied? Are they level 4? Don't they all need more lab space? Why is the lab focused on diseases that rarely if ever occur in the US? This seems to move from public health to defense/offense.
- 34.7 { 5. BU waited six months to report to the public on the accident with Tuleremia in 2004. This took place WHILE they were applying for approval for this Level 4 lab. One would hope that BU would want to be especially vigilant about following the rules they already had while they are applying for the ability to work with much more dangerous materials. Is this how they act when they are under scrutiny? How do we know they won't engage the same delay and/or cover up if there was an accident at the proposed lab?
- 34.8 { 6. I've seen a number of comments about evacuation. Evacuation in that part of Boston is a joke about 16 hours of the day. It's not doable.
- 34.9 { 7. I've also heard that if something catastrophic were to happen the actual response would be to quarantine the area, not evacuate it. Is this true? Why hasn't this been addressed with the community? How do you think parents will respond if they are separated from their children by a quarantine in the case of an accident? Is anyone planning for handling that? There are a number of schools and preschools in the blocks surrounding the lab.
- 34.10 { 8. What of the risk of another country looking at the work being done at this lab and deeming it as a violation of the 1925 Geneva Convention and the 1972 Biological Weapons Convention, both ratified by the US, and both which ban research in bio weapons? What if another country decides to use this lab as permission to conduct their own efforts into developing bio weapons?
9. The city of Boston is not prepared to respond to an emergency, according to Boston City Councilor Charles Yancey when he spoke at the hearing about the lab on April 19, 2012, "I've interviewed police commissioners, fire commissioners and commissioners of public health, and none of those individuals were able to convince me the city of Boston is prepared to respond to that emergency," Yancey said. "I've asked our firefighters directly: are they prepared to deal with that type of emergency? And they told me they haven't even been trained yet. I've asked our police officers: what would our response be? And they had no answers."
10. We have had to catastrophic events in the last dozen years that highlight our inability to plan for all contingencies that people or nature have to offer. September 11 was completely unimaginable. It now is. What happened at Fukushima should have humbled all of us. A lab full of highly contagious, infections diseases would take a catastrophic intentional attack or a massive earthquake and add unknown horrors to what would already be a terrible situation. Fires can be put out, but viruses and bacteria are alive and do everything they can to spread and multiply. Why would we put that in our neighborhood?

Please do not approve this lab. Please do not put myself, my friends and neighbors at risk. There is nothing sensible about having a Level 4 lab at this location.

Thank you,

Elizabeth Skidmore
50 Atherton St
Roxbury, MA 02119

Letter 34

Elizabeth Skidmore

Finally, faculty at Boston University, including those that would work within the NEIDL, will not perform classified or secret research. All research that will be conducted in the NEIDL will be open and transparent. Senior administration of both the NEIDL and Boston University have also signed a pledge stating that no classified research will be conducted in the facility.

34.3 See response to comment 34.2

34.4 Chapter 5 Transportation Analysis of the Draft Supplementary Risk Assessment provides information regarding the transportation of the pathogens. In addition to meeting all Department of Transportation regulations concerning the transport of pathogens, transportation to the NEIDL includes:

- Detailed information on the packaging and shipment requirement to protect the integrity of the pathogens during the transportation;
- The additional safeguards such as an added over-pack case, known as “Pelican Case”, that provides an extra fifth layer of protection for the vial of the pathogens;
- Use of unique transponders for each package, and an additional one for the vehicle carrying the package, and Global Positioning System (GPS) tracking throughout the transportation process;
- Use of a designated vehicle for delivery of shipments to Boston University as well as pre-screened drivers transporting the pathogens;
- The additional outer package that Boston University has specified provides significant protection and will be secured in the middle of the vehicle to minimize damage in the event of an accident;

Boston University will also coordinate all BSL-3 and BSL-4 shipments with the Boston Public Health Commission as the lead agency. The Boston Public Health Commission coordinates such shipment plans with the Boston Fire Department and Boston Police Department as well as other state agencies, if appropriate. Each delivery will utilize a specific route that is most appropriate, using approved highways and major thoroughfares, but not through residential areas, depending on where the shipment originates. These routes are selected to comply with all restrictions on transportation of hazardous materials or vehicle sizes. The oversight agencies lead by the Boston Public Health Commission review the specifics of a proposed route of each delivery and advise on its appropriateness. These transportation policies are already in place for the transport of Select Agents to the Boston University Medical Campus.

Letter 34

Elizabeth Skidmore

- 34.5** Boston University is currently engaged in research in a number of these diseases, including sexually transmitted diseases (HIV, gonorrhea, etc.), respiratory infections and other bacterial pathogens commonly found in the US population. Studying these pathogens will continue to be a major focus of research at Boston University. Research conducted in the NEIDL will also be carried out on pathogens that are major threats in the US, such as Tuberculosis, but also on infectious diseases that impact the populations of other countries so that the nation can be prepared against new threats.
- 34.6** See response to comment 34.5.
- 34.7** Boston University has established procedures for transparency and accountability, including an independent Office of the Associate Vice President for Research Compliance that has responsibility for oversight of research activities including those of the NEIDL. The Office has developed and implemented comprehensive training programs, a dedicated Research Occupational Health Program responsible for routine medical surveillance of individuals working with biological agents, incident reporting procedures, and periodic inspection programs. The Office, which does not report through the NEIDL Director's Office but to the Provost of the Boston University Medical Campus, has full responsibility for oversight of the NEIDL and is staffed with the appropriate expertise for the type of research and pathogens used at the NEIDL.
- 34.8** The containment of an infectious disease relies on early diagnosis and treatment and reducing the spread of the infection by preventing contact between the infected individuals and the community. This is accomplished by asking those with an infection to stay in their homes (sometimes referred to as quarantine or shelter-in-place). Evacuation is not part of a typical public health response to an infectious disease. The Boston Public Health Commission Infectious Disease Bureau is the public agency that makes decisions about management of infectious diseases. The Office of Emergency Management is responsible for coordinating all emergency management programs for the City of Boston.

Letter 34

Elizabeth Skidmore

- 34.9** No bioweapons research will take place at the NEIDL. The production of bioweapons is prohibited by Article 1 of the *Biological Weapons Convention* of 1972. Research at the NEIDL will be performed for scientific research and biodefense purposes (i.e. developing effective vaccines, therapeutics, and diagnostics). All research at the NEIDL will be conducted in accordance with applicable federal, state and local regulations. For more information on the purpose of the NEIDL, please refer to Chapter 1.1 and Chapter 1.3 of the Final Supplementary Risk Assessment. The NEIDL is owned and operated by Boston University. The possibility of a foreign nation claiming the laboratory to perform biological weapons research is not in the scope of this document nor is it reasonably foreseeable.
- 34.10** Boston University has coordinated with the Boston Public Health Commission, Boston Fire Department and Boston Police Department in developing emergency response procedures for incidents within the laboratory. As part of that coordination, the agency representatives have toured the facility and are familiar with emergency response procedures and will also participate in periodic joint emergency drills.

Building a Healthy Boston

April 25, 2012

National Institutes of Health
Attn: NEIDL Risk Assessment
6705 Rockledge drive, Suite 750
Bethesda, MD 20892-7985

Mr. Ryan Bayha:

Boston Public Health Commission appreciates the opportunity to provide comments on the Draft Supplementary Risk Assessment for the National Emerging Infectious Diseases Laboratories and provide information on City of Boston regulation of laboratories.

Section 10.5.4 of the Draft Supplementary Risk Assessment states, "Unlike the chemical and nuclear industry, no governmental agency regulates or enforces worker or public exposure to biological agents. Nor is there legislation or a governmental entity that has set occupational or public exposure limit values for biological agents."

The Boston Public Health Commission has detailed inspecting, project review, and permitting processes in place that regulate BSL-2 research using Recombinant DNA and all BSL-3 and BSL-4 laboratories operating in the city. The requirements include disease surveillance and reporting. Our regulations were written with assistance from leading research experts and scientists and approved by the city's Board of Health. Our inspectors are well-trained, our work is coordinated with other city departments, and we are able to respond to safety concerns through our inspecting, permitting and surveillance/reporting activities. In addition to the health commission's permitting requirements for select BSL-2 laboratories and all BSL-3 and BSL-4 laboratories, all laboratories in the Boston are required to obtain a registration with the Boston Fire Department for storage of hazardous materials and a Certificate of Occupancy from Inspectional Services. Research institutions also must obtain a sewer discharge permit from the Massachusetts Water Resources Authority before opening.

The City of Boston feels confident that our current regulations and our coordinated permitting, inspecting, and enforcement practices are sufficient to ensure the continued safety of Boston research laboratories. Thank you.

Sincerely,

Barbara Ferrer, Ph.D., MPH, M.Ed.
Executive Director

Letter 35

Barbara Ferrer, Ph.D., MPH, M.Ed.

Boston Public Health Commission

35.1 The 3rd paragraph of Section 2.1.7 of the Draft Supplementary Risk Assessment has been revised and read as follows: “In addition, the operation of the NEIDL must comply with various city (including the Boston Public Health Commission), state, and federal regulations before operations with pathogens begin and throughout facility operations.”

The 3rd paragraph of Section 10.5.4 of the Draft Supplementary Risk Assessment has been revised and read as follows: “Unlike the chemical and nuclear industry, there are no explicit occupational or public exposure limit values for biological agents.”

For use of recombinant DNA, a permit is required from the Boston Public Health Commission Board, as outlined by Section 1.03.a of Recombinant DNA Technology: Use Regulations (City of Boston). Accordingly, Section 1.3 of the Risk Assessment stipulates that Boston University’s research operations would be governed by all applicable federal, state, and local laws, regulations and guidance. This includes the Boston Public Health Commission.

May 1, 1012

To: National Institutes of Health

From: Vicky Steinitz, Coordinator, Cambridge United for Justice with Peace

Re: Draft Risk Assessment for the NEIDL -- 2012

As a United for Justice with Peace activist, I have been involved in efforts to convince NIH that the NEIDL should not be located in the densely populated, urban neighborhood of the South End/Roxbury from the moment I heard that Boston University had submitted a proposal to build the lab here. I represent hundreds of peace and justice activists who see the decision to place such a dangerous lab in the inner city as a prime example of the “war at home” being waged against a vulnerable, low-income population of color. The Coalition which has grown over the years of this struggle unites residents of the area directly affected by the lab with citizens from surrounding cities and towns. Elected officials in five of those communities – Arlington, Brookline, Cambridge, Newton and Somerville – have passed ordinances opposing the construction of BSL4 laboratories in densely populated urban areas. In my community, Cambridge, the building of BSL4 labs is prohibited because of the risks they present. I am attaching a Citizen’s Letter signed by concerned citizens across the nation calling for a moratorium on all select agent research until questions surrounding the proliferation of BSL4 labs are addressed.

History is important here and helps explain the suspicion with which I view this latest effort to assess the risks of the NEIDL. I do not believe that BU has told the truth throughout the risk assessment process and I do not trust the neutrality of NIH or its primary commitment to safeguarding the health and safety of the community. A few specific comments illustrate my concerns:

- 36.1 { 1) Community involvement: The Draft Risk Assessment contains a lengthy list of community meetings to back up the claim that the community has had ample opportunity to participate in decision-making about the lab. Yet, many of these meetings were inaccessible (in Bethesda, MD.), poorly advertised, or held at impossible times for residents. Frequently, the meetings involved lengthy presentations by Blue Ribbon Panel members on contractors with public comment reserved for a few moments at the end of the meeting when many in the audience had given up and left.

One memorable example which illustrates the fraudulence of the account of community participation: The RA reviews the risks of 13 pathogens and the draft alleges that this list was formed with community participation. I was at the meeting where NIH tried to get us to choose the pathogens we wanted them to study when what the community wanted was for NIH to explain why they were putting this dangerous

Letter 36
Vicki Steinitz

36.1 NIH has actively and extensively engaged the community and has sought community input throughout the supplementary risk assessment process. All meetings of the NIH Blue Ribbon Panel, many of which occurred in Boston, were open to the public and videocast for those who could not attend in person. The videocasts of those meetings were placed on the NIH Blue Ribbon Panel website for those who wished to view the meetings at a later date. Meetings were widely advertised on the NIH Blue Ribbon Panel website, local Boston newspapers, and the Federal Register. Each meeting included a portion of time for public comment. Finally, all materials discussed at these meeting are accessible via the Blue Ribbon Panel website.

lab in a densely populated urban environmental justice community. I think it's fair to say that the overwhelming consensus was against researching any of these pathogens.

- 36.2 { While the RA rests heavily on the analysis of these thirteen pathogens, there is no assurance that they will be the ones studied. Indeed, the community has no idea of what will actually be researched if the lab opens or by whom. Boston University has not released any information about research plans or investigators. We wonder, if select agents other than the thirteen listed are introduced to the lab, will there be an additional RA to assess their risks with opportunities for public comment?
- 36.3 { 2) Despite extensive coaching by both the NIH staff and the NRC panel, the latest NRC Letter Report raises numerous concerns about the RA. Tetra Tech claims that all their estimates are “conservative,” yet NRC believes their estimate of the frequency of unreported needle sticks is “low” and criticizes their failure to address this issue. Similarly, the NRC criticize the RA treatment of the risks associated with the carrying out of fomites. (Fomites are surfaces to which pathogens can become attached like lab coats and research instruments which pathogens may then leave the lab undetected.)
- 36.4 { According to the NRC letter, they should have done an independent analysis of the fomite “carry out” risk at the NEIDL. While the RA constantly asserts that all best practices will always be adhered to and a “culture of safety” will rule, we all know that “accidents happen” and particularly in this year of unexpected happenings, we should expect the unexpected.
- 36.5 { 3) Biological pathogens are different: they are living organisms with no shelf life; they reproduce and mutate, often in unexpected ways. No governmental agency regulates or enforces worker or public exposure to biological agents. This lack of oversight and uniform regulations is very worrisome to the community. We worry about worker infections and are skeptical of the oft-repeated claims that secondary transmission is so unlikely as not to be worth consideration.
- 36.6 { 4) We question the decision to use nuclear energy as a model for deciding on the 6-mile radius chosen for study. There's no connection between the effects of a nuclear accident and a biological one, not to mention the ever-changing pronouncements about the effects of the Fukushima disaster. Given the concentration of low income, medically challenged, EJ residents in the area surrounding the lab, it would have been prudent to choose a smaller, perhaps one-mile radius, which of course would magnify the differential impacts on the three sites. The RA challenges its own credibility by its claims of no significant differences among the sites.

Letter 36
Vicki Steinitz

- 36.2** Chapter 3.3 of the Draft Supplementary Risk Assessment explains that the thirteen agents were selected because they encompass four broad categories “to describe the general nature of risks from infectious pathogens to laboratory workers and to the public at large, and to describe in broad terms the range of potential effects from the release of such pathogens.” Therefore, any existing or new agents that fall under one of the four risk groups would represent risks that are similar to one of these 13 agents and would not require additional risk assessment because the consequences are within the bounds of the agents and accident scenarios studies under the Draft Risk Assessment. If a new pathogen is identified, its classification into these risk groups is under the auspices of the World Health Organization and the Centers for Disease Control and Prevention.
- 36.3** Based on the National Research Council’s letter report from the November 2, 2011 meeting, Section 4.2.3.3.1 of the Draft Supplementary Risk Assessment was revised to be responsive to the NRC’s concern and now reads: “Needlestick events in BSL-3 that are not promptly detected and reported are assigned to frequency category B (1 in 100 to 10,000 years). This frequency category assignment is appropriate and even conservative because: (1) the historic estimate is on the boundary of frequency categories A and B, (2) historic values likely overstate the value for current facilities due to enhanced practices, equipment, and facilities (see Section D.1.1 of Appendix D), and (3) the NEIDL is expected to have lower incident rates due to its attention to sharps safety (see Section F.7.2.1 of Appendix F) and the enhancement of safety (see Section 2.1 of Chapter 2). Section F.7.3.2 of Appendix F provides additional details.”
- 36.4** The rationale of why fomites were not selected for detailed analysis is discussed in Section 4.1.3.3.3 of the Draft Supplementary Risk Assessment and on page {insert page] of the Final Supplementary Risk Assessment.
- 36.5** The 3rd paragraph of Section 10.5.4 has been revised to read: “Unlike the chemical and nuclear industry, there are no explicit occupational or public exposure limit values for biological agents.” The Boston Public Health Commission regulates the use of all BSL-3 and BSL-4 agents within the City of Boston where the NEIDL is located. This oversight is mandated under the Biological Laboratory Regulations that established the criteria for the registration of the laboratories and approval of research projects. The Boston Public Health Commission also has the Disease Surveillance and Reporting Regulation that mandates a medical surveillance and reporting program. The biological Laboratory Regulations provide specific worker protection which states “any employee absent from the work place due to illness for a period of

- 5) Which brings me to my final comment. I see the RA as primarily a public relations document designed to convince the citizens of MA and those who will judge its adequacy – MEPA, the state and federal courts – that the NEIDL does not represent a threat. I've listened to the Bethesda meetings which seemed to consist mainly of NIH, Blue Ribbon Panel, and NRC advice to Tetra Tech of what to say and how to say it so that the community's concerns will be mollified. Well, I haven't been convinced and I don't think many other community members have been either.

Letter 36
Vicky Steinitz

two (2) or more consecutive work days shall be evaluated by the Occupational Health Officer or designee prior to returning to work. If the Occupational Health Officer has a reasonable suspicion that the employee's illness may be related to an exposure to any high risk agent, the Occupational Health Officer shall immediately notify the Boston Public Health Commission in accordance with the guidelines for the Implementation and Enforcement of Boston Public Health Commission's Disease Surveillance and Reporting Regulation".

- 36.6** A 10-kilometer (km) radius was defined around the proposed NIH Boston University Medical Campus NEIDL site. A guideline of 1-km radius study area within the city limits and a 2.4-km radius outside city limits is provided by the U.S. Nuclear Regulatory Commission as generally sufficient for assessing potential environmental justice impacts associated with activities other than nuclear power plants (NUREG 2003). For NEIDL, environmental justice data were collected for a radius of 10 km of each of the three sites, which is 10 times the city recommendation of the U.S. Nuclear Regulatory Commission. The larger radius is used to ensure that all potentially affected areas are considered. Demographic data were collected from the U.S. Census Bureau's 2000 decennial census for each census tract within the 10-km area; that is the most recent year for which data are available at the census tract geographic level.

Biodefense Research and Development Policy: A Citizen Perspective

The U.S. does not yet have a rational approach to determining how much biodefense laboratory capacity is needed, what research we should be doing, and how to ensure it is being conducted safely.

Part 1: The concern

We, the undersigned, face the reality or prospect of federally-funded high containment biodefense labs being situated in our communities. We represent citizen groups from many localities throughout the U.S. who have specific health, safety and environmental concerns about their presence in our neighborhoods and cities. We are united in our belief that the proliferation of these laboratories represents a significant threat not just to our communities, but also to our nation, and the world. We agree with Biological Weapons Convention non-proliferation experts that we risk creating a biowarfare arms race with those who do not trust and cannot verify U.S. intentions. The spread of these labs makes us all less safe.

Since the August 2008 revelations that the 2001 anthrax letters originated from within the premier U.S. biodefense lab, it has become tragically clear that Congress must move quickly to re-evaluate the nation's biodefense programs. We share many concerns about the expansion of bio-safety level 3 and 4 laboratories in federal facilities, and in the hundreds of poorly regulated or unregulated academic and private sector laboratories around the country.

- **Failure to acknowledge community concerns.** We have tried in numerous ways to call attention to problems of community safety and the limited roles afforded citizens in communities where laboratories are proposed and sited. And we have experienced years of dismissive responses to these concerns from those promoting and funding laboratory expansion. The anthrax letters case, bio-lab accidents and security breaches reported in the last several years make clear that the specific and repeatedly dismissed health, safety, and environmental concerns communities have raised are real and require a more adequate response.
- **Flawed risk assessments.** In each of our communities, we have found that environmental impacts and hazards associated with these labs have not been analyzed with thoroughness, clarity and scientific rigor. It is not possible to mitigate unacknowledged risks. In particular, we have been appalled by the failure to take environmental justice considerations into account in siting laboratories. Additionally, there has been inadequate community input to the planning and design of risk assessments, resulting in assessments that do not reflect community concerns.
- **Accidents.** Initially we were told that there was virtually no possibility of accidents in high containment labs; it has become clear however that many laboratory accidents have occurred and many have gone unreported. This is demonstrated by the tularemia infections at Boston University, revealed by a whistle blower, and the Brucella infections at Texas A & M, uncovered by the Sunshine Project. The CDC has records on more than 100 reported accidents in the past several years in Level 3 and 4 labs.
- **Lack of effective regulation.** It has also become clear that laboratory regulation and oversight are poor, as detailed by the Government Accountability Office in 2007 and 2008. The GAO reports that safety programs and protocols are inadequate and have not been followed with consistency and rigor. Many

Letter 36
Vicki Steinitz

- private and academic BSL-3 laboratories are essentially unregulated.
- **Lack of transparency.** Transparency is a prerequisite for effective oversight, for establishing trust with communities and with others who may not trust the intentions of the United States. It is required to make the Biological Weapons Convention a viable treaty. Yet the work conducted in U.S. biodefense labs is not transparent. Despite great effort, community groups have been unable to obtain vital information about what is actually happening or planned for these laboratories. Security concerns are used as an excuse to restrict citizen access to reports of ongoing or planned studies. Freedom of Information Act requests about accidents and the minutes of Institutional Biosafety Committee meetings are routinely denied.
- **Defining acceptable risks.** “Low-probability” but “high-consequence” accidents that could result in a public health disaster in our communities are of great concern. Who decides what is an acceptable level of risk? Should an academic institution, a corporation, or a federal agency decide what is acceptable risk for the at-risk citizens?

Our concerns extend far beyond our individual communities.

- **Dangerous growth in labs and workers handling select agents.** We are sobered by the fact that since the anthrax letter attacks, the number of workers in these labs has grown from a small number to over 16,000; bio-safety laboratory space has grown up to twenty-fold since 2001. Yet by most accounts, including the GAO and the World at Risk report, the “unbridled increase” in research and development with bio-warfare pathogens has made the world less safe.
- **Poor research agenda oversight.** The research agenda of U.S. biodefense programs has also expanded greatly in the wake of the 2001 anthrax letters. Who sets priorities for biodefense research? For example, who decided it was acceptable to genetically recreate, transport, and do research on the formerly extinct 1918 flu virus, regardless of the risks involved? There are far too many comparable examples.
- **Misplaced funding priorities.** Since 2001, there has been an exponential increase in funding for biodefense research on exotic pathogens posing theoretical risks, while funding for infectious disease research has declined slightly. In 2005, more than 750 scientists, including Nobel Prize-winners, decried the diversion of funds to biodefense programs away from vital and pressing research of broad applicability on infectious diseases and pandemics.
- **Dual-use research hazards.** We are concerned about the threats associated with exotic, genetically modified pathogens, which can serve as bio-weapons agents. Dual-use research is either offensive or defensive, based only upon intent. Much BSL-3 and BSL-4 research is dual-use by its very nature, which increases the risk of misuse, and can raise serious questions about U.S. compliance with the Biological Weapons Convention.
- **Risk of internal sabotage.** Now we also know that the possibility of internal sabotage is quite real. We have been told officially that both the weaponized anthrax and the perpetrator of the only bio-terror attack in our history came from within the U.S. biodefense program.

We need a new policy and a new model for responding to biothreats.

Letter 36
Vicki Steinitz

We cannot afford to simply continue the uncritical bio-defense building boom of the last eight years.

- **We need an integrated, coherent federal policy.** Since 2001, biodefense funding has provided a \$60+ billion economic boon, much of it for the private sector. Biodefense programs are spread among many federal departments. However, according to the GAO and others these programs are frequently duplicative and poorly coordinated. We have seen no evidence of an integrated federal policy, still less one openly debated by Congress. Congress needs to evaluate current research and development priorities, funding levels and research requirements in relation to verifiable threats to human and livestock health. Our country needs a fact-based assessment of biological threats, both natural and man-made.
- **We need to demilitarize biomedical research.** We are aware that intense debate is taking place within the scientific community about whether or not much of the current biodefense research agenda is relevant to, or would be effective in protecting the population against natural or intentional biological threats. The emphasis on national defense in biomedical research results in profoundly different programs than those that would be based upon a public health and civic model. For instance, the focus of biodefense research on “one bug, one drug” strategies has become dominant at the expense of the development of broad-spectrum counter-measures which could be much more useful in situations like the current swine-flu pandemic. At the same time, funding has been cut for public health programs and local preparedness against potential natural or lab-generated outbreaks.
- **We need a stand down and a time out.** We need a national moratorium on the opening of new biodefense facilities and, simultaneously, a serious and transparent reevaluation of the big picture. We need a great many more answers before our government pours yet more money into these programs and creates new public health risks and international strain.

Will the concerns of citizens be heard?

The concerns of citizens are easily drowned out or dismissed amid the many voices representing financial, academic and political interests. We offer the following recommendations in hopes that the perspective of the public will at last be heard in this new Congress and Administration. We do not attempt to address all aspects of bio-defense policy, but focus specifically on the need to curb the proliferation of high containment bio-safety laboratories in our communities and to create a transparent, integrated system for federal oversight and regulation of research and development activities with select agents and other dangerous pathogens.

Part 2: Actions for the Congress and the Administration

We believe that there is an urgent need for action by the current Congress and by the Obama administration. In September 2009, the Government Accountability Office made many of these same recommendations. Consistent with standard procedures for other federal science programs that pose potential threats to health and safety, we call upon our elected representatives to:

1. **Call an immediate halt to development of new biodefense facilities and those that are not yet operational, until the many serious questions have been resolved:**

Letter 36
Vicki Steinitz

2.

Questions include those related to:

- public safety,
- appropriate locations for high containment laboratories,
- biosafety and biosecurity compliance,
- laboratory regulation,
- select agent use and control,
- dual-use research,
- citizen involvement,
- risk of bioweapons proliferation.

3. Conduct a top-to-bottom review of the biodefense program and spending priorities, based upon scientifically credible assessments that are independent of economic interests.

The review should include:

- A complete evaluation of the nation's current bio-research capacity.
- A sound risk assessment of natural bio-threats and potential bio-terrorism threat, and ways that threat can be addressed.

Note: We are familiar with earlier assessments, and the serious criticisms by the National Research Council about how they were conducted. (http://www.nap.edu/catalog.php?record_id=12206) We also note that the 2006 Homeland Security risk assessment was conducted by Battelle laboratories, a leading beneficiary of biodefense laboratory funding.

- Evaluation of the efficacy of dual-use research with select agents in protecting the population from bio-threats.

4. Make a real commitment to other approaches to threat mitigation such as international diplomacy and public health measures.

- Make the U.S. a real partner to the Biological Weapons Convention by agreeing to international monitoring and signing the implementation protocols of the treaty.
- Work diplomatically to contain the bio-weapons arms race that has begun to flourish amid the increased research.
- Refocus research onto existing public health risks.

5. Create a single, integrated, comprehensive system for federal oversight of all biodefense and bio-safety lab research, federal, academic and private.

- Consolidate the current diffuse, multi-agency regulatory and oversight systems.

Letter 36
Vicki Steinitz

- Develop and implement mandatory lab practices standards against which oversight can be conducted.
- Develop and implement a system of mandatory licensing and high level security clearances for all who work with select agents, and other dangerous pathogens.
- Establish a National Bio-Safety Facilities Safety Board to implement a system of independent safety reviews of all bio-labs, with mandatory compliance for remediation of safety violations, and reporting directly to Congress. This Board could be based upon the successful model of the Defense Nuclear Facilities Safety Board, which monitors the nuclear weapons complex. *See attached proposal for details.*
- Require transparency to Congress and the public, about lab practices, accidents, research agenda and what pathogens are being used at labs.

Note: Recommendations such as these have been made by virtually every governmental and non-governmental report dealing with U.S. biodefense in the past several years. Practices involving significant oversight and regulation have long been an assumed way of doing business for those working with nuclear materials. Licensing of professionals who deal with matters of public safety is universal, from medical professionals to airline pilots. In all these cases there is an agreed civic understanding, a social contract that assumes that the public risks associated with the work of these individuals require such regulation. It is time the same is done for work with biological pathogens that represent a danger to the general public.

5. Give citizens a meaningful place at the table as these changes are made.

- There will need to be more hearings in Congress and in local communities in order to determine how best to move forward. **Include the expert testimony of those of us living with current and proposed bio-defense laboratories in our communities.** We have a personal investment in safety, the unique perspective of “front-row seats,” and a wealth of detailed knowledge about the issues. We are not paid lobbyists pro or con. We are the people directly impacted.
- Communities are significant stakeholders and should have key roles in the siting, design, regulation and operation of bio-safety laboratories. Both the general public and local governments need to be involved because their interests are not necessarily the same. While local officials may have economic interests in inviting laboratories into their communities, citizens may have different vulnerabilities and concerns. **Citizen input needs to directly inform all aspects of laboratory planning, design, development and operations.** There needs to be a new model, a new mechanism to insure that this happens. What is required is a process and culture of accountability to communities, rather than a culture that patronizes communities.

In conclusion, we want to emphasize that the difficulty in regulating cannot be an excuse for inaction.

We recognize the unique nature of biological research that makes finding solutions to regulation and oversight difficult. We realize that some beginning steps have been taken to address some of our concerns since the

Letter 36
Vicki Steinitz

summer of 2008, when the country was focused on the anthrax letters case. We understand and support the importance of basic bio-medical research that bears unexpected and important fruit. Yes, it is the century of biology, with all of its extraordinary promise for human health.

But *difficult* cannot be an excuse for the current lack of oversight, and the dangerous practices that have been occurring in so many of these labs. We cannot continue to use the internally generated anthrax letters as a justification for unbridled research with select agents, particularly in high population communities.

First steps have been taken, but without a fundamental look at biodefense research and development policy. It is imperative that we be clear about spending our research dollars to address real and present threats to human health. It is imperative that the nation step off the bio-defense bandwagon, take a deep breath and embark upon a path that does not create more risks than it fixes.

Subject: Comment - BU Biolab

I am writing to express my deeps concerns about the proposed BU Biolab. As a Union Park resident in the South End, I am fearful that my family could be exposed to deadly viruses. This exposure would be possible through negligence at the facility, a terrorist attack, or some other act of god. Given that there are multiple threats of something going wrong, I strongly believe the proposal should be cancelled in the current location. The South End is residential in character and there is no place for this biolab in the heart of Boston. It should be moved to a more remote location.

Please confirm receipt and that this note was added to the objectors list. Thank you.

RE: Comments on the Draft Supplementary Risk Assessment for the National Emerging Infectious Diseases Laboratories

To Whom It May Concern:

The Draft Risk Assessment for the Boston University National Emerging Infectious Diseases Laboratories (NEIDL) lacks an analysis of the projects impact on Boston's homeless population.

Rosie's Place is a sanctuary for poor and homeless women located within one-quarters of a mile from the BioSquare Research Lab. We provide a safe and nurturing environment that helps over 10,000 poor and homeless women a year maintain their dignity, seek opportunity and find security in their lives.

38.1

Many of the women we serve are homeless and most of our homeless guests stay at shelters or on the street in the vicinity around the slotted location for the NEIDL. As you are in the process of assessing the health impact of the proposed NEIDL project in Boston, we encourage you to include Boston's homeless population in your study. Due to homeless individuals' transience and greater susceptibility to infectious diseases, their vulnerability is even higher than the general low-income population.

There are six shelters that our guests stay at within a 1-mile radius of the BioSquare Research Lab. Additionally, many of our homeless guests receive medical care at Boston Medical Center and the Boston Healthcare for the Homeless Program, which are across the street from the proposed lab.

We appreciate your mention of environmental justice, and your study of the potential disproportionate health impact on minority and low income populations in the draft of the Risk Assessment. In your final draft we hope you consider including a safety analysis for our city's homeless residents, particularly those who stay in such a close radius to the proposed Boston location.

Thank you for your time and consideration. If you have any questions, please feel free to contact me at asheldon@rosiesplace.org or 617-318-0244.

Anne Sheldon
Public Policy Assistant

Letter 38
Anne Sheldon

- 38.1** The Draft Supplementary Risk Assessment followed NEPA and the Council on Environmental Quality (CEQ) guidance for conducting the Environmental Justice analysis. Per CEQ guidance, available demographic data from the U.S. Census Bureau census tracts and block numbers were used to identify the composition of the potentially affected population. The U.S. Census Bureau census tract and block number data does not include statistics inclusive of homeless population data.

Re: Draft Risk Assessment Report for the Boston University National Emerging Infectious Diseases Laboratories

Dear Sir or Madam:

We represent the plaintiffs in federal and state lawsuits regarding the proposed National Emerging Infectious Diseases Laboratories (the "NEIDL") at Boston University Medical Center. *Allen et al. v. National Institutes of Health et al.*, Civil Action No. 06-10877-PBS (D. Mass.); *Ten Residents of Boston v. Boston Redevelopment Authority et al.*, Civil Action No. 5-0109-BLS1 (consolidated with No. 5-02665) (Suffolk Sup. Ct.). This letter provides our clients' comments regarding the Draft Risk Assessment Report ("RA") for the NEIDL. The RA inadequately addresses both (1) feasible alternatives to the NEIDL and its proposed location; and (2) the potential risks of the NEIDL to nearby environmental justice ("EJ") communities. It also largely ignores many of the comments of the National Research Council's Committee on Continuing Assistance to the National Institutes of Health on Preparation of Additional Risk Assessments ("NRC"). These inadequacies and omissions are especially troubling given the project's proposal to house extremely rare and lethal pathogens within a densely populated urban area. Also troubling is that the RA, despite opaque assertions to the contrary, appears not to address the multitude of public comments submitted to the National Institutes of Health ("NIH") and Boston University ("BU") over the past decade that express grave concern and opposition to the NEIDL. Despite the numerous comments and substantial input from community members, NIH once again appears to have failed at its task of preparing an adequate risk assessment in accordance with NEPA requirements. For the reasons set out in further detail below, our clients request that NIH withdraw the RA and initiate a public process to reconsider alternative uses for the facility constructed at BU/Boston Medical Center.

The following sections provide our clients' comments on the RA, both generally and with respect to the individual chapters. These comments are in addition to those raised verbally by

Letter 39
Anderson & Kreiger LLP

- 39.1** Given the technical nature of the document, the NIH prepared a *Reader's Guide* to accompany the Draft Supplementary Risk Assessment. The *Reader's Guide* was sent to each person who requested the Draft Supplementary Risk Assessment and was also published on the Blue Ribbon Panel's web site (<http://nihblueribbonpanel-bumc-neidl.od.nih.gov/>). The intent of the *Reader's Guide* was to provide the reader with a brief synopsis of the approach, methods, and results contained in the Draft Supplementary Risk Assessment.
- 39.2** Whenever possible and/or appropriate plain language was used in the Draft Supplementary Risk Assessment. The Draft Supplementary Risk Assessment was developed, in part, based on the input of which agents and scenarios members of the Boston community wanted to see analyzed. Considering the public's input into these scenarios, equal significance was given to each of the scenarios analyzed.
- 39.3** A thorough evaluation of the site characteristics at each of the proposed alternative sites, (urban, suburban, and rural) was included in Appendix B of the Draft Supplementary Risk Assessment. The information contained in Appendix B, as well as Section 2.2 of the Draft Supplementary Risk Assessment, shows that the only site that could reasonably accommodate the NEIDL's mission is the urban site, located at the Boston University Medical Campus.
- 39.4** The analyses do address external differences such as population and meteorology, so the only differences not addressed are the building and its operations. There is no basis for assuming that operations within a facility would be different solely because of its location, since all the mandatory building and operational safeguards would be in place regardless of where the NEIDL was located. Thus, operations (e.g., standard operating procedures, personal protective equipment, etc.) are assumed to be the same for all three sites. Differences in the building design would have negligible effects on the results of the analyses because of the nature of the analyses. The centrifuge and needlestick analyses are only affected by the operations inside the facility, which would likely be identical.

our clients and other community members at the public hearing on the RA held on April 19, 2012 at Roxbury Community College (the "Hearing").

General Comments

39.1

A. The RA is overly dense and inaccessible to a lay audience.

In its Letter Report dated December 15, 2011 regarding the 90% Draft of the RA (the "Letter Report"), the NRC noted that the draft was "an extremely large and technically complex document. It strongly recommended that "both an Executive Summary written for the lay audience and a summary of Chapter 11 that synthesizes and interprets the major findings of the RA in plain language be developed to facilitate public understanding." Letter Report at 8. Despite that, the RA has only grown and still fails to include any useful summaries. It now consists of over 1700 pages of mostly technical information that is largely inaccessible to a non-expert. In addition, the document offers disjointed analysis with limited cross-references between sections (another improvement recommended by the NRC), leaving readers with no option but to thoroughly review every chapter and its appendices to determine whether an analysis promised in one chapter has actually been carried out in another.

39.2

The dense and meandering RA not only fails to address the NRC's comments, but also fails to comply with Council on Environmental Quality ("CEQ") guidance urging federal agencies to prepare "concise," "plain language" NEPA documents that "focus on significant issues" and discuss impacts "in proportion to their significance" rather than producing "an encyclopedia of all applicable information." Nancy H. Sutley, Chair, CEQ, *Memorandum for Heads of Federal Departments and Agencies re: Improving the Process for Preparing Efficient and Timely Environmental Reviews under the National Environmental Policy Act* (Mar. 6, 2012) (the "CEQ Memorandum").¹

39.3

B. The RA, like previous risk assessments of the NEIDL, fails to meaningfully analyze alternatives.

The RA avoids any meaningful discussion of why the NEIDL should be placed in a densely populated urban neighborhood rather than an alternative, less dense one.² As courts, NRC reports, and public comments to NIH have consistently recognized over the history of NIH

¹ Compounding the practical difficulties in reviewing the RA is that NIH issued a draft risk assessment in November 2011 for NRC and public review, then withdrew that version from its website before issuing the current draft in February 2012. Many community members had downloaded and begun reviewing the November 2011 draft before it was withdrawn and were required to undertake a new analysis when the February 2012 draft was issued.

² The RA also ignores the *Alternative Vision* document developed by our clients and other community members for use of the existing NEIDL building. To this point, BU and NIH have largely ignored the *Alternative Vision* despite the fact that it provides both entities with a method for moving forward with operation of the NEIDL in a way that addresses community needs and concerns. We would be happy to provide your office with a copy of the *Alternative Vision* proposal upon request.

Letter 39
Anderson & Kreiger LLP

The maximum reasonably foreseeable (MRF) earthquake analysis would be unaffected because: 1) it assumes a total loss of biocontainment features so design differences are not relevant, 2) it assumes a ground-level release so building height differences are not a factor, and, 3) the facility design would adjust for potential site differences in seismic hazard. The frequency of an aircraft crash would be affected by a different design, but this analysis was performed solely to demonstrate that the MRF earthquake bounds it and this conclusion would not be altered. Therefore, because the alternate design information is not available or producible, and because it would not significantly alter the results if it were available, the facility design is assumed to be the same for all three sites. The risk assessment addresses the effect of commuting on potential secondary transmission for the three sites (see Section 9.3.14).

- 39.5** A threat assessment was developed as a separate component of the Draft Risk Assessment in response to concerns raised by the public regarding the capability of the facility's security systems inclusive of security/law enforcement personnel, electronic systems, policies, and procedures in place to prevent, withstand, or respond to a malevolent action (e.g., disgruntled or unbalanced lab worker, insider threats, terrorist action) against critical systems and assets at NEIDL that could result in the exposure of personnel or release of a pathogen into the community. (Chapter 6, Section 6.1.1) Because the analysis contains sensitive information, the threat assessment is a confidential/official use only document. Additionally, a threat assessment for select agents requires the plan must be reviewed annually and revised as necessary. Drills or exercises must be conducted at least annually to test and evaluate the effectiveness of the plan. Both Boston University and NIH security personnel have reviewed the analysis and conclusions of the threat assessment.

A detailed description of why the consequences of a malevolent act that result in a pathogen release from the facility will be less than the consequences for the MRF earthquake was presented in Chapter 6.8 of the Draft Supplementary Risk Assessment.

39.3

and BU's protracted permitting process, the requirement to analyze alternatives is the "heart of the environmental impact statement" required by NEPA. 40 C.F.R. § 1502.14. *Accord, Dubois v. United States Dept. of Agriculture*, 102 F.3d 1273, 1286 (1st Cir. 1996). Although the RA purports to analyze a potential suburban and rural alternative for the NEIDL, its analysis of these sites is cursory at best and is plainly written to justify the choice of the urban location rather than meaningfully analyze the other sites.

39.4

At several points, the RA blithely dismisses the differences between the potential sites without data or any rigorous analysis. For instance, it implausibly assumes that the NEIDL building would have been constructed in the same manner regardless of its location. Thus, it ignores the impacts of the available space or local zoning on the building's height, footprint, and other dimensions, and, in turn, the effects of those structural differences on secondary transmission risks or the risks of malevolent attack, among others. Even more glaringly, the RA fails to analyze how NEIDL employees would be expected to commute to the NEIDL at each of the three proposed sites, effectively ignoring the potential effects of the use of public transportation on potential risks, as well. Although the RA acknowledges the importance of such data, it claims that they are unavailable. However, the RA does not even attempt to gather readily available data on the commuting patterns of the employees of the BSL-1 and BSL-2 portions of the NEIDL building.

39.5

C. The RA avoids any meaningful analysis of the risk of a malevolent attack.

Similarly, the RA avoids any meaningful discussion of the risk of a malevolent attack on the NEIDL, another major concern consistently presented by community members to NIH. Instead, it merely notes that the consequences of malevolent acts are likely to be similar to those from accidental or natural occurrences such as needlestick incidents and earthquakes. This cursory treatment is flawed for two reasons. First, the consequences of a natural disaster and those of a malevolent attack *intended* to harm a large number of individuals are fundamentally different. An earthquake cannot target the most vulnerable points of the NEIDL structure, but the planner of a malevolent attack can, indeed presumably would, focus on specific portions of the laboratory or the release of specific pathogens. The RA must analyze this issue sufficiently to assure the public that (1) such threats have been adequately considered; (2) measures have been or will be taken to mitigate them; and (3) if such an attack occurs, procedures are in place to avoid or limit widespread harm.

39.6

Second, even if the consequences of a malevolent attack and an accidental or natural occurrence were equal, their probability is not. As criminologist James Alan Fox recently commented, "[w]hile one may calculate the probabilities of certain calamities, the likelihood of a terrorist mission targeting the facility or of a disgruntled employee intent on sabotage is inestimable." James Alan Fox, *Fatal flaws in biolab report*, Boston.com (April 24, 2012) (attached as Exhibit A). Further, as Fox explains, the RA's use of the Crimes Against Persons/Property Index (the "CAP Index") to predict the risk of malevolent attack is flawed since "[t]his statistic predicts such things as rape, robbery and burglary that might impact on a commercial establishment, such as a restaurant or a retail store, but is silent on the kind of

Letter 39
Anderson & Kreiger LLP

- 39.6** CAP Index reporting was one of only several variables used to define the potential threats at each of the three sites.
- 39.7** Medically Vulnerable Subpopulations (MVSP) are addressed throughout the Draft Supplementary Risk Assessment where appropriate, including:
- Chapter 3 addresses “Disease in Medically Vulnerable Subpopulations” for each pathogen.
 - Section 8.6 addresses the initial infection in MVSP for each pathogen.
 - Section 9.3 14 addresses secondary transmission in MVSP for each pathogen.
 - Section 11.7.4 provides the risk characterization for the MVSP.
 - Appendix I provided the detailed information for the analyses of MVSP.
- 39.8** NIH still concurs with the 2002 panel recommendations. While scientific advances have been made in the past decade, the need for this type of facility continues to be essential towards the development of effective vaccines, therapeutics and diagnostics against emerging or reemerging infectious diseases or agents that could be used against the United States for the purpose of bioterrorism.
- 39.9** Boston University will follow all applicable federal, state, and local regulations, including those of the Boston Public Health Commission.
- 39.10** Under the National Environmental Policy Act (NEPA), alternatives must be considered and discussed to a comparable level of detail, which usually also necessitates that the alternatives be developed to a comparable level. In order to undertake an analysis of the relative risks of siting the facility at a rural, suburban or urban location, the Draft Supplementary Risk Assessment assumed the risk of a release from the facility was constant regardless of location. It is assumed that any facility built at an alternative location would be designed and constructed with the same high standards of biosafety containment protection, earthquake resistance, and external force protection and that the risk of release would be the same. The fact that the facility design in this case had been developed in such a complete form could be considered an advantage in that it permitted more precision in the scenario modeling.

39.6

concerns associated with a research laboratory.” As Fox reports, the president of the company producing the CAP Index agrees that the Index “is definitely not designed to determine probabilities associated with terrorism or employee disgruntlement.” The RA should not rely on irrelevant data in areas as important as the security of a building designed to house some of the world’s most dangerous pathogens.

The glaring omission of a meaningful analysis of the risk of a malevolent attack follows a pattern of unwillingness by NIH and BU to fully confront such risks. In a decision regarding the risk assessment required under the Massachusetts Environmental Policy Act (“MEPA”), then-Massachusetts Superior Court Judge (now Supreme Judicial Court Justice) Ralph Gants noted that the risk of an intentional infection by a laboratory worker of himself or a co-worker “must be recognized to exist.” *Ten Residents of Boston v. Boston Redevelopment Authority*, 21 Mass. L. Rptr. 324, 2006 WL 2440043 at *13 (Mass. Super. 2006). Judge Gants stated that a risk assessment could not avoid analyzing these risks by pointing to the presence of security checks and security protocols to avoid them. He noted that, although CIA and FBI agents are subject to even more rigorous background checks than those likely to be used at the NEIDL, there were security breaches even within those agencies, and “there is no good reason to assume that [the NEIDL proponents] need not fear this risk.” *Id.* Although there are differences between the risk assessments under NEPA and MEPA, a failure to address the probability and consequences of a malevolent attack on a building housing dangerous pathogens is plainly inadequate under either standard.

In addition to these general concerns, our clients have concerns about specific chapters of the Risk Assessment, as well. Those concerns are outlined below.

Chapter 1: Introduction

39.7

- The Letter Report states that the draft RA included statements which “imply that the major concern in [the EJ] area is differences in population density among sites.” Letter Report at 9. The NRC commented that this chapter should include a comment describing how the principles of Environmental Justice seek to compare population characteristics, not just density, including, “variations in host population susceptibilities to infectious agents and access to appropriate healthcare.” *Id.* The RA does not adequately address those comments. Very little mention is made in this chapter or elsewhere of the unique characteristics of either EJ communities generally or EJ communities in Boston that would be impacted by the NEIDL. Where a discussion of EJ does exist, it is often limited to identifying EJ communities rather than addressing the potential impacts of the NEIDL on them.

39.8

- 1-2³: The RA references the conclusions of a Blue Ribbon Panel (“BRP”) on “Bioterrorism and Its Implications for Biomedical Research” convened in 2002 that an insufficient amount of BSL-3 and BSL-4 space existed to protect the United States from bioterrorist attack. That conclusion, even if accurate then, is outdated. The RA does not include

³ Where relevant, references to specific pages of the RA are provided.

The proposed research program determines the building space and personnel needs, and that program is the same for all sites. In the South End location, the NEIDL would rely on some of the research support facilities in nearby buildings on the Boston University Medical Campus. If those same support facilities were needed in Tyngsborough or Peterborough, the final facility might require additional square footage. The personnel needs would be the same at all sites as would the standard operating procedures.

39.11 The NEIDL has been constructed to provide safe and secure laboratory space. The systems that support containment, waste management, utilities and building systems were designed for those uses. The maintenance of those systems and the upkeep of the level of safety required for the building are issues that are addressed in the annual permit application to the Boston Public Health Commission and during inspections of laboratory space. The Boston Public Health Commission's oversight includes the review and approval of plans on commissioning, decontamination, decommissioning, hazard evaluation, inspections as well as others. Boston University must seek prior approval from the Boston Public Health Commission for any changes it makes to the approved procedures including those that address building systems, security technologies or other changes that may be implemented over the years. In addition, the Centers for Disease Control and Prevention (CDC) will perform inspections of laboratories within the NEIDL conducting research on Select Agents.

39.12 With regards to the ongoing safety of NEIDL operations, Boston University must comply with the requirements of the Boston Public Health Commission, which has full oversight over the activities of all BSL3- and BSL-4 research. This oversight includes the permitting of the facility and includes the review and approval of plans. Boston Public Health Commission oversight includes the review of each individual research project approved by the Boston University Institutional Biosafety Committee (IBC) and the space it will be using. In order to approve the permit, the Boston Public Health Commission has established specific operational and safety requirements that must be submitted by the NEIDL describing the operational safety and procedures it will implement at the NEIDL; once approved, Boston University must seek prior approval from the Boston Public Health Commission for any changes it makes to the approved practices. The publicly available Boston University Biological Safety Manual also provides information on the various aspects of biological safety that Boston University will follow at the NEIDL.

39.8

a current statement of the need for additional BSL-3 or BSL-4 space that takes into account the advances in scientific research, the changing nature of terrorism risks, and the proliferation of high-level laboratories since 2002.

39.9

- **1-9:** The RA notes that CDC and NIH guidelines will be followed for recombinant DNA (“rDNA”) research. However, Boston Public Health Commission (“PBHC”) regulations unequivocally forbid rDNA research in BSL-4 laboratories in Boston. The RA should not assume that rDNA would be permitted in all areas of the NEIDL.

39.10

- **1-17:** As stated in the general comments above, the RA assumes, without any evidence or factual support, that the NEIDL structure would be the same regardless of its location. This conclusion fails to take into account potential differences caused by local zoning or available space. For instance, a NEIDL structure at a rural site may be lower with a larger footprint. In addition, because portions of the NEIDL are already being used by BU for BSL-1 and BSL-2 research, a building sited elsewhere may be smaller and incorporate less of these spaces. These changes in architecture would affect, among other things, earthquake and airplane crash risks and pathogen transmission probabilities and patterns. The size of the building and the number of employees would also be likely to affect the risk that the NEIDL would be a target of malevolent attack. Without a reasonable analysis of potential differences in building architecture, placement and access, a meaningful comparison of risks at each site is impossible.

Chapter 2: Facility Design, Operations, and Site Descriptions

39.11

- The RA is based on an assumption of the “as built condition” of the NEIDL. Even if this assumption were proper for all three sites currently (which, as stated above, it is not), the RA fails to take into account how the NEIDL will age, be maintained over time, and be updated to account for changes in security technology, or how aging systems within the building may affect the potential risks of a pathogen release from the building. *See also Ten Residents*, 2006 WL 2440043 at *14 (“Any reasonable evaluation of a risk requires an understanding of the probability of the risk occurring over the life of the Project and the magnitude of harm that could arise if it were to occur.”).

39.12

- Chapter 2, and the RA as a whole, does not distinguish between operational controls against a release of pathogens that are required by the terms of NIH funding and those that BU ultimately has the discretion to employ. A disclosure of the practices and procedures that will actually be followed if BSL-3 and BSL-4 research takes place at the NEIDL is vital to the public’s understanding of the potential risks of the project and of the entities that will be responsible for mitigating those risks. As our client, Klare Allen, noted at the Hearing: community members must know who to call if a problem is suspected with the operation of the NEIDL.

39.13

- **2-6:** The RA references isolation facilities at the Boston Medical Center (“BMC”) as resources available to treat persons infected with pathogens from the NEIDL. The

Letter 39
Anderson & Kreiger LLP

39.13 Boston Medical Center (BMC) is a key part of the emergency response network for the City of Boston and has facilities to accept and treat individuals with unknown /potential infectious diseases including decontamination and negative pressure treatment areas located both in the ER and inpatient units. As a facility that responds to and treats issues involving infectious diseases the hospital supports, works, exercises and trains with first responders from the City of Boston and has developed detailed protocols for how to deal with a variety of pathogens including many that will be studied at the NEIDL. Responding to a potentially exposed person from the NEIDL is significantly easier than most cases because there is specific information immediately available about agents the person was working with, symptoms of the disease and how to respond to an individual who may have been exposed. In addition to the joint drills and training with the City of Boston responders, Boston University infectious diseases staff are available to the Emergency Department staff at any time to help respond to and coordinate an event. The overlapping responsibilities of BMC hospital epidemiology and NEIDL occupational health which includes the expertise of Infectious Diseases clinicians and the ongoing training of fellows on first response contribute to a high level of preparedness.

39.14 The Boston Public Health Commission has oversight responsibilities over the NEIDL and represents the residents of the City of Boston. The IBC has two voting community members that are not affiliated with Boston University who participate at deliberations related to each research protocol involving the use of pathogens or recombinant DNA. The Community Liaison Committee (CLC) is made up of six community members, of which, three have been appointed in the last two years. CLC meetings are open to the public and minutes from past meetings are available on the CLC Web site (<http://www.bu.edu/neidl/community/clc/guidelines/>)

39.15 Please see response to comment 39.5.

39.13

Massachusetts Nursing Association (“MNA”), however, has consistently made it clear that BMC has insufficient capacity to handle an outbreak involving those pathogens. *See Position Statement of MNA re: Proposed BU Biosafety Level 4 Lab* (January 2005), attached as Exhibit B. In addition, as MNA members testified at the Hearing, BMC has routinely been underfunded during the economic recession and has faced significant staffing reductions. The RA does not state that new isolation facilities, equipment, or funding for additional personnel is proposed for BMC.

39.14

- **2-15:** The RA references the BU Institutional Biosafety Committee (“IBC”) as an institution charged with oversight of research at the NEIDL. Our clients and other community members have repeatedly asked that non-BU entities also be given an oversight role for research conducted at the NEIDL, with no response from BU or NIH. None of the oversight entities referenced in the RA is accountable to the surrounding communities or directly represent them. Although the Community Liaison Committee (“CLC”) established by BU includes community members, these members are appointed by BU, serve indefinitely, and are not in direct contact with the community. Our clients and other community members opposed to the NEIDL project have tried, repeatedly, to gain seats on the CLC but have had their applications ignored. Further, CLC meetings are currently held at 9:30 a.m. when many community members are working. The CLC has also resisted efforts to open its meetings to the public.

39.15

- **2-23, 24:** The analysis of police and emergency response capabilities for the three locations is plainly written to highlight the City of Boston’s quantitatively greater capabilities without analysis of the City’s challenges in responding to emergency situations including greater population density, criminal activity, the potential need to navigate (and the vulnerability of) various bridges and tunnels that traverse important access roads, or traffic. As is the case with other issues neglected in the RA, information and statistics on these factors is readily available and should be used to accurately depict the potential sites’ differing abilities to respond to an emergency involving the NEIDL. In addition, Boston City Councilor Charles Yancey testified at the Hearing that Boston Police and Boston Fire Department officials have made it clear to him that the City is not equipped to respond to an emergency involving the NEIDL.

Chapter 3: Pathogens

39.16

- The RA fails to address the concern raised in the Letter Report that this chapter is needlessly lengthy and lacks cohesion. Moreover, contrary to the CEQ’s guidance that “[i]mpacts should be discussed in proportion to their significance,” the RA does not highlight which pathogens are riskier than others. CEQ Memorandum at 4. In fact, the more dangerous pathogens to be studied in BSL-4 areas of the NEIDL are discussed towards the end of the chapter.

39.17

- The chapter is filled with unnecessary information such as the origins of the names of different pathogens or their first discovery. This trivial information further muddies an already unclear document without informing members of the public (1) what the risks of exposure to these pathogens may be and (2) what the project proponents intend to do about those risks.

Letter 39
Anderson & Kreiger LLP

39.16 Chapter 3 of the Draft Supplementary Risk Assessment provides background information for each of the 13 pathogens in a format that introduces the pathogens, their characteristics, and relevant material to set the stage for further analyses. The goals are to introduce the 13 pathogens to the reader and provide a basis for their selection for analysis in the Draft Supplementary Risk Assessment (Section 3.5). The listing of pathogens in the risk assessment follows a logical order with BSL-3 pathogens (bacteria and viruses) followed by BSL-4 pathogens (all viruses). It is a useful resource for the reader to use when reading other portions of the risk assessment as questions about a given pathogen arise.

39.17 Please see response to comment 39.16

39.18 All statements pertaining to transmission of pathogens are based on basic science, clinical and epidemiological reports available in the published scientific literature at the time of the analyses. Section 3.5 of the Draft Supplementary Risk Assessment states how data concerning human infectious doses for the 13 pathogens under study in the risk assessment are minimal or absent in the literature. As a result, opinion was elicited from a panel of experts (as described in Appendix H) and was used to supplement data from the literature for infectious doses. All other data in Chapter 3 was obtained from the sources listed in Section 3.4 and are individually referenced throughout Section 3.5.

39.19 The estimates of differential susceptibility of MVSP and subsequent effects on infection and mortality were addressed in detail throughout the Draft Supplementary Risk Assessment, including:

- Section 8.6 addresses the initial infection in MVSP for each pathogen.
- Section 9.3 14 addresses secondary transmission in MVSP for each pathogen.
- Section 11.7.4 provides the risk characterization for the MVSP.
- Appendices I, K and L provides the detailed information for the analyses of MVSP.

39.18 { • The chapter continues to include general statements such as “person to person transmission does not happen,” without explaining the reasons for these conclusions. The NRC recommended in the Letter Report that NIH avoid such comments. Letter Report at 10. The RA also fails to consistently apply the Letter Report’s recommendation to distinguish carefully between conclusions based on expert opinion and those based on data or the reasonable assumptions underlying either source of information.

39.19 { • At several points throughout the chapter, the authors state that no literature is available regarding transmission of a certain pathogen or its effects on Medically Vulnerable Subpopulations (“MVSPs”) without attempting to draw inferences from related diseases or knowledge of the effects of certain symptoms on MVSPs. This is a significant problem in the RA’s analysis, given that the NEIDL will be located in an EJ community containing MVSPs.

39.20 { • 3-61: The RA notes that “[t]here are no reports of laboratory-acquired infections with Lassa viruses or any other BSL-4 pathogens after institution of appropriate biosafety practices.” This comment incorporates an assumption that appropriate biosafety practices will always be followed, which both the NRC and community members have noted is unrealistic.

39.21 { • 3-74, 75: The discussion of Nipah virus provides an example of the RA’s failure to take site-specific issues into account. It concludes with the statement that the possibility of person-to-person transmission is low because it requires “close contact that may be culture- and region-specific.” However, there is no analysis of how the communities surrounding the alternative sites share the cultural characteristics of communities afflicted by the virus, including, for instance, the size of households or cultural practices that could encourage close contact. Merely suggesting that secondary transmission of the virus has only taken place in regions of the world where it is endemic does nothing to shed light on the risk of someone’s intentionally or accidentally carrying that virus to an area where it is not endemic.

39.22 { • 3-74, 75: The discussion of Nipah virus also notes that “[t]here is a potential for this pathogen to be used in malevolent, intentional release scenarios as it is viable in certain high-sugar foods for several days.” This comment highlights the concern raised in the Letter Report that NIH has failed to adequately assess *the likelihood* of both accidental and intentional releases of pathogens from the lab (including a fomite carry-out scenario or malevolent attack) separately from *the potential consequences* of such releases. Instead, the RA attempts to once again dismiss the need for analyzing a fomite carry-out scenario and comes to the conclusion that any risk created by malevolent attack has been adequately analyzed in connection with the risk of an earthquake.

Chapter 4: Event Sequence Analysis

39.23 { • The RA addresses only 13 pathogens. Given the importance of the choice of pathogens to the analysis, NIH and BU should commit to reopen the RA and provide opportunities for public input if new pathogens are proposed for study at the NEIDL.

Letter 39
Anderson & Kreiger LLP

39.20 As discussed in Appendix F.1.2, of the Draft Supplementary Risk Assessment, this analysis is consistent with the NEPA regulations and with the Department of Energy (DOE) NEPA Guidance for implementation of those regulations. Consistent with the requirements of 40 CFR 1502.22 (the requirements for dealing with incomplete and unavailable information), this analysis identifies the limitations of the data used, discusses the options and significance of assumptions made, and provides a basis for use of these assumptions and data. The results presented herein reflect the uncertainty in both the data and the models used for this evaluation.

The analyses consider the variability and uncertainty of the data and models in each phase of the analysis. Consistent with the DOE NEPA Guidance, the analyses of the sequence from the initial event through exposure rely on conservatism to compensate for uncertainty/variability. This conservatism begins with the definition of the scenario. There are multiple failures in the centrifuge release scenario including: 1) a leak from the tube into the rotor, 2) failure of the rotor seal and ignoring the potential seal of the centrifuge lid, 3) the potential that a Powered Air Purifying Respirator (PAPR) has severely reduced performance, and 4) failure to detect or report the event per requirements. The needlestick scenario assumes that all needlesticks result in an infectious exposure. The MRF earthquake analysis is the extreme case because it assumes failure of all biocontainment features. In addition, the exposure calculations use conservatism, such as using maximum pathogen concentrations, using bounding release fractions, and utilizing high breathing rates. The variability and uncertainty associated with each key input of the exposure event sequences is estimated and discussed at the end of the subsection for each event in Appendix F (i.e., Appendix F.6 through F.9). The initial infection calculations that different bases could be used and performs the calculation with both expert-based and literature-based dose-response relationships (see Section 8.2.2). The uncertainty associated with initial infection and secondary transmission are addressed quantitatively in Chapters 8 and 9. Therefore, the methodology and results address uncertainty explicitly and are consistent with the NEPA requirements and DOE NEPA Guidance.

National Institutes of Health
Attn: NEIDL Risk Assessment
May 1, 2012
Page 8 of 17

39.24

• **4-16:** As stated above, the RA does not address the concern raised in the Letter Report regarding an adequate analysis of the fomite carry-out scenario. It simply distinguishes the NEIDL from agricultural research facilities in an attempt to demonstrate that such an analysis is not necessary. It does not provide any independent analysis of the fomite carry-out risk at the NEIDL. Such an analysis is especially necessary given the potential use of fomites as a vehicle for a malevolent attack.

39.25

• Chapter 4, and the RA generally, assume that facility employees will either be laboratory workers with access to pathogens or administrative staff without such access. Laboratory workers are also assumed to have training in the handling of the pathogens involved. The RA ignores, however, a third category of workers that includes maintenance and janitorial staff. Such workers may have access or exposure to pathogens in conducting their job and are likely to be less familiar with the proper procedures for handling them.

39.26

• **4-21:** The RA's Conclusion that there is no reasonable mechanism for exposure of a facility worker to a centrifuge infectious aerosol release ignores the possibility of erroneous entry by a facility worker into a laboratory. As stated above, an assumption that no breaches of best practices or NEIDL policies is highly unrealistic.

39.27

• **4-25, 26:** The Letter Report questioned an earlier draft's conclusion that the frequency of unreported needles sticks is "low," *i.e.*, only once in 1 to 100 years, based on the NRC's experience. Despite that, the RA only summarily addresses the frequency of such events and continues to assign this lower probability to needlestick events.

39.28

• **4-42:** The RA uses a conservative assumption that the HVAC system would remain operational during an earthquake and that that system, "including its dampers, sealed walls, and the room airlocks would confine" a pathogen release. Whether or not this assumption is conservative with respect to laboratory workers, it is inherently *not* conservative with respect to the public because of the conclusion that the *entire* HVAC system would remain operational. A more conservative assumption would be that the HVAC system would remain operational but that the sealed walls and room airlocks would not. At the very least, an explanation of why this is or is not plausible is warranted.

39.29

• **4-43:** The Letter Report noted that the analysis of the probability of an infected animal escape during an earthquake was "not entirely convincing." Despite that, the RA only quickly discusses this possibility and does not address what would occur if an animal did escape.

39.30

• Professor John E. Ebel, a seismologist, has reviewed the RA on behalf of the Plaintiffs and concluded that the earthquake ground motion to which the building is designed is not clear.⁴ According to Dr. Ebel, the RA indicates that the building is designed to a peak ground

⁴ Professor Ebel has been a research seismologist for over 30 years with a specialty in seismicity and seismic hazard analysis. He has published numerous studies on the seismic hazard in New England and the vicinity. A copy of his Curriculum Vitae is attached as Exhibit C.

Letter 39
Anderson & Kreiger LLP

39.21 Regarding Nipah virus, the full statement in the Draft Supplementary Risk Assessment reads “There is a possibility of person-to-person transmission of Nipah virus via respiratory secretions; however the risk is low and requires close contact that may be culture- and region-specific (Luby, Hossain et al. 2009).” The statement of low risk is supported by the evidence cited in the same section that person-to-person transmission rates were found to be low (no sustained person-to-person transmission despite many separate introductions) in endemic settings, specifically in Bangladesh, a resource-poor setting with extremely limited infection control practices. An assumption of different cultural or regional practices at the three NEIDL sites compared to Bangladesh is not required to conclude that the risk of person-to-person Nipah virus transmission would be low.

Site characteristics are addressed in Appendix B of the Draft Supplementary Risk Assessment. Differences in characteristics of populations at the three sites with respect to contact rates are addressed in Appendix L (Appendix L.2, L.2.9, L.3.14).

39.22 Since that National Research Council review, additional text was added to Section 4.1.3.3.2 of the Draft Supplementary Risk Assessment that more thoroughly explains why a scenario involving fomites was not selected for analysis. Malevolent acts are analyzed in Chapter 6 and they include removal of pathogens from the facility. The theft scenario is not unique to a given pathogen form and can apply equally to a fomite, vial, or other form.

39.23 Chapter 3.3 of the Draft Supplementary Risk Assessment explains that the thirteen agents were selected because they encompass broad categories “to describe the general nature of risks from infectious pathogens to laboratory workers and to the public at large, and to describe in broad terms

39.30

acceleration ("pga") of .12 g, which is the value that has been the basis of the seismic provisions in the Massachusetts State Building Code. If the natural period of the building is about 2 seconds, then the ground acceleration at that frequency may be less than or greater than .12 g. The RA is unclear on the ground motion at that frequency. Furthermore, there is no indication if any structures or machines within the building (centrifuges, etc.) have a seismic design, or if the RA considers earthquakes only in the design of the structure itself.

39.31

- Dr. Ebel also noted that the RA does not make clear whether an independent analysis of the seismic design for the facility was carried out, or if the building was merely designed to applicable Massachusetts Building Code standards with no independent analysis of the seismic hazard. In Dr. Ebel's experience, a special seismic hazard analysis is often carried out to fully quantify the probabilities of different levels of ground motions for a unique facility such as the NEIDL.

39.32

- Dr. Ebel was unable to determine how the RA arrived at the probability of the 2-second ground motion. The RA indicates that it is less than 1×10^{-5} based on the USGS seismic hazard maps. Dr. Ebel could not determine how the RA utilized the USGS seismic hazard maps. However, he is aware that on the 2008 USGS national seismic hazard maps, a pga of .11g has a probability of about 4×10^{-4} , which is many times greater than 1×10^{-5} . Based on his knowledge of these seismic hazard curves, Dr. Ebel does not believe that .12g pga is less than 1×10^{-5} , and would predict that it is in fact much greater.

39.33

- There are failure scenarios related to earthquakes that are not considered in the report. For example, Dr. Ebel noted that it is not clear what types of containers pathogens will be stored in. If the pathogens are stored in brittle containers (glass, brittle plastic, etc.), one must be concerned about these brittle storage containers being shaken from their storage locations during an earthquake. If the containers with pathogens are vibrated off a shelf or lab bench onto the floor and break, pathogens may escape into the building. Earthquake shaking that can cause such vibrations might also be strong enough to break windows in the building if those windows are not properly designed and constructed. If those two events occurred in an earthquake, then the environment outside the building could be exposed to pathogens even though the building itself did not collapse. There is no discussion of this kind of scenario in the RA, nor considerations of other failure scenarios that might be triggered by an earthquake.

39.34

- 4-47: The RA's analysis of potential airplane crashes focuses entirely on accidental crashes. This analysis fails to address the fact that the NEIDL structure at the Boston location would be a tall building in a densely populated city and may be an attractive target for a malevolent attack seeking to harm a large number of people. Ignoring the possibility of such an attack artificially lowers the probability of a risk of an airplane crash and underestimates the potential differences in risk between the three sites, especially given the proximity of the Boston NEIDL site to Logan Airport and the distance of the other sites from a large international airport. The RA also lacks an analysis of potential damage to nearby structures due to an intended attack on the NEIDL.

Letter 39
Anderson & Kreiger LLP

the range of potential effects from the release of such pathogens”. Therefore, any existing or new agents would represent risks that are similar to one of these 13 agents and would not require additional risk assessment because the consequences are within the bounds of the agents and accident scenarios studies under the Draft Supplementary Risk Assessment. Furthermore, community input into the research at the NEIDL will continue in two distinct forums within the processes established by Boston University. The first is the NEIDL CLC whose members are representatives of various neighboring community groups and which will continue its advisory role during the operations of the NEIDL. The second is the IBC, the committee which must approve all research involving pathogens. The IBC has two community members, and neither of them are affiliated with Boston University. The IBC members participate in all regularly scheduled monthly meetings and provide input on the proposed research projects. The minutes of all IBC meetings are posted on their publically available website. These minutes include a description of the proposed research, the pathogens that would be studied, the biosafety level, and the committee’s deliberations.

39.24 Please see response to comment 39.22.

39.25 All support staff, including maintenance and janitorial staff, will receive the appropriate training prior to their entry into the BSL-3 and BSL-4 areas. Appendix A.4.3 provides a training matrix that shows the appropriate training for administrative staff, visitors, vendors, service personnel, community members, operations and maintenance staff, IBC and Institutional Animal Care and Use Committee (IACUC), NEIDL emergency response team, and public safety emergency responders. Furthermore, due to access controls, it would be highly unlikely for a maintenance or janitorial worker to be exposed to a pathogen in the course of his or her duties.

Chapter 5: Transportation Analysis

39.35

• Members of the public expected that an analysis of NEIDL employees' and visitors' commuting patterns would have been included in this chapter given its title and the absence of this analysis elsewhere. This is an important analysis for a host of issues, including secondary transmission, the potential for malevolent acts, and the size of the population potentially exposed to pathogens. This analysis would also fundamentally affect the study of alternatives given the significant differences in potential commuting options between the urban site and the suburban and the rural sites. Further, this analysis is possible. Commuting statistics can be obtained from planning and transportation agencies. In addition, NEIDL employees already have been hired to operate the BSL-1 and BSL-2 portions of the laboratory. Their commuting patterns should be analyzed as a starting point of a commuting analysis.

39.36

• 5-7: The RA does not address the background checks or security requirements that will be required for drivers bringing materials to and from the laboratory. This is yet another example of the RA's failure to take into account the risk of a malevolent act.

39.37

• 5-14: An inset box on this page recognizes potential failures to correctly package pathogens. The RA then lists some of these types of errors and concludes, with no data, that they are unlikely. This is plainly insufficient. The RA should, at the very least, explain what safeguards NIH or BU will insist that packagers of materials not in their employ maintain and the potential consequences if those safeguards are not adopted.

39.38

• 5-26: The RA assumes that responders to a crash can be identified, contacted, and given treatment. However, even if responders can be identified and contacted, risks of secondary transmission remain in the time between exposure and contact. In addition, several of the pathogens proposed for study have no identified cure. Thus, even if responders are contacted, there is little that can be done to assist them or people with whom they have already come in contact. Finally, the RA and NEIDL proponents have emphasized that state-of-the-art protective equipment will be required for facility workers. It is unlikely that first responders will have access to such equipment.

39.39

• The chapter does not assess site-specific transportation issues in adequate detail. For instance, no mention is made of specific traffic patterns in Boston or the fact that, a delivery vehicle would likely have to travel over multiple bridges and through several tunnels to reach the NEIDL. These unique features of Boston's roadway system could affect the potential for a malevolent attack on the shipping vehicle and the emergency response time of first responders to a crash involving the release of pathogens.

Chapter 6: Threat Assessment

• The Letter Report correctly notes that this chapter may not "alleviate public concern" given that much of the data and information used therein cannot be reported for security reasons.

Letter 39
Anderson & Kreiger LLP

39.26 Equipment failures and personnel errors were considered throughout the analyses. The access control systems (e.g., biometrics or proximity card technologies) and staffing prevent a worker from inadvertently entering a laboratory. In addition, the worker would have to fail to use the appropriate personal protective equipment (PPE) for the laboratory and also make the entry at the same time as an accidental aerosol release from the centrifuge in order for the worker to be exposed. The potential that a worker attempting to enter the wrong laboratory, the access control system failing to prevent the worker's entry, the worker failing to don the appropriate PPE, and for an aerosol release to occur all at the same time is not reasonably foreseeable.

39.27 Based on the National Research Council letter report from the November 2, 2011 meeting, Section 4.2.3.3.1 of the Draft Supplementary Risk Assessment was revised to be responsive to the Council's concern and now reads: "Needlestick events in BSL-3 that are not promptly detected and reported are assigned to frequency category B (1 in 100 to 10,000 years). This frequency category assignment is appropriate and even conservative because: (1) the historic estimate is on the boundary of frequency categories A and B, (2) historic values likely overstate the value for current facilities due to enhanced practices, equipment, and facilities (see Section D.1.1 of Appendix D), and (3) the NEIDL is expected to have lower incident rates due to its attention to sharps safety (see Appendix F.7.2.1) and the enhancement of safety (see Section 2.1 of Chapter 2 Appendix F.7.3.2 of provides additional details."

39.28 The text in Section 4.2.4.3.2 of the Draft Supplementary Risk Assessment has been revised and appears in the Final Supplementary Risk Assessment as:

"The HVAC is assumed to be operational because this maximizes the potential for public exposure, which is the primary focus of this risk assessment. Cracks in the wall and leaks in the airlocks would not affect the potential for public exposure for the following reasons: 1) only cracks (rather than gaping breaches) would be expected for the Beyond Design Basis, 2) the negative pressure of the HVAC would ensure that any leakage is into the operating HVAC system, and 3) the outer shell of the building provide an additional confinement barrier."

National Institutes of Health
Attn: NEIDL Risk Assessment
May 1, 2012
Page 11 of 17

It is therefore difficult to address the adequacy of the chapter. Among other things, it is virtually impossible to determine what security procedures, emergency response protocols, employee background checks, or monitoring systems will be in place at the NEIDL.

39.40

• Our clients are especially concerned about the lack of transparency regarding background checks for NEIDL visitors and employees. It is our understanding that over the past several months, hundreds of people have been permitted to tour the proposed Boston site with only a minimal background check. Community members inquiring as to how these individuals were granted access were instructed to contact various NIH and BU officials who were unable to answer their questions as to the procedure for the background checks. The security of the NEIDL is too vital to allow such limited accountability. For instance, even the ability of unknown individuals to become familiar with the layout of the lab and the operation of its security systems during a routine tour presents immense potential for future risk.

39.41

• 6-11: The RA notes that “adversary-consequence scenarios were reviewed by BU Police Department personnel and the BU executive director of Public Safety and determined to be credible bounding scenarios.” The RA does not address these individuals’ training, ability to conduct such an analysis, or methodology.

39.42

• 6-17, 18: The RA does not adequately address the consequences of the theft of a pathogen from the NEIDL or its relative effects based on locations. Such a threat can be analyzed using population and crime statistics as well as an analysis of prior targets of bioterrorist activity. Such an analysis would not be, as the RA concludes, speculative.

39.43

• The RA appears to have ignored several high-profile cases of pathogen loss including, among other things, the disappearance of thousands of vials of pathogens from Fort Detrick and malevolent releases of anthrax. The facts surrounding these actual instances of pathogen loss contradict the RA’s conclusion that these are low-probability and low-impact events. These real-world experiences at high-security labs should be addressed in the RA.

39.44

• The RA does not account for actual escape data for SARS. The NRC’s scathing criticism (November 5, 2010) of the Tetra Tech analysis pointed out the failure to account for the three SARS lab escapes. It was assumed that NIH would explicitly incorporate this data into its analysis. Instead, the RA only briefly mentions these escapes, and then proceeds to conduct the SARS risk analysis on entirely theoretical grounds as prior drafts had done. Our comments also incorporate by reference the comments submitted to NIH by Dr. Lynn Klotz on April 22 and April 24, 2012 regarding the RA’s inadequate analysis of a potential SARS release.⁵

• The RA mentions specific cases of lab-borne infections at the BU Medical Center only in passing, including cases of tularemia and Neisseria meningitidis. These omissions are especially problematic given the RA’s emphasis on management practices as a means to mitigate risks and

⁵ A copy of Dr. Klotz’s Curriculum Vitae is attached as Exhibit D.

Letter 39
Anderson & Kreiger LLP

39.29 The last sentence of the paragraph has been revised as follows in order to clarify: “The potential consequences of an animal escape are addressed in Chapter 7 (Environmental Persistence of Pathogens).”

39.30 The peak ground acceleration is defined by the United States Geological Survey as “the maximum acceleration experienced by the particle during the course of the earthquake motion” (see <http://eqint.cr.usgs.gov/parm.php>). Therefore, the ground acceleration will be no greater than the peak acceleration.

Section 4.2.4.1 of the Draft Supplementary Risk Assessment was revised and appears in the Final Supplementary Risk Assessment as:

“For Seismic Performance Category C, the building structure must stay functional after a seismic event. (Massachusetts 1997). The BSL-4 suites are structurally separated from the adjoining floors. Such a structural separation allows for movement if an earthquake occurs, while maintaining structural integrity of the BSL-4 suites. BSL-4 suites have 12-inch-thick, reinforced concrete walls with special epoxy covering that acts as a sealant. The critical equipment (e.g., HVAC, air-locks, fire protection system, building automation system, etc.) are designed to survive the design basis earthquake and all equipment is designed so that it does not compromise biocontainment features. All fixtures for the BSL-4 suite were designed specifically for the facility and are Underwriters Laboratories tested to ensure that the facility retains its air-tightness.”

39.31 Attachment D.2 of Appendix F explains that “Weidlinger Associates, Inc. (WAI) performed an evaluation of the current containment box structural design when subjected to the seismic loads and deformation requirements of 780 Code of Massachusetts Regulations (CMR) for seismic category D. In accordance with 780 CMR, WAI has performed a dynamic modal analysis and generated a new lateral load distribution for each level of the building.”

National Institutes of Health
Attn: NEIDL Risk Assessment
May 1, 2012
Page 12 of 17

the Letter Report's recommendation that the RA demonstrate a commitment to a culture of safety.

39.45

• The disaster scenarios in this draft risk assessment fail to take into account the hardness of anthrax spores once released into the environment (they are capable of withstanding explosions) or their potential lethality over considerable distance should they be released by air. For instance, there is no mention of the fact that minute quantities of anthrax can be infective. The RA also ignores real-world experiences with anthrax exposure, most notably during the 2001 anthrax letter attacks.

Chapter 7: Potential for Released Pathogens To Become Established in the Environment

• The same comments on the analysis of pathogens in Chapter 3 apply here. This chapter is full of dense technical detail and fairly little analysis accessible to a lay leader.

39.46

• At several points in the chapter, it is noted that a release from a release lab animal "can't be ruled out." Despite that, there is no accompanying analysis of the likelihood of such a release or its consequences.

39.47

• The chapter does not address where rodents potentially released from the laboratory by an earthquake, or rodents they may come into contact with, are likely to migrate to. Given Boston's large stock of older housing, especially in affected EJ communities, such an analysis should be included.

Chapter 8: Health Effects – Initial Infection

39.48

• 8:24- The RA states that the probability of at least one initial infection or death from release of Rift Valley Virus is estimated as 84%. A risk this significant should be highlighted in the summary of the RA and placed up front, not buried deep within the results of Chapter 8. There must also be further analysis and discussion of the need to study this dangerous pathogen at the NEIDL in the first place given this high level of risk.

39.49

• As is the case in most of the RA, Chapter 8 and its appendices repeatedly refer to the "proportion" of persons classified as a member of a MVSP at each potential NEIDL site. However, the *actual number* of people within MVSPs, not their *proportion to the population* as a whole, is more relevant since it more accurately reflects the size of the population potentially affected by exposure to pathogens. A focus on proportions of MVSPs appears to be an attempt to understate the risks at an urban site and overstate them at a rural or suburban site, resulting in an inability to meaningfully compare the risks associated with each site and, in fact, a bias toward the urban site.

39.50

• The RA does not address the comment in the Letter Report that data on individuals who may fall into multiple MVSPs should be used and presented. It continues to rely primarily on

Letter 39
Anderson & Kreiger LLP

39.32 The text for Sections 4.2.4.3.1 and 4.2.4.3.2 of the Draft Supplementary Risk Assessment has been revised and appears in the Final Supplementary Risk Assessment as:

4.2.4.3.1 Maximum Reasonably Foreseeable Earthquake Affecting BSL-3 and BSL-4

Frequency Category. The NEIDL structure was designed to withstand an earthquake with a peak acceleration of 0.12g (g is the acceleration of gravity), per the requirements of the Massachusetts Building Code. The fundamental period of the NEIDL structure is 2 seconds and seismic shaking at the fundamental period has the potential of causing the greatest damage. Based on the U.S. Geological Survey (USGS) seismic hazard maps, the annual exceedance probability for a 2-second 0.12 earthquake that results in severe damage to the facility is assigned to frequency category C (1 in 10,000 to 1 million years). The MRF earthquake is assigned to frequency category C, but this is considered conservative because a significantly more severe, hence less likely, earthquake would be required to result in a total collapse of the NEIDL structure. See Attachment E of Appendix F for details of this frequency category assignment.

4.2.4.3.2 Beyond Design Basis Earthquake Affecting BSL-3 and BSL-4

Frequency Category. The NEIDL structure was designed to withstand an earthquake with a peak acceleration of 0.12g (g is the acceleration of gravity), per the requirements of the Massachusetts Building Code. The fundamental period of the NEIDL structure is 2 seconds and seismic shaking at the fundamental period has the potential of causing the greatest damage. (BUMC 2005) Based on the U.S. Geological Survey (USGS) seismic hazard maps, the annual exceedance probability for a 2-second 0.12 earthquake that results in significant damage to the facility is assigned to frequency category C (1 in 10,000 to 1 million years). See Attachment E of Appendix F for details of this frequency category assignment.

39.33 This comment is only relevant to the Beyond Design Basis (BDB) earthquake because the MRF earthquake assumes failure of all biocontainment features. As explained in Section F.8.3.2.1 of the Draft Supplementary Risk Assessment, the BDB earthquake event sequence analyzed includes the following:

39.50

analysis of one MVSP characteristic at a time, ignoring situations in which, for instance, an individual is both pregnant and diabetic or HIV-infected. This practice, as the NRC found, leads to optimistic and underestimated potential differences among vulnerable groups.

39.51

- The RA does not correct the problems of false precision (*e.g.*, 1.5×10^{-47}) noted in the Letter Report, especially since many of the parameters presented in this chapter and the accompanying appendices continue to be based on estimates and expert opinion, not actual data.

Chapter 9: Secondary Transmission

39.52

- This chapter fails to address releases designed to cause secondary transmission as a result of a malevolent act or how effective such releases might be. As mentioned above, malevolent acts are, by design, different than accidental releases in their probability to cause widespread harm.

39.53

- 9-15: This chapter's analysis of the potential for secondary transmission between sites is surprisingly brief given its importance to the ultimate siting decision and the Massachusetts Supreme Judicial Court's emphasis on a study of alternatives in the context of secondary transmission. Like other analyses of alternatives in the RA, it also suffers from a lack of data on commuting patterns that have the potential to greatly affect the probability of an infected person's contact with other members of the public.

Chapter 10: Environmental Justice

39.54

- 10-4: The RA refers to public input dating back to 2004. It is not clear what this public input includes or how it informed the analysis. Details as to how the RA evolved as a result of or was influenced by public comments would be helpful. An appendix containing prior public comments should also be considered. In addition, the Plaintiffs and other members of the Roxbury and South End communities have raised serious concerns with the openness and transparency of the community input process including the inaccessibility of NIH meetings and materials and the community's interaction with the CLC. These concerns have not been addressed.

39.55

- 10.2 Executive Order 12898 directs federal agencies to promote access to information and to facilitate public participation in matters relating to human health and the environment. There should be "meaningful involvement" of people in decisions about activities that could affect their environment or health. This directive was specifically intended to bring minority and low-income persons into the decision-making process and to take their concerns into account. The nature of the entire nine-year development and approval process in which Boston University has been engaged violates the letter and spirit of Executive Order 12898. There has been no involvement of the Roxbury or South End residents in the decisions to apply for the NIH grant, locate the NEIDL in a densely populated environmental justice area, or research deadly pathogens there.

Letter 39
Anderson & Kreiger LLP

“As a result of the earthquake, one or more containers of pathogens in liquid suspension falls and an airborne release results. Non-breakable containers will be used whenever possible (CDC and NIH 2007), so a broken container is not likely, but a container spill is possible. Containers are allowed to be opened only inside a BSC.”

Therefore, fragile containers (e.g., glass) will not be used, but spills are included in the event sequence. There are no windows in the external walls of the BSL-3 and BSL-4 laboratories. Section F.8.3.2.1 has been revised as follows to clarify:

“While loss of structural integrity is not expected, there could be a compromise to other biocontainment features. (Note: There are no windows in the BSL-3 or BSL-4 exterior walls.) One of the more affecting potential consequences would be continued operation of the HVAC system with a partial compromise of the HEPA filtration system. That configuration could result in prompt release of the aerosol with a limited attenuation. A loss of airflow is also possible, but that would result in a very gradual release and a lower public exposure, so that failure mode is not considered further.”

39.34 The consequences of an accidental aircraft crash into the NEIDL were addressed in Section 4.2.5.2 of the Draft Supplementary Risk Assessment. The consequences of an intentional aircraft crashing will be no more severe than the consequences of an accidental crash. An increased fuel loading would increase the likelihood of a severe fire, which would tend to inactivate any pathogens released.

39.35 The transportation analysis was performed consistent with the guidance for NEPA transportation analysis. Commuting patterns of workers will not affect the frequency of release due to crashes (see Section 5.3.2.2) and would only have the potential to affect the secondary transmission. A pathogen release due to a transportation crash within 10 km of the facility was determined to be beyond reasonably foreseeable, so secondary transmission would be even less likely.

39.56

• In response to allegations in the United States District Court regarding the lack of community information and consultation, Judge Saris asked the Plaintiffs to prepare a Community Outreach Plan. That proposal was filed on January 10, 2007. It has been completely ignored by NIH and BU.

39.57

• 10-7: The RA states vaguely that "health disparities are noted in Massachusetts." It should clarify which health disparities exist in each of the identified Massachusetts locations, as well as in the New Hampshire location. To conduct a proper EJ analysis, NIH must analyze which health effects are exacerbated in the EJ communities at issue.

39.58

• 10-7 The RA repeatedly cites Massachusetts' healthcare reform law to imply that all Massachusetts residents have access to healthcare. Although NIH acknowledges that there are still barriers to utilizing healthcare, it analyzes those barriers only cursorily and cites no public health studies, data, or other information to address the disparities in health care access and utilization. The Massachusetts healthcare reform law has been heavily studied and data regarding its effects are available. The RA cannot present the law as a panacea to healthcare access issues without addressing this information.

39.59

• 10-9: Regarding occupational exposure limits, the RA contrasts chemical and nuclear research with biological research, noting:

Unlike the chemical and nuclear industry, no governmental agency regulates or enforces worker or public exposure to biological agents. Nor is there legislation or a governmental entity that has set occupational or public exposure limit values for biological agents. These limits have not been set because of the essential difference between biological agents and other hazardous substances are their ability to reproduce/replicate.

There is, however, no further analysis of how the self-imposed exposure limits used in biological research should be managed or controlled. The Plaintiffs and community members have repeatedly stated their concern that it is precisely this lack of uniform regulation and oversight that could contribute to infections among laboratory workers with the potential for secondary transmission to community members.

39.60

• 10-11: The chart of public involvement opportunities provided in the RA includes several meetings held in Bethesda, Maryland, that were not accessible to members of the Boston communities. In some cases, even the internet telecast of these meetings was difficult or impossible to access. Further, the brief descriptions that "members attended and provided comments on [subject of meeting]" do not capture what influence, if any, the public involvement had on the RA.

39.61

• 10.12: Nuclear energy is not an appropriate model to use for an analysis of EJ communities with regard to the proper radius for analysis. There is little or no relationship between the effects of a nuclear accident and those of a biological accident, and no explanation is

Letter 39
Anderson & Kreiger LLP

- 39.36** Boston University requires a number of shipping safeguards, including use of qualified carriers, background check requirements on drivers, two drivers with each vehicle and others, such as the use of GPS. These practices were detailed in Chapter 5 of the Draft Supplementary Risk Assessment. These practices are currently in place with BSL-3 Select Agent shipments and involve City of Boston Response Agencies during shipment planning and are part of the protocols submitted to the Boston Public Health Commission for permitting. The carrier selected to transport select agents to the NEIDL will subject their drivers to security background checks as part of the employment process and NEIDL public safety officials will be provided proof of these checks. Also, there will be two cleared drivers for all Select Agent transports to and from the NEIDL. The transport vehicle and package will be monitored by GPS tracking and NEIDL public safety officials will have, in advance, the drivers' names, photo ID and clearance information. Upon arrival at the NEIDL the drivers ID and information will be verified and the truck and packages will undergo inspection prior to entering the perimeter.
- 39.37** Boston University will employ all packagers of materials on its property and will follow all applicable regulations as well as Boston University-specific protocols involving a sealed, liquid-tight hardened outer container. Shipments will be packaged, sealed and secured in that container within the appropriate level of containment. Boston University will instruct those shipping from other locations to Boston University of the requirements and will provide the same outer container to be shipped in the same manner to the shipper. Upon receipt, Boston University will open the outer container within the appropriate level of containment to ensure safe receipt and to minimize consequences related to possible breakage within the outer container. Packaging details, including pictures, were presented Chapter 5 of the Draft Supplementary Risk Assessment.
- 39.38** Section 5.3.6 of the Draft Supplementary Risk Assessment states that the frequency for a truck or plane crash that results in the release of infectious pathogens is Beyond Reasonably Foreseeable (one in more than 1 million years). Section 5.3.4 evaluates the potential level of exposure from a transportation crash to ensure that the consequences would not be large.

39.61

given in the RA justifying the use of the nuclear model as a substitute. It would be more beneficial for the RA to look at a smaller radius given the fact that pathogens are most readily transmitted person-to-person or vector-to-person. Such a difference would also clarify the difference between the various sites.

39.62

- Appendix I-3 states that the RA excludes people with asthma from the susceptibility analysis because “there is no known direct association of asthma with increased susceptibility to infection from the 12 pathogens.” Next, it states, without justification, that individuals with compromised immune systems were also excluded from the susceptibility analysis because of the small number of these individuals. These decisions are arbitrary and unsupported and appear to be based on the RA’s reference to national and state data rather than local data.

39.63

- **10.18- 26:** The RA’s assumption that health disparities in urban and suburban populations are similar is completely unsupported. Data should have been obtained to compare the actual existing disparities in the proposed locations.

39.64

- The RA notes a lack of data supporting the proposition that “any social contacts, regardless of race, ethnicity, or economic status are or are not more likely to become infected from an infected worker leaving the NEIDL.” Similar comments are made with regard to MVSPs and EJ status, all in support of the RA’s conclusion that there is no real difference in the risks associated with transmission in an urban, suburban or rural location. However, there is no discussion of how these factors correlate with the likelihood that individuals live in more densely populated homes or neighborhoods or use public transportation, factors that would be expected to affect secondary transmission rates. The effects of these factors are knowable; they can be documented through census data and sociological studies. Such data would be expected to demonstrate that individuals with a lower economic status are more likely to live in densely populated dwellings (including public or subsidized housing) and to use public transportation more frequently than individuals with a higher economic status. These factors bring individuals into contact with others more frequently, including potentially infected NEIDL workers, than individuals residing in single-family housing or commuting in personal vehicles.

Chapter 11: Risk Characterization

39.65

- **11-4, 5:** The RA notes that “[m]any of the 30 candidate events are bounded by (*i.e.*, have a frequency and consequence that is less than) other candidate events.” Folding the candidate events into one another because they have the same, or lesser, frequency significantly misrepresents the true scope of the risk, which should actually include the frequencies of *all* candidate events summed together. The event-by-event analysis employed in the RA results in a focus on the low probability of any *specific* event. The RA does not, however, assess the risk that one or more of the events addressed will occur. This choice of analyses presents an incomplete and fragmented picture of the risks of the NEIDL project as a whole.

39.66

- The RA’s use of candidate events also ignores the possibility that multiple events could take place at the same time or that the occurrence of one event could make another more likely.

Letter 39
Anderson & Kreiger LLP

If a release due to a transportation crash were to occur, the exposure levels would be much lower (5.3%) than that of an exposure resulting from the MRF earthquake. The resulting conditional probability of an infection would range from about 9.3% at the urban site to 0.11% at the rural site. Therefore, not only is the frequency of a transportation crash that causes a pathogen release small, but the potential consequences are also small.

39.39 Please see response to comment 39.36.

39.40 NEIDL employees will undergo comprehensive background and security checks which may include the following:

- Criminal background check and fingerprinting in accordance with Boston University public safety requirements,
- Department of Justice Background check,
- Basic background check; verification of SSN, academic credentials, past employment, licenses and credentials, sexual offender registry information check, credit history check, Driving record,
- Medical clearance process which may include; evaluation, drug screening, initial psychological screening, immunization/titer level review.

Visitors to the NEIDL will be pre-registered through public safety and will have restricted access based upon the purpose of the visit. Visitors will be subjected to federal database checks and will be screened (persons and packages) by public safety officers prior to entering the building. Visitors are under escort at all times while inside NEIDL. Boston University has established background check criteria for all individuals who enter the NEIDL, including all individuals who register for a tour of the facility. There are no exceptions to these requirements and for security and confidentiality reasons the information on these checks cannot be disclosed publicly.

39.41 Adversary-consequence scenarios were reviewed by The Boston University Executive Director of Public Safety and members of the Boston University Police and Public Safety Department. The Executive Director of Public Safety, Thomas Robbins, is a 33 year law enforcement professional who served with the Massachusetts State Police for 27 years.

39.66

For example, if the building or lab space is compromised by an earthquake or other natural disaster, a malicious actor (whether a lab worker or someone from outside) might well take the opportunity to remove pathogens from the lab and release them in the City. A malicious release could be catastrophic, especially because first-responders and other emergency resources would likely already be overtaxed. The risk of multiple events occurring in this way is not even considered by the RA.

39.67

- Some risks that would be created by malevolent acts that are *not* directly related to the release of pathogens (e.g., fire, building collapse, violence in order to obtain pathogens), are unlikely to occur absent the placement of a target for those acts (i.e., the NEIDL) in any of the sites studied. The additional risks of these non-biological attacks on the lab, and the varying nature of these risks depending on the location of the lab, should have been analyzed. The RA includes no analysis of the likelihood of malevolent acts in different sites. Due to the potential to cause greater injury and loss of human life and disruption of economic and political activity, a facility's placement in an urban area would be expected to create a greater risk of a malevolent attack than in a rural or suburban area. *See also Ten Residents of Boston*, 2006 WL 2440043 at * 17 ("when one recognizes that the true 'worst case' scenario involves the risk of contagion, not inhalation, then the density of the population surrounding the Biolab may have greater consequences for the extent of the harm arising from that 'worst case.'").

39.68

- **11-24:** The RA's conclusion that increased population density does not result in increased risk again ignores commuting patterns. Location of the NEIDL at the urban site would likely lead to greater use of public transportation by NEIDL employees than its placement in the suburban or rural site. The available public transportation connections to the NEIDL are also located such that individuals would travel through the identified EJ communities in Boston. The risks to these communities associated with these differential patterns of public transportation use should be analyzed.

39.69

- **11-26-28:** The RA points to lack of published data on the effect of particular pathogens on EJ communities. However, there is no attempt to extrapolate from data on similar diseases or symptoms to better understand the potential and effect of secondary transmission on these communities. This data should be analyzed to determine if locating the lab in this EJ community is riskier than locating it at other sites.

Conclusion

After several years of litigation, their many attempts at community involvement, and several rounds of comments by the NRC, our clients understandably expected NIH to create a much improved assessment that adequately addressed the risks of siting the NEIDL in each of the three different potential locations. Instead, the RA provides yet another blatant *post-hoc* rationalization of the choice to locate the NEIDL and its dangerous research in the densely populated, urban, EJ neighborhood. While this RA is indeed longer and more complex than before, in the end, this most recent attempt at justifying the risks of placing this facility in an urban location is nothing more than smoke and mirrors. This RA, like previous environmental

Letter 39
Anderson & Kreiger LLP

39.42 Please see response to comment 39.5.

39.43 Appendix D of the Draft Supplementary Risk Assessment included the 2001 *B. anthracis* letter incident and similar events that resulted in potential exposures. The incident presumably referred to in this comment (i.e., "...disappearance of thousands of vials of pathogen...") involved old working stock vials, some dating back to the Korean War, that had not been used for some time and had not been entered into the pathogen inventory database. There was not any actual loss of pathogens as a result of this event and it was considered a clerical error. To address this type of scenario, the risk assessment included "Inadequate pathogen accountability" as one of its candidate event groups (see Table E-2 of Appendix E).

39.44 The three historic SARS incidents referenced in the comment were considered in the Draft Supplementary Risk Assessment (see Table D-6 of Appendix D); however, these foreign incidents were not used to estimate the laboratory-acquired infection (LAI) rates for the NEIDL because they are not directly applicable for SARS research at the NEIDL. The Beijing incident is not applicable because it did not occur in a BSL-3 or 4 laboratory, which would be the case at the NEIDL. The Singapore incident involved a worker with "minimal training", which is not consistent with the training and certification requirements at the NEIDL. There is insufficient information on the Taipei incident to determine whether their protocol were similar to those of the NEIDL. It should be noted that the recent CDC study of LAI rates (NRC 2011) also excluded these and all other foreign data from its evaluation. The risk assessment analyses were performed on the basis of NEIDL-specific biocontainment features (see Section F.2), while considering the potential for equipment failures and personnel errors. These NEIDL-specific protocol (e.g., use of hooded PAPR for all BSL-3 activities) dramatically affect the outcome of mishaps and must be considered for a relevant analysis. Use of data that are based on different biocontainment features would result in different results that are not predictive for the NEIDL. The NEIDL-specific results are summarized in Table 11-6c, which reports the frequency of public infections due to an undetected/unreported needlestick (urban site) for the relevant pathogens, for example 1 in 760 to 27,000 years for SARS.

National Institutes of Health

Page 17 of 17

assessments of the NEIDL, raises more questions than it answers and fails on many issues to provide rigorous analysis or useful conclusions as to the risks of the project.

As the Massachusetts Superior Court previously stated with respect to the NEIDL, the project:

is no ordinary project, and the potential risks it poses to the environment and public health are extraordinary and, potentially, catastrophic.... One prays that these risks are small but, in an imperfect world, these risks inevitably exist and they must be addressed, both by taking all reasonable steps to reduce the likelihood that they could occur and to limit the potentially catastrophic harm that could result if they were to occur.

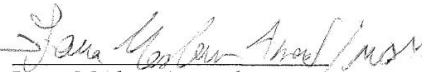

Ten Residents of Boston, 2006 WL 2440043 at 10. Given these risks, and the mistrust this project has engendered in the Roxbury and South End Communities, it is regrettable that NIH, yet again, neglected the opportunity to provide the public with a transparent and complete document. We ask that NIH withdraw the RA, address the comments presented above fully and fairly, and reconsider the need for BSL-3 and 4 research at the NEIDL through an open public process.

Thank you for your consideration.

Sincerely,

Peter Shelley

Letter 39
Anderson & Kreiger LLP

- 39.45** The characteristics of *B. anthracis* and historic incidents, including the 2001 letter incident, were addressed in Section 3.5.1.1 of the Draft Supplementary Risk Assessment. Persistence of *B. anthracis* in the environment was addressed in Section 7.3.1 of the Draft Supplementary Risk Assessment.
- 39.46** As discussed in the subsections of Section 7 of the Draft Supplementary Risk Assessment, earthquakes have the potential to release potentially infected lab animals and aerosolized pathogens that could persist in the environment. These subsections address the corresponding frequency categories and qualitatively discuss the consequences.
- 39.47** Please see response to comment 39.46.
- 39.48** The result to which this comment refers is a central estimate for the probability of at least one infection with Rift Valley Fever Virus at the urban site, conditional on the occurrence of an MRF earthquake release. The risk associated with this potential consequence must also consider the frequency with which the initiating event (the MRF earthquake) is estimated to occur: between 1 in 10,000 and 1 in 1 million years. This result was highlighted in the Risk Characterization chapter in Table 11-6b in Section 11.6.2, as well as in Conclusion #1 under Section 11.8.2 and Conclusion #2 under Section 11.8.3.
- 39.49** The population sizes of the three sites were included in the MVSP analyses and are reflected in the results. For example, Table 8-23 in Section 8.6.2.1 of the Draft Supplementary Risk Assessment shows higher estimated conditional probabilities for one or more infections among pregnant women at the urban site compared to the other sites, even though the proportion of pregnant women was assumed to be the same at all sites.
- 39.50** The National Research Council letter report acknowledged the lack of data on MVSP who may be in more than one category. Page 12 of the National Research Council letter report states: “The Committee recognizes that data on such factors may be scarce.” The analyses were therefore restricted to MVSP in single categories.

Letter 39
Anderson & Kreiger LLP

The Draft Supplementary Risk Assessment acknowledges that if an individual were to be a member of more than one MVSP, it is likely that their susceptibility would be greater as compared to an individual who is a member of a single MVSP.

- 39.51** The comment in the National Research Council letter report about false precision was addressed through the addition of text under Table 8-9 in Section 8.5.2 of the Draft Supplementary Risk Assessment: “Many of the probabilities listed in the third column are exceedingly small and are not presumed to precisely represent the actual probability of an infection occurring. The numerical results are used only to the extent that they contribute to the argument that the frequency of infections from this event occur well into frequency category D.” The numbers were retained in the table for transparency in reporting what the results of the calculations were.
- 39.52** As discussed in Section 6.8 of the Draft Supplementary Risk Assessment, malevolent acts that result in a release directly from the facility were addressed by comparison to accidental releases, as recommended by DOE NEPA Guidance. Also as discussed in Section 6.8, consequences resulting from thefts from the facility cannot be projected because of the potential consequences of such a release, after-the-fact at an unknown location, would be speculative and is beyond the scope of this risk assessment.
- 39.53** Section 9.3.14 of the Draft Supplementary Risk Assessment provides a summary of the site differences from the secondary transmission analyses, for which extensive detail is presented in Appendix L. Data from the U.S. Census on commuting patterns of residents and workers at the three sites were incorporated in several different simulations of secondary transmission among the public. Details can be found in Sections L.2.5 and L.3.14.
- 39.54** NIH has actively and extensively engaged the community and has sought community input throughout the supplementary risk assessment process. All meetings of the NIH Blue Ribbon Panel, many of which occurred in Boston, were open to the public and videocast for those who could not attend in person. Meeting locations in Boston were planned with the assistance of members of the Boston community in order to make attendance as accessible

Letter 39
Anderson & Kreiger LLP

as possible. The videocasts of those meetings were placed on the NIH Blue Ribbon Panel Web site for those who wished to view the meetings at a later date. Meetings were widely advertised on the NIH Blue Ribbon Panel web site, local Boston newspapers, and the Federal Register. Each meeting included a portion of time for public comment. Finally, all materials discussed at these meeting are accessible via the Blue Ribbon Panel web site (<http://nihblueribbonpanel-bumc-neidl.od.nih.gov/>).

39.55 This comment is outside the scope of the draft Supplementary Risk Assessment.

39.56 In a letter to the plaintiff's counsel, attorneys from Boston University outlined the community outreach plan and invited the plaintiffs to submit suggestions. However, the plaintiffs did not respond. Since 2007, the plan has been expanded and updated to include:

- An increase and upgrading of the community relations staff. Boston University reports they will soon open a full-time community-accessible office on their campus. NEIDL senior staff, are also fully engaged in the outreach effort and recently conducted 24 tours of the facility for more than 250 community representatives, elected officials, and members of the Boston University/Boston Medical Center community and residents of neighboring communities.
- Boston University remains fully engaged with the neighborhood and community associations recognized by the City of Boston, such as the Blackstone/Franklin Square Association, Worcester Square Neighborhood Association, Old Dover Neighborhood Association and the Newmarket Business Association. With an increased staff, the Boston University staff is able to attend meetings in other important neighborhoods like South Boston, Roxbury and Dorchester. The Community relations staff reports they have participated in well over 500 community meetings and events since the grant was awarded.
- The 6 member NEIDL's CLC is now expanding and will increase community participation by adding at least four new community representatives. The CLC has held regular meetings, and has become a vital community link.

Letter 39
Anderson & Kreiger LLP

- The Chairman of the CLC is routinely consulted by senior NEIDL staff on community matters and sets agendas for the CLC meetings.
- The NEIDL website, an important information source for the community, has been updated several times since 2007 to reflect the recent developments at the NEIDL (beginning research in the NEIDL's BSL-2 labs, the tours, planned research, etc.).
- More than 1 million dollars in scholarships were given to area residents by Boston University for City Lab, a college level program that prepares recipients for careers in the life sciences.
- The use of an expanded email notification system used to inform the public of important developments at the NEIDL.
- Boston University continues to maintain public repositories of public documents related to the NEIDL at 4 branches of the Boston Public Library.

39.57 The Draft Supplementary Risk Assessment acknowledges the presence of health disparities in Massachusetts. The health effects on environmental justice communities in the urban and suburban sites due to health disparities were discussed in terms of increased susceptibility to infection and secondary transmission in Chapters 10 and 11 of the Draft Supplementary Risk Assessment (section 11.7.5). No environmental justice communities were noted at the New Hampshire site.

Appendix I of the Draft Supplementary Risk Assessment provided a discussion on the susceptibility of specific MVSP (i.e., 25 the very young and the elderly, diabetics, those with HIV/AIDS, and pregnant women) using site-specific data from the three sites (in Massachusetts and New Hampshire). Quantitative analysis of health disparities would be beyond the scope of the risk assessment since there are no data to support the analysis.

The issue of exacerbation of chronic health conditions in MVSP was acknowledged in Appendix I.3.3 the Draft Supplementary Risk Assessment. Consideration of health disparities would be considered beyond the scope of the risk assessment as there is no data to support the analysis.

Letter 39
Anderson & Kreiger LLP

39.58 To address the public, state and federal courts interest in the demographic and health information regarding the community surrounding the NEIDL and how it relates to environmental justice populations, apart from the demographic data, the Draft Supplementary Risk Assessment addressed additional considerations such as health disparities among populations surrounding the urban and suburban site and access to healthcare at urban and suburban NEIDL sites. The available literature recognizes that large proportions of environmental justice communities suffer from health disparities (e.g life expectancy, morbidity, risk factors, quality of life). The literature also shows that environmental justice communities most often are comprised of individuals that have lack of access to health services. The analysis for this risk assessment therefore considered factors and available data regarding environmental justice communities and access to services in the state of Massachusetts, keeping in mind that equal accessibility to health services and medical care is not necessarily the same as equal utilization of health services and medical care. The findings are unique for the State of Massachusetts as this State has a very different health care system then most states in the Union. Massachusetts has a state regulated health care insurance coverage system which was implemented in 2006. Health care insurance coverage for people above 100% poverty level and up to 300% of the poverty level began in February 2007. Additionally, Boston University Medical Campus, a tertiary level care facility, has one million patient visits each year. Annually, one half, or 500,000, of the patients seeking care at Boston University Medical Campus have an annual income below \$20,000.00 a year, and 70% of the patients come from underserved populations (BMC, 2008). Similarly, the environmental justice communities farther away from the suburban NEIDL in Lowell, Massachusetts, access to medical care is available through the Lowell Community Health Center served nearly 35,000 local residents in 125,000 visits during 2009; 94 percent of the patients have incomes below the federal poverty level, and the majority were racial and ethnic minorities with limited English proficiency. The other large provider is Saints Medical Center that provides care to nearly 315,000 residents in 25 towns in the greater Lowell area. The Massachusetts Health Care Insurance Reform Law of 2006 applies to the populations at both the urban and suburban sites in Massachusetts. The law does not apply to populations at the rural site because it is in New Hampshire.

Letter 39
Anderson & Kreiger LLP

39.59 This comment is outside the scope of the Draft Supplementary Risk Assessment.

39.60 See response to comment 39.54.

39.61 A 10-kilometer (km) radius was defined around the proposed Boston University Medical Campus NEIDL site. A guideline of 1-km radius study area within the city limits and a 2.4-km radius outside city limits is provided by the U.S. Regulatory Commission as generally sufficient for assessing potential environmental justice impacts associated with activities other than nuclear power plants (NUREG 2003). For NEIDL, environmental justice data were collected for a radius of 10 km of each of the three sites, which is 10 times the city recommendation of the U.S. Nuclear Regulatory Commission. The larger radius is used to ensure that all potentially affected areas are considered. Demographic data were collected from the U.S. Census Bureau's 2000 decennial census for each census tract within the 10-km area; that is the most recent year for which data are available at the census tract geographic level.

39.62 The issue of asthma was qualitatively addressed in the Draft Supplementary Risk Assessment with respect to the available literature on the association of asthma with the pathogens studied in the risk assessment (Chapter 3, individual pathogen descriptions). The potential adverse effect of the pathogens on asthma is also qualitatively addressed in the Draft Supplementary Risk Assessment (Appendix I, page I-10, section I.3.3, Impact of Pathogen on Underlying Medical Vulnerabilities, lines 11-19). The risk assessment acknowledges that asthmatics are one of the diverse groups of MVSP in the community (see page I-3, lines 4-5). The risk assessment further acknowledges that the diseases caused by the pathogens addressed in this risk assessment, especially those associated with respiratory disease such as influenza, may exacerbate asthma (Page I-3, lines 25-26 and page I-10, lines 11-19).

Letter 39
Anderson & Kreiger LLP

The criteria for selecting a specific group within MVSP for detailed analysis for the Draft Supplementary Risk Assessment were explicitly stated in lines 10-13 of page I-3: (1) the condition should be relevant in a bio-medical sense and confer increased susceptibility to a pathogen, such as those under study for this risk assessment (bacteria and viruses); and (2) reliable estimates of the subpopulation should be available from federal, state, and local government sources that could be cited. The objective of performing the MVSP analysis was to generate estimates of initial infections after exposure to a pathogen and secondary spread in the community. The consequences assessed for the MVSP were infections and deaths and no evidence was found to warrant assuming an increased infection rate or an increased death rate for asthmatics exposed to or infected with pathogens under consideration. Based on review of the existing literature on asthma and the pathogens studied in this risk assessment (see Chapter 3, individual pathogens), there is no known direct association of asthma with increased susceptibility to infections from the pathogens considered in this risk assessment. Thus, based on criteria described above, asthma was excluded from a detailed quantitative analysis. With regard to the comment on data on individuals with compromised immune systems: publicly available data were noted to be only at the national and state level and not at the local level.

39.63 The draft Supplementary Risk Assessment acknowledged that health disparities are present in Massachusetts. The Draft Supplementary Risk Assessment did not assume that health disparities are similar in urban and suburban populations and these disparities were discussed separately in sections 10.5.2 and 10.7 of the Draft Supplementary Risk Assessment.

39.64 The Draft Supplementary Risk Assessment considers differences in social contact rates for urban populations due to increased population density as compared to the urban and rural sites (Appendix L.2.9.1). Estimated differences in contact rates between residents at the urban, suburban, and rural sites were applied in the secondary transmission analyses, as described in Section L.2.9.1 of the Draft Supplementary Risk Assessment.

Letter 39
Anderson & Kreiger LLP

The contact rate estimates were based on demographic data about homes, places of work, and service locations near the three sites. The effects of these site differences on the overall results were summarized in Section 9.3.14 and quantitative details can be found in Section L.3.14 of the Draft Supplementary Risk Assessment. Use of public transportation was not specifically addressed because assessment of potential links between public transit ridership and risk of acquiring infection is an open area of research and no clear correlations were found in the literature that could be used to support any further adjustments in assumed site-specific contact rates.

39.65 The inclusion of total risk was discussed with the Blue Ribbon Panel and excluded from the Draft Supplementary Risk Assessment because not all potential scenarios were analyzed. Summation of the frequency for those events that were analyzed would present a misleading perspective that would not serve the public interest.

39.66 Two concurrent independent events was considered beyond reasonably foreseeable and, therefore, beyond the scope of this analysis. However, concurrent events where there is a potential common cause were addressed in the Draft Supplementary Risk Assessment. For example, Section 5.2.3.1.1 of the Draft Supplementary Risk Assessment addressed common cause failures of transportation packaging failures, Appendix F.6.3.2.3 addressed common causes of centrifuge release and HVAC loss, Appendix F.6.3.3.1 considered common causes of reduced filtration in multiple Powered Air Purifying Respirators, the MRF earthquake analyses included a common cause of all biocontainment features, and the BDB earthquake considered the common cause of a release and HVAC compromise (see Section 4.2.4).

The comment addresses a potential malevolent act following an earthquake, which is only one very low likelihood scenario out of a host of theft scenarios. Theft scenarios were addressed in Section 6.8 of the Draft Supplementary Risk Assessment.

Letter 39
Anderson & Kreiger LLP

39.67 Please see response to comment 39.5.

As stated in Section 6.1 of the Draft Supplementary Risk Assessment, the threat assessment addressed malevolent acts for all three sites evaluated. As discussed in Section 2.0, the facility and its operations are assumed to be the same for all three sites. Therefore, the likelihood of success and the consequences associated with any malevolent act would be the same for all three sites. As shown in Section 6.8, the threat assessment considered events that did not include release of pathogens. The threat assessment included acts that result in loss of mission, several losses of laboratory personnel, and loss of technology scenarios.

39.68 Please see response to comment 39.4.

39.69 Where practical and scientifically defensible, the risk assessment attempts to extrapolate from diseases similar to those caused by the 13 pathogens studied. This is discussed in the context of 1918 H1N1 influenza virus and the recent 2009 influenza pandemic (section 3.5.1.4), SARS associated corona virus having some similarities to influenza (section 3.5.1.5) and Marburg virus having similarities to Ebola virus (section 3.5.2.2). The risk assessment acknowledges that environmental justice communities are likely to be at higher risk of infection and experience adverse outcomes as a result of all infections (section 11.7.5). There are no data or published reports to support further extrapolations.

Re: Boston High Risk Lab
To: TWIMC

To whom it may concern:

I am writing to oppose the siting of your (sic) unapproved so far bio- research facility here in Boston. The idea of building such a facility in a city known for its medicine and research begs the question as to why Boston has evolved into such a center, and not warmer, more pleasant climated cities such as New Orleans, for instance. It is, of course, because of the New England weather. It can be cold, bitterly so; so cold infact that diseases cannot, or rather, could not, spread. This is historical fact that many school children know.

Now we live in a changing climate wherein the last winter (2011-12) was the warmest on record here in the Northeast, or at least in the last century. It is for this reason alone that extreme caution must taken here. Add to this future global warming, and what once secure ^{was} becomes a vast breeding ground. So now not only must we cope with the proliferation of known and controlable diseases but also rare and incurable ones as well.

It is hoped that your group has more commonsense than those who came up with this idea. I am,

Yours truly,

Peter Ureneck

Attn: NEIDL Risk Assessment

To Whom It May Concern:

I'm writing this letter concerning the National Emerging Infectious Diseases Laboratory (NEIDL) at Boston University. I believe that NEIDL underscores the need for both scientific research and safety precautions.

NEIDL's proximity to the center of scientific and medical knowledge here in Boston just makes sense. I'm of the opinion that if a facility similar to NEIDL was sited in a distant location, such as Tyngsborough, the potential for accidental release of infection agents could be greatly increased because of the long transportation distance required. Certainly, the sooner dangerous infectious agents can be isolated, the shorter the travel to the facilities for their study, the lower the overall risk posed and the more effective they can be controlled or eliminated.

Therefore, I fully support the complete licensing and operation of NEIDL in Boston. I am confident that the staff of Boston University's NEIDL facility and its partners will address issues, as required, to safeguard our community.

Sincerely,

Lorrie Armstrong

April 4, 2012

National Institutes of Health
Attn: NEIDL Risk Assessment
6705 Rockledge Drive, Suite 750
Bethesda, MD 20892-7985

To Whom It May Concern:

As a resident of the city of Boston, I am writing to express my support for the National Emerging Infectious Diseases Laboratories (NEIDL) located on the Boston University Medical Campus. Having toured the NEIDL and seen the Draft Supplementary Risk Assessment, I trust in Boston University's ability to safely conduct valuable scientific research at the NEIDL.

I feel that the Risk Assessment demonstrates a very complete review of the potential risks associated with the laboratory. The Risk Assessment found that the researchers working within the facility were at the greatest level of risk; however the facility's safeguards and safety procedures significantly mitigate that risk. I feel that the Risk Assessment adequately shows that the risk of researchers or local residents becoming infected from agents studied in the NEIDL is generally extremely low to beyond reasonably foreseeable; for example, with SARS, Ebola, and plague, the likelihood of one to a few cases of infection might possibly occur within the range of 100-10,000 years, but infection is not likely over the anticipated lifetime of the facility (50 years).

Regarding the facility's location, I feel that the South End of Boston is an appropriate location for the NEIDL, given that so much research infrastructure is already well established on the BU Medical Campus. The Risk Assessment findings demonstrated that there are no differences in the risk of infections or fatalities to lab workers between the South End, Peterborough, and Tyngsboro sites, and that there is very small and not significant difference with comparing the locations, because the range in estimates for the three sites overlaps considerably.

Accounting for the design of the building, the safety procedures, the security systems, and other important issues, the evaluation of risk associated with the NEIDL's operation seems to have been very thorough. I am reassured that the National Research Council and its scientific experts conducted a

Letter 42
Valerie Shelley

review of the methodology used in this Risk Assessment, and noted that it was a substantial improvement over previous documents and that it was scientifically sound and credible.

After years of review and delay, I would like to see the NEIDL carryout its mission to conduct extremely important and potentially life-saving research. I support the NEIDL's mission and the long-anticipated full opening of this important facility.

Sincerely,

Valerie Shelley

To Whom It May Concern:

I am writing in support of Boston University's (BU) National Emerging Infectious Diseases Laboratories (NEIDL) in Boston's South End. I believe the National Institute of Health's Draft Supplementary Risk Assessment verifies that BU has the expertise and proper security measures currently in place to safely conduct valuable scientific research at this facility.

To assure a comprehensive study, the NIH's Draft Supplementary Risk Assessment uses very conservative assumptions to analyze the likelihood of an incident, and consequently the risk to the community, from conducting biosafety research in the NEIDL. As a resident of the City of Boston, I believe the potential scenarios outlined are credible and realistic and that the NIH incorporated the concerns and input of the community in this report.

The South End of Boston is an appropriate location for the NEIDL as the infrastructure for research is already well established on the BU Medical Campus. The Risk Assessment shows that there are no differences in the risks of infections or fatalities to lab workers at the three different sites analyzed (South End, Peterborough and Tyngboro) and that the potential risk to the community is very small and not significantly different when comparing the locations, because the range of values in the estimates for the three sites overlaps considerably.

The Risk Assessment also finds that greatest level of risk is to the researchers that would be working in the NEIDL. Given the state-of-the-art safeguards built into the design of the facility as well as the appropriate level of precautions that would be used by researchers, this risk is significantly minimized. For example, in the 1918 H1N1 scenario, the estimate for one or more infections is between 1 in 100-10,000 years.

I believe that the NIH has provided a detailed and thorough evaluation of the design of the facility and its safety and security systems. I am also reassured by the National Research Council's panel of expert scientists, who conducted a review of Risk Assessment this past December and found its analysis to be scientifically and technically credible.

The research that the NEIDL is looking to conduct has the potential to discover cures for deadly infectious diseases that can save lives. I am satisfied by the findings of the NIH's Draft Supplementary Risk Assessment and support the full opening of the NEIDL.

Sincerely,

Letter 43
J. Carter

April 28, 2012

National Institutes of Health
Attn: NEIDL Risk Assessment

Bethesda, MD 20892-7985

To Whom It May Concern:

I am writing in support of Boston University's National Emerging Infectious Diseases Laboratories (NEIDL) in Boston's South End. I believe the National Institute of Health's Draft Supplementary Risk Assessment verifies that BU has the expertise and proper security measures currently in place to safely conduct valuable scientific research at this facility.

The NIH's Draft Supplementary Risk Assessment provides a detailed and comprehensive review of the risks associated with conducting biosafety research in the NEIDL. The assessment uses conservative assumptions to analyze the possibility of an incident occurring at the NEIDL. As a resident of the City of Boston, I believe the potential scenarios outlined are credible and realistic and that the NIH incorporated the concerns and input of the community in this report.

Given the infrastructure already in place at Boston University's Medical Campus, I believe the South End is the appropriate location for the NEIDL. The Risk Assessment looked at three different sites in Massachusetts – Peterborough, the South End, and Tyngsboro – and found that there is no difference in the risk of infections or fatalities to the researcher.

The Risk Assessment finds that greatest level of risk is to the researchers who would be working in the NEIDL. Given the state-of-the-art safeguards built into the design of the facility as well as the appropriate level of precautions that would be used by researchers, this risk is significantly minimized. With air filtration and redundant operating and security systems in place, there is sufficient evidence to support the NIH's claims about the potential risks posed to researchers and local residents. The ranges of risk to the general public fall well beyond the NEIDL's anticipated lifetime of 50-years.

Having visited the facility and read the Risk Assessment, I believe the NIH has provided a detailed and thorough evaluation of the design of the facility and its safety and security systems. I am also reassured by the National Research Council's panel of expert scientists, who conducted a review of Risk Assessment this past December and found its analysis to be scientifically and technically credible.

The research that the NEIDL is looking to conduct has the potential to discover cures to deadly infectious diseases that can save lives. I am satisfied by the findings of the NIH's Draft Supplementary Risk Assessment and support the full opening of the NEIDL.

- Expertise and Proper Security Measures

I affirm the findings of the NIH's Draft Supplementary Risk Assessment, and believe that Boston University has the expertise and proper security measures currently in place to safely conduct valuable scientific research at the NEIDL.

- Conservative Assumptions

The NIH Draft Supplementary Risk Assessment uses very conservative assumptions to analyze the likelihood of an incident, and consequently, the risk to the community, from conducting biosafety research in the NEIDL. Further, I believe that the potential scenarios outlined are credible and realistic and that the NIH incorporated the concerns and input of the community in this report.

- Location

The South End of Boston is an appropriate location for the NEIDL, and the infrastructure for research is already well established on the Boston University Medical Campus. The Risk Assessment shows that there are no differences in the risks of infections or fatalities to lab workers at the three different sites analyzed (South End, Peterborough and Tyngsboro), and the potential risk to the community is very small and not significantly different when comparing the locations, because the range of values in the estimates for the three sites overlaps considerably.

- Risk Assessment

The Risk Assessment also finds that greatest level of risk is to the researchers who would be working in the NEIDL. Given the state-of-the-art safeguards built into the design of the facility as well as the appropriate level of precautions that would be used by researchers, this risk is significantly minimized. For example, in the 1918 H1N1 scenario, the estimate for one or more infections is between 1 in 100-10,000 years.

I believe that the NIH has provided a detailed and thorough evaluation of the design of the facility and its safety and security systems. - State-of-the-Art Equipment to Ensure Safety

I have had the opportunity to tour the NEIDL since I started my tenure on the CLC, and have met with lead researchers and security personnel who will be working in the laboratory. I also viewed the systems and learned of the policies that will make the research in the facility safe. From background checks to retina scan security systems to the special air filters and protection equipment, Boston University has incorporated state-of-the-art equipment and measures into the NEIDL to ensure the safety of the researchers and the public.

- City of Boston

The City of Boston has strict operating requirements for research laboratories, and I am confident that, under the oversight of the Boston Public Health Commission and city public safety departments, the NEIDL will conduct research safely and securely.

The research that will be conducted in this facility has the potential to discover cures for deadly infectious diseases that can save lives, and will have an impact on public health locally, nationally and globally. I am satisfied by the findings of the NIH's Draft Supplementary Risk Assessment and support the full opening of the NEIDL.

Thank you for this opportunity!

Sincerely,

Linda K. Lukas

Re: April 19, 2012 NIH hearing in Boston
Date: May 1, 2012

This constitutes comment on the April 19, 2012 NIH hearing held in Boston, Massachusetts on the subject of Boston University's (BU) proposed biolab.

I attended the NIH hearing along with several MNA nurses, and I testified in opposition to the siting of the lab and with objections to the quality and findings contained in the Tetra Tech risk analysis.

This hearing concerned the most recent attempt (of *multiple* 'bite-of-the apple' risk analyses that the university has been allowed) by Tetra Tech. Boston University continues its attempts to show that this facility, *already* built, *should* be built and allowed to operate on the campus of Boston Medical Center. I testified on behalf of the Massachusetts Nurses Association, which has long opposed the siting of this laboratory in an incredibly risky and foolishly dangerous site on the campus of a major medical center, in the heart of downtown Boston.

I am attaching the original MNA position statement. Nothing has changed. The TetraTech analysis is seriously flawed and this project is an example of outrageous environmental racism on the part of the federal government.

As Massachusetts and federal courts have determined, the decision to site this lab was "arbitrary and capricious" and this latest risk analysis contains nothing that would determine otherwise.

I have also attached "AN OPEN LETTER TO BIODEFENSE DECISION MAKERS, April 2012" which the Massachusetts Nurses Association has signed onto, which offers additional information supporting our position and our extensive objections to this project.

We strongly urge Boston University and NIH to reject the siting of the proposed - and already strategically outdated BU biolab - and instead adopt the alternative proposal for use of the facility. This proposal has been prepared by several respected scientists who oppose the proposed use of this facility and who have outlined numerous true public health research projects which are badly needed and which could be performed in this facility - research on antibiotic resistant infections, drug resistant Tuberculosis, sexually transmitted diseases, influenza, and so forth.

Sincerely,

Mary Crotty

NIH Supplemental Review
Faneuil Hall
Boston, MA

April 25, 2005

**Massachusetts Nurses Association
Position Statement
On the Proposed BU Biosafety Level 4 Lab**

CANTON, Mass. -- The Massachusetts Nurses Association is the professional association for registered nurses in the Commonwealth and is committed under our professional ethics to advance public policy that protects the health and safety of all residents of our communities. It is with this mission in mind that we register our opposition to the placement of any Biosafety Level 4 laboratory (BSL-4 lab) in an urban, densely populated area, where the accidental or deliberate release of a deadly biological agent could have a devastating impact on a large population of residents.

Therefore, we believe the BSL-4 lab proposed for a site located very near and directly between Boston Medical Center and the I-93 on-ramp should not be built in inner-city Boston.

While the stated purpose of enhancing public health is commendable, a number of questions arise concerning the decision to build this facility in this place at this time. Among the areas of concern are the following:

Safety

While it is true that those working within the facility will be at the greatest risk of exposure, any breach would potentially infect those living and working nearby, as well as those at some distance, through known or unknown human vectors.

Are nearby hospital emergency departments prepared to contain, and treat victims of, such an outbreak? Indications are that they are not. Congressman Barney Frank testified last year that Massachusetts hospitals are not prepared for the "average Friday night," referring to overcrowding and frequent diversion of emergency patients.

Is evacuation of the community possible? Massachusetts was recently ranked as one of the states least prepared to respond to a disaster in the entire country. While this proposed laboratory is cited as a means of enabling the country to better respond to terrorist threats, the threat posed by the laboratory does not appear designed to resolve Massachusetts' disaster preparedness deficiencies.

What will be done with the waste products of this laboratory? Will waste be adequately processed prior to disposal? Will adequate care be taken to maintain the efficiency of this equipment? It takes 48 hours to verify these tests. Will waste products be held long enough for the completion of tests to confirm decontamination of the load? Where? Will any organisms or parts of organisms be chemically disinfected and poured down the drain? Is incineration or transportation to another site the last stage in decontamination of waste products? What is the environmental impact of the total disposal process?

Letter 49
Mary Crotty

Security

The assertion that there have been no reported breaches at existing Level 4 laboratories is of little predictive value. Most of these laboratories are described as “urban,” but none are in as congested a neighborhood or with such a narrow buffer. Despite increasingly tight rings of internal security and a nearly impenetrable ground perimeter, has there been any thought of attack from the air or from surface-launched projectiles? The proposed laboratory is within two air-miles of Logan Airport and traffic helicopters regularly fly over this area near the heart of Boston. The only way to avoid harm from an accidental or intentional plane crash into the facility is to remove it to a location where this occurrence would present a lesser threat.

In July 2004, I-93, the major transportation thoroughfare across Boston, was closed during the Democratic National Convention out of just such a concern. Moreover, indications are that the anthrax attack on this country in 2001 was birthed using anthrax specimens originating in a U.S. government facility.

Competent Staff/Maintenance

In support of maximum safety and security, all individuals entering this facility in whatever capacity need to pass muster both with government agencies and with appropriate credentialing bodies. While those using and maintaining this laboratory need to be assessed to be of the highest caliber, history shows that there is still no guarantee that mistakes and security breaches will never occur.

The fact that this laboratory will be used as a teaching facility and the fact that cost-containing impulses may lead to the employment, even on an ad hoc basis, of service and support personnel less than fully competent raise long-term concerns. As doors, units and biosafety cabinets are opened and closed, the airflow system must remain balanced to ensure that the potentially contaminated air not enter open areas. All contaminated air is to exit through hepa filters. Failure to maintain such filters has had disastrous effects in the past. Preventative maintenance with on-board skilled staff is necessary to ensure all equipment is serviced and operating appropriately.

Transparency

Will the exact nature of the organisms being studied or developed be open knowledge? With international cooperation at an all-time low and with long-standing treaties and covenants being abrogated, any military or proprietary secrecy would help create a climate of suspicion, possibly fostering a germ-warfare arms race.

The Ontario nursing community in the spring and summer of 2003 found official denial by both provincial and municipal officials to be prolonging and exacerbating the SARS outbreak it was mobilized to defeat. It is particularly alarming that Boston University failed to meet its legal requirements to disclose recent safety lapses and resulting harm to workers, and that subsequently, other regulatory agencies and public officials also failed to publicly disclose the potentially lethal outbreaks.

Letter 49
Mary Crotty

Oversight

In a democracy, those affected by such a project have a right to know and object to potential threats to their well-being. The professional, technical and residential communities, and organs of government at all levels, need ongoing representation on all oversight committees. Private-citizen appointments to such bodies should be made from a list of nominees submitted by long-standing groups which are independent of Boston University and the federal government.

Accountability

Boston University's spokespeople have asserted that there will be a "number" of oversight committees, but the MNA's concern is that there also be a single, ultimately accountable entity charged with the responsibility for planning and responding to an emergency or unexpected attack from or on the laboratory. Moreover, Massachusetts currently has no regulatory program for BSL-4 laboratories.

Massachusetts does have standards for other inherently dangerous facilities such as landfills and power plants as to where they might be sited, how the location decision is to be made, operations and maintenance requirements and other appropriate standards to protect the public health and environment. Similar requirements are equally relevant and important for BSL-4 laboratories. The recent multiple failures to protect workers, to report incidents appropriately, and to provide accurate information in legal filings for the proposed laboratory have underscored the need for legislation to provide the accountability, and to protect the public health and common good.

Notwithstanding our strong opposition to this project, if policymakers ultimately decide to support construction of this facility at this site, it is imperative that a single responsible entity be identified and be required to develop and communicate to the community a *safety plan* that outlines community response, protection and evacuation in the event of the accidental or deliberate release of any infectious organism or infectious substance and/or potentially infectious RNA or DNA material considered a biohazard. We would further request that members of the community participate in the development of that *safety plan*, and that there be quarterly review of both the plan and the status of the project.

Any risk/benefit analysis of this Level 4 laboratory-construction proposal must take into account the criteria associated with these principles. In situations such as these, it is prudent to err on the side of caution.

Letter 49
Mary Crotty

AN OPEN LETTER TO BIODEFENSE DECISION MAKERS

April 2012

Three years ago citizen groups from around the country expressed their concerns about the proliferation of high containment biodefense laboratories. These concerns are detailed in the attached report. Citizens facing the reality or prospects of high containment biodefense labs in their communities were troubled by the absence of a coherent federal policy for how much laboratory capacity is needed, what should be the research priorities, and how to insure the safety of these labs.

Now, others nation-wide join those who petitioned three years ago in making clear our united conviction that the spread of these labs makes us all less safe. Our understanding of the risks associated with the proliferation of biodefense laboratories has only intensified in the ensuing years. And so we, the undersigned, write again to urge federal and state decision-makers to heed the call of those most affected and to place a moratorium on the opening of new biodefense facilities until there has been a serious and transparent reevaluation of the entire program.

The overall decrease in funding for bio-defense research in the 2013 budget, the absence of funding for construction of the NBAF lab in Kansas, and the decision to halt plans for the Medical Countermeasures Test & Evaluation Facility at Ft. Detrick provide an opportunity to re-evaluate priorities and restrict further growth. But the funding cutbacks may also threaten the maintenance of safety standards and encourage the competitive race for research grants and facilities, regardless of their contribution to health security, or the safety performance of the institutions. Indeed, we worry that the cutbacks at particular sites make others such as the NEIDL at Boston University more vulnerable. We are concerned that if approved for operation, the NEIDL as well as other labs will be used for unknown purposes. We still do not see a coherent overall policy, as made shockingly clear by Wil S. Hylton in the New York Times in late October 2011.

We have learned a great deal in recent years about risks we were not told about by those promoting laboratory expansion. Controversy over the dangers posed by the creation of a highly contagious form of bird flu points to the limits of government control over critical decisions. The Center for Disease Control took a year and a half to report the plague-related death of a University of Chicago researcher. Similarly, the *Salmonella* typhimurium outbreak that sickened 109 people in 38 states has finally been linked by the CDC to faulty lab training practices. The secrecy and lack of transparency of the incident reporting process means communities most directly affected by the presence of these dangerous labs are often the last to learn of mishaps.

There has been a great deal of discussion in Washington and in the biodefense industry during the past several years about virtually all of the issues communities raised in the attached letter. Additional safety procedures have been promulgated. Some policies have been modified. However, there has been little progress on the core issues associated with the proliferation of biodefense research, as discussed in our letter. Instead, Public Health funding has been slashed. Meaningful evaluation of the U.S.'s approach to dealing with natural or manmade biological threats has not occurred. Transparency about the research agenda remains elusive. And consequently, the U.S.'s research intent continues to be suspect internationally even as the Biological Weapons Convention is being reviewed.

We are dismayed about how relevant the attached letter remains, all these years later. We ask again, urgently, that our government take a fundamental look at what it is doing with its biodefense research programs and halt construction and commissioning of new BSL-3 and 4 biodefense laboratories until it has done so.

Letter 49
Mary Crotty

Biodefense Research and Development Policy: A Citizen Perspective

The U.S. does not yet have a rational approach to determining how much biodefense laboratory capacity is needed, what research we should be doing, and how to ensure it is being conducted safely.

Part 1: The concern

We, the undersigned, face the reality or prospect of federally-funded high containment biodefense labs being situated in our communities. We represent citizen groups from many localities throughout the U.S. who have specific health, safety and environmental concerns about their presence in our neighborhoods and cities. We are united in our belief that the proliferation of these laboratories represents a significant threat not just to our communities, but also to our nation, and the world. We agree with Biological Weapons Convention non-proliferation experts that we risk creating a biowarfare arms race with those who do not trust and cannot verify U.S. intentions. The spread of these labs makes us all less safe.

Since the August 2008 revelations that the 2001 anthrax letters originated from within the premier U.S. biodefense lab, it has become tragically clear that Congress must move quickly to re-evaluate the nation's biodefense programs. We share many concerns about the expansion of bio-safety level 3 and 4 laboratories in federal facilities, and in the hundreds of poorly regulated or unregulated academic and private sector laboratories around the country.

- **Failure to acknowledge community concerns.** We have tried in numerous ways to call attention to problems of community safety and the limited roles afforded citizens in communities where laboratories are proposed and sited. And we have experienced years of dismissive responses to these concerns from those promoting and funding laboratory expansion. The anthrax letters case, bio-lab accidents and security breaches reported in the last several years make clear that the specific and repeatedly dismissed health, safety, and environmental concerns communities have raised are real and require a more adequate response.
- **Flawed risk assessments.** In each of our communities, we have found that environmental impacts and hazards associated with these labs have not been analyzed with thoroughness, clarity and scientific rigor. It is not possible to mitigate unacknowledged risks. In particular, we have been appalled by the failure to take environmental justice considerations into account in siting laboratories. Additionally, there has been inadequate community input to the planning and design of risk assessments, resulting in assessments that do not reflect community concerns.
- **Accidents.** Initially we were told that there was virtually no possibility of accidents in high containment labs; it has become clear however that many laboratory accidents have occurred and many have gone unreported. This is demonstrated by the tularemia infections at Boston University, revealed by a whistle blower, and the Brucella infections at Texas A & M, uncovered by the Sunshine Project. The CDC has records on more than 100 reported accidents in the past several years in Level 3 and 4 labs.
- **Lack of effective regulation.** It has also become clear that laboratory regulation and oversight are poor, as detailed by the Government Accountability Office in 2007 and 2008. The GAO reports that safety programs and protocols are inadequate and have not been followed with consistency and rigor. Many

Letter 49
Mary Crotty

private and academic BSL-3 laboratories are essentially unregulated.

- **Lack of transparency.** Transparency is a prerequisite for effective oversight, for establishing trust with communities and with others who may not trust the intentions of the United States. It is required to make the Biological Weapons Convention a viable treaty. Yet the work conducted in U.S. biodefense labs is not transparent. Despite great effort, community groups have been unable to obtain vital information about what is actually happening or planned for these laboratories. Security concerns are used as an excuse to restrict citizen access to reports of ongoing or planned studies. Freedom of Information Act requests about accidents and the minutes of Institutional Biosafety Committee meetings are routinely denied.
- **Defining acceptable risks.** “Low-probability” but “high-consequence” accidents that could result in a public health disaster in our communities are of great concern. Who decides what is an acceptable level of risk? Should an academic institution, a corporation, or a federal agency decide what is acceptable risk for the at-risk citizens?

Our concerns extend far beyond our individual communities.

- **Dangerous growth in labs and workers handling select agents.** We are sobered by the fact that since the anthrax letter attacks, the number of workers in these labs has grown from a small number to over 16,000; bio-safety laboratory space has grown up to twenty-fold since 2001. Yet by most accounts, including the GAO and the World at Risk report, the “unbridled increase” in research and development with bio-warfare pathogens has made the world less safe.
- **Poor research agenda oversight.** The research agenda of U.S. biodefense programs has also expanded greatly in the wake of the 2001 anthrax letters. Who sets priorities for biodefense research? For example, who decided it was acceptable to genetically recreate, transport, and do research on the formerly extinct 1918 flu virus, regardless of the risks involved? There are far too many comparable examples.
- **Misplaced funding priorities.** Since 2001, there has been an exponential increase in funding for biodefense research on exotic pathogens posing theoretical risks, while funding for infectious disease research has declined slightly. In 2005, more than 750 scientists, including Nobel Prize-winners, decried the diversion of funds to biodefense programs away from vital and pressing research of broad applicability on infectious diseases and pandemics.
- **Dual-use research hazards.** We are concerned about the threats associated with exotic, genetically modified pathogens, which can serve as bio-weapons agents. Dual-use research is either offensive or defensive, based only upon intent. Much BSL-3 and BSL-4 research is dual-use by its very nature, which increases the risk of misuse, and can raise serious questions about U.S. compliance with the Biological Weapons Convention.
- **Risk of internal sabotage.** Now we also know that the possibility of internal sabotage is quite real. We have been told officially that both the weaponized anthrax and the perpetrator of the only bio-terror attack in our history came from within the U.S. biodefense program.

We need a new policy and a new model for responding to biothreats.

We cannot afford to simply continue the uncritical bio-defense building boom of the last eight years.

- **We need an integrated, coherent federal policy.** Since 2001, biodefense funding has provided a \$60+

Letter 49
Mary Crotty

billion economic boon, much of it for the private sector. Biodefense programs are spread among many federal departments. However, according to the GAO and others these programs are frequently duplicative and poorly coordinated. We have seen no evidence of an integrated federal policy, still less one openly debated by Congress. Congress needs to evaluate current research and development priorities, funding levels and research requirements in relation to verifiable threats to human and livestock health. Our country needs a fact-based assessment of biological threats, both natural and man-made.

- **We need to demilitarize biomedical research.** We are aware that intense debate is taking place within the scientific community about whether or not much of the current biodefense research agenda is relevant to, or would be effective in protecting the population against natural or intentional biological threats. The emphasis on national defense in biomedical research results in profoundly different programs than those that would be based upon a public health and civic model. For instance, the focus of biodefense research on “one bug, one drug” strategies has become dominant at the expense of the development of broad-spectrum counter-measures which could be much more useful in situations like the current swine-flu pandemic. At the same time, funding has been cut for public health programs and local preparedness against potential natural or lab-generated outbreaks.
- **We need a stand down and a time out.** We need a national moratorium on the opening of new biodefense facilities and, simultaneously, a serious and transparent reevaluation of the big picture. We need a great many more answers before our government pours yet more money into these programs and creates new public health risks and international strain.

Will the concerns of citizens be heard?

The concerns of citizens are easily drowned out or dismissed amid the many voices representing financial, academic and political interests. We offer the following recommendations in hopes that the perspective of the public will at last be heard in this new Congress and Administration. We do not attempt to address all aspects of bio-defense policy, but focus specifically on the need to curb the proliferation of high containment bio-safety laboratories in our communities and to create a transparent, integrated system for federal oversight and regulation of research and development activities with select agents and other dangerous pathogens.

Part 2: Actions for the Congress and the Administration

We believe that there is an urgent need for action by the current Congress and by the Obama administration. In September 2009, the Government Accountability Office made many of these same recommendations. Consistent with standard procedures for other federal science programs that pose potential threats to health and safety, we call upon our elected representatives to:

- 1. Call an immediate halt to development of new biodefense facilities and those that are not yet operational, until the many serious questions have been resolved:**

Questions include those related to:

- public safety,
- appropriate locations for high containment laboratories,
- biosafety and biosurety compliance,

Letter 49
Mary Crotty

- laboratory regulation,
- select agent use and control,
- dual-use research,
- citizen involvement,
- risk of bioweapons proliferation.

2. Conduct a top-to-bottom review of the biodefense program and spending priorities, based upon scientifically credible assessments that are independent of economic interests.

The review should include:

- A complete evaluation of the nation's current bio-research capacity.
- A sound risk assessment of natural bio-threats and potential bio-terrorism threat, and ways that threat can be addressed.

Note: We are familiar with earlier assessments, and the serious criticisms by the National Research Council about how they were conducted. (http://www.nap.edu/catalog.php?record_id=12206) We also note that the 2006 Homeland Security risk assessment was conducted by Battelle laboratories, a leading beneficiary of biodefense laboratory funding.

- Evaluation of the efficacy of dual-use research with select agents in protecting the population from bio-threats.

3. Make a real commitment to other approaches to threat mitigation such as international diplomacy and public health measures.

- Make the U.S. a real partner to the Biological Weapons Convention by agreeing to international monitoring and signing the implementation protocols of the treaty.
- Work diplomatically to contain the bio-weapons arms race that has begun to flourish amid the increased research.
- Refocus research onto existing public health risks.

4. Create a single, integrated, comprehensive system for federal oversight of all biodefense and bio-safety lab research, federal, academic and private.

- Consolidate the current diffuse, multi-agency regulatory and oversight systems.
- Develop and implement mandatory lab practices standards against which oversight can be conducted.
- Develop and implement a system of mandatory licensing and high level security clearances for all who work with select agents, and other dangerous pathogens.
- Establish a National Bio-Safety Facilities Safety Board to implement a system of independent safety reviews of all bio-labs, with mandatory compliance for remediation of safety violations, and

Letter 49
Mary Crotty

reporting directly to Congress. This Board could be based upon the successful model of the Defense Nuclear Facilities Safety Board, which monitors the nuclear weapons complex. *See attached proposal for details.*

- Require transparency to Congress and the public, about lab practices, accidents, research agenda and what pathogens are being used at labs.

Note: Recommendations such as these have been made by virtually every governmental and non-governmental report dealing with U.S. biodefense in the past several years. Practices involving significant oversight and regulation have long been an assumed way of doing business for those working with nuclear materials. Licensing of professionals who deal with matters of public safety is universal, from medical professionals to airline pilots. In all these cases there is an agreed civic understanding, a social contract that assumes that the public risks associated with the work of these individuals require such regulation. It is time the same is done for work with biological pathogens that represent a danger to the general public.

5. Give citizens a meaningful place at the table as these changes are made.

- There will need to be more hearings in Congress and in local communities in order to determine how best to move forward. **Include the expert testimony of those of us living with current and proposed bio-defense laboratories in our communities.** We have a personal investment in safety, the unique perspective of “front-row seats,” and a wealth of detailed knowledge about the issues. We are not paid lobbyists pro or con. We are the people directly impacted.
- Communities are significant stakeholders and should have key roles in the siting, design, regulation and operation of bio-safety laboratories. Both the general public and local governments need to be involved because their interests are not necessarily the same. While local officials may have economic interests in inviting laboratories into their communities, citizens may have different vulnerabilities and concerns. **Citizen input needs to directly inform all aspects of laboratory planning, design, development and operations.** There needs to be a new model, a new mechanism to insure that this happens. What is required is a process and culture of accountability to communities, rather than a culture that patronizes communities.

In conclusion, we want to emphasize that the difficulty in regulating cannot be an excuse for inaction.

We recognize the unique nature of biological research that makes finding solutions to regulation and oversight difficult. We realize that some beginning steps have been taken to address some of our concerns since the summer of 2008, when the country was focused on the anthrax letters case. We understand and support the importance of basic bio-medical research that bears unexpected and important fruit. Yes, it is the century of biology, with all of its extraordinary promise for human health.

But **difficult** cannot be an excuse for the current lack of oversight, and the dangerous practices that have been occurring in so many of these labs. We cannot continue to use the internally generated anthrax letters as a justification for unbridled research with select agents, particularly in high population communities.

First steps have been taken, but without a fundamental look at biodefense research and development policy. It is imperative that we be clear about spending our research dollars to address real and present threats to human health. It is imperative that the nation step off the bio-defense bandwagon, take a deep breath and embark upon a path that does not create more risks than it fixes.

**Re: Draft Risk Assessment Report for the Boston University
National Emerging Infectious Diseases Laboratories.**

Dear Sir or Madam:

I write as staff attorney at the Lawyers' Committee for Civil Rights and Economic Justice. The Lawyers' Committee is co-counsel with Anderson & Kreiger LLP and the Conservation Law Foundation in two concurrent lawsuits, brought on behalf of a group of African-American and Latino residents of Roxbury and the South End. This letter conveys our concerns regarding the National Emerging Infectious Diseases Laboratories, concerns that emanate from those directly at risk. The comments of the Roxbury and South End residents must be taken into account under state and federal law and under the Executive Order 12898. That Order explicitly directed federal agencies to bring minority and low-income persons into the decision-making process.

From the fall of 2003, when the National Institutes of Health awarded a grant to Boston University for the construction and operation of a BioContainment facility, the Lawyers' Committee has been opposed to Level 3 and 4 research in downtown Boston. On July 11, 2005, our office filed a Title VI administrative complaint against Boston University at the Office for Civil Rights of the U.S. Department of Health and Human Services.¹ That Complaint alleged that the siting of this BioSafety Level 3 and 4 laboratory places an unwarranted burden of risk on an already vulnerable population of color. Any accidental release from that laboratory would have a disparate

¹ The administrative complaint was later the object of a Mandamus action filed in U.S. District Court in Massachusetts on May 4, 2007. [No. 1:07-cv-10861-PBS]. The Court (Saris, J.) ruled on August 26, 2008 that the Office for Civil Rights had three months after the issuance of the final Environmental Impact Statement to make its decision on the administrative complaint.

Letter 50
Lawyers' Committee for Civil Rights

impact on communities already disadvantaged in terms of health status and environmental hazards.

The siting decision violates the Civil Rights Act. The decision-making process violates the terms of Executive Order 12898. Contrary to that directive, there has been no “meaningful involvement” of the low-income residents of color in the decision to construct this laboratory. There has been no consultation regarding the location of the laboratory in densely populated Boston or the research agenda involving deadly pathogens. The residents who live in the shadow of the NEIDL draw no benefit from this laboratory. They did not build it; they will not work there; and the diseases studied are not those that afflict them. We are witnessing a return to the environmental racism of an earlier day when lead smelters and polluting factories were dumped on the poor.

50.1

50.2

Boston University has publicly declared at least twice that it intends to comply with all local, state, and federal laws. Thus far, it has not complied with the Boston Jobs Residents Policy, with OSHA, with the public disclosure requirements of the Boston Public Health Commission, or the community consultation requirements of the National Environment Policy Act. There never was a consideration of alternative sites and never were the risks mitigated. This third assessment simply rubber stamps a funding decision already made.

50.3

The alternative site conclusions of this Risk Assessment fly in the face of common sense. The Assessment considers that there is a similar risk of exposure in a sparsely settled rural area as in downtown Boston. If the risk of exposure is similar, the consequences of exposure are not. The NEIDL is located in a neighborhood that ranks lowest in key health status indicators:

- In 2008, Roxbury had the highest infant mortality rate among Boston neighborhoods, namely 65 percent.
- Fifteen percent of Roxbury adults have asthma. That is more than twice the rate of the Allston/ Brighton neighborhood.
- The diabetes hospitalization rate for Roxbury is twice that of Boston.
- Among all Boston neighborhoods, the 2009 rates of tuberculosis are highest in the South End (18.3 new cases per 100,000 persons) and Roxbury (13.5 new cases).
- In 2009, the rate of hospitalization for heart disease is highest in Roxbury, namely 30.3 per 1000 persons. That rate is 50 percent higher

Letter 50

Lawyers' Committee for Civil Rights

- 50.1** NIH prepared an Environmental Impact Statement (EIS) for the NEIDL in accordance with National Environmental Policy Act (NEPA). NIH held several meetings for the purpose of soliciting public feedback on both the draft EIS and supplemental EIS prior to publishing a final EIS. The NEPA process has also been followed during the course of the supplementary risk assessment process.
- 50.2** NEPA and the implementing Council on Environment Quality regulations require Federal agencies to analyze reasonable alternatives to a proposed action, including the no-action alternative. The NIH's Final Environmental Impact Statement (EIS) for the Boston University NEIDL analyzed fully the potential impacts of the NEIDL at the current location in Boston and the no-action alternative. The Final EIS also identified two additional alternative sites. These sites were identified as potential alternatives to the proposed action but, upon further study, were found to be unsuitable and were eliminated from further study.
- 50.3** A thorough evaluation of the site characteristics at each of the proposed alternative sites, (urban, suburban, and rural) was included in Appendix B of the Draft Supplementary Risk Assessment. The information contained in Appendix B, as well as Section 2.2 of the Draft Supplementary Risk Assessment, shows that the only site that could reasonably accommodate the NEIDL's mission is the urban site, located at the Boston University Medical Campus. Medically vulnerable sub-populations (MVSP) are addressed throughout the Draft Supplementary Risk Assessment where appropriate, including:
- Chapter 3 addresses "Disease in Medically Vulnerable Subpopulations" for each pathogen.
 - Section 8.6 addresses the initial infection in MVSP for each pathogen.
 - Section 9.3 14 addresses secondary transmission in MVSP for each pathogen.
 - Section 11.7.4 provides the risk characterization for the MVSP.

Appendix I provided detailed information for the analyses of MVSP.

than the overall Boston rate.

- Roxbury has the highest percentage of individuals living below poverty level within the Boston area. Contrast 38 percent of the population living below poverty level in Roxbury with the 17 percent for Boston.

50.4

We believe that the public health needs of the residents who live in the shadow of the NEIDL should be the subject of research funded with public health dollars. Ebola, Marburg Virus, Lassa Virus, Junin Virus are not even remotely related to the health problems confronting Boston's disadvantaged minority residents.

50.5

There are now 9 or 10 Level 4 laboratories in operation or near operation in the United States. It is not clear what agency, if any, is monitoring the choice of research projects, their implementation, the hiring protocols, the screening of lab workers and the periodic re-screening of those same workers. At the local level, community residents are concerned that the Boston Public Health Commission is insufficiently staffed and funded to be able to perform its regulatory functions. Given the large number of biological laboratories already in existence in the Greater Boston area, each of which has institutional biosafety committees approving countless research projects, the Public Health Commission is already stretched in its oversight role. It cannot possibly assure the neighborhood residents that it will have the capacity to be an effective monitor of the NEIDL.

Thank you for your attention.

Sincerely,

Laura Maslow-Armand, Esq.

Letter 50

Re: Comments on Draft Risk Assessment Report for the Boston University
National Emerging Infectious Diseases Laboratories (RA)
Distributed February 2012

Summary

On balance, the Draft Risk Assessment distributed in February 2012 and reviewed at a public meeting held at Roxbury Community College on April 29, 2012 is a significantly better assessment than the assessments prepared previously by the NEIDL's proponents -- Boston University and the NIH.

Although the current Draft Risk Assessment is significantly better than previous assessments prepared by the NEIDL's proponents, it is still inadequate. Comparing the current draft to previous risk assessments prepared by the various proponents of the NEIDL Level 3 and 4 laboratories provides a very low threshold for adequacy. The National Research Council and others have repeatedly stated that previous risk assessments were seriously flawed and did not provide any reliable basis for understanding the risks associated with the NEIDL laboratories.¹

Some observers may argue that given the limited availability of information and knowledge about the effects of the pathogens to be studied in the laboratories and the limited availability of operational data from similar, university-operated laboratories mean that the current Draft Risk Assessment is the best (most technically sound) assessment that can be prepared.

These observers may be correct.

¹ The NIH's appointment of a Blue Ribbon Panel of experts to oversee the preparation of this new risk assessment and its retention of the NRC to review its progress provide clear evidence of the woeful inadequacies of previous attempts to prepare assessments that could provide the needed basis for making informed decisions regarding the laboratories.

Letter 51
David S. Mundel

But, even the best assessment possible is an inadequate assessment if it can not provide decision makers, including members of the potentially impacted communities, with an understanding of the potential risks resulting from the operations of the NEIDL Level 3 and 4 laboratories. These decision makers must understand these risks prior to judging whether they are acceptable or unacceptable.

On balance, a review of the current draft indicates that it does not provide a transparent, clear, and reasonable estimate of the potential risks resulting from a small number of selected accidental and malevolent incidents that could arise from the operation of the Level 3 and 4 biocontainment laboratories in Boston's South End.

- 51.1 { The analyses of the incidents selected for study are generally inadequate and biased. The inadequacy is largely caused by the analytically poor treatment of the uncertainties caused by the lack of relevant research and the limited availability of operational and other data. The biases are often subtle and thus extremely dangerous given the demands placed on readers of a 1700 page document that lacks a coherent and accurate summary.
- 51.2 { Although the report notes that changes in many important assumptions could invalidate the conclusions, several of these important assumptions remain unexamined. For example, although the report notes that changes in the operational practices of the NEIDL laboratories could make the conclusions of the risk assessment invalid, the nature and possibility of such changes were never examined.
- 51.3 { In addition, the current draft does not provide any estimate of the total risk to the individuals in the communities surrounding the NEIDL laboratories that could result from the entire range of possible events that could occur if the laboratories become operational.

Because of these inadequacies, the current draft does not provide an adequate basis for deciding whether or not the proposed operation of the laboratories should be approved and as a result, any decision that allows the laboratories to become operation would be arbitrary and capricious rather than well-founded and reasonable.

This review of the current Draft Risk Assessment is primarily based on my evaluations of five key aspects of the report. These evaluations are included in the next five sections of this written comment.

Next Steps -- Although the authors of the current draft and the NIH report that the draft is a "90 percent complete work product", it is clear that significantly more than an additional ten (10) percent of the work effort is needed to produce an acceptable risk assessment that provides an adequate and credible basis for considering the possibility of allowing the laboratories to become operational.

Letter 51
David S. Mundel

51.1 As discussed in Section F.1.2 of the Draft Supplementary Risk assessment, this analysis is consistent with the National Environmental Policy Act (NEPA) regulations and with the Department of Energy ([DOE](#)) NEPA Guidance for implementation of those regulations. Consistent with the requirements of 40 CFR 1502.22 (the requirements for dealing with incomplete and unavailable information), this analysis: “identifies the limitations of the data used, discusses the options and significance of assumptions made, and provides a basis for use of these assumptions and data. The results presented herein reflect the uncertainty in both the data and the models used for this evaluation.” (Appendix F.1.2)

The analyses consider the variability and uncertainty of the data and models in each phase of the analysis:

- Consistent with the DOE NEPA Guidance (DOE 2002), the analyses of the sequence from the initial event through exposure rely on conservatism to compensate for uncertainty/variability. For example, exposure calculations are based on maximum pathogen concentrations, utilize high breathing rates, ignore potential vaccinations, assume all needlesticks result in infection, and assume failure of multiple biocontainment features. For example, the centrifuge release assumes 1) a leak from the tube into the rotor, 2) failure of the rotor seal, 3) the potential for a severely reduced performance of the PAPR, and 4) failure to detect or report the event. The Maximum Reasonably Foreseeable (MRF) earthquake analysis is the extreme case because it assumes failure of all biocontainment features.
- The variability and uncertainty associated with each key input of the exposure event sequences is estimated and discussed at the end of the subsection for each event in Appendix F (i.e., Sections F.6 through F.9).
- The initial infection calculations that different bases could be used and performs the calculation with both expert-based and literature-based dose-response relationships (see Section 8.2.2).
- The uncertainty associated with initial infection and secondary transmission are addressed quantitatively in Chapters 8 and 9.

Section I --

The current Draft Risk Assessment does not provide a complete estimate of the risk of operating the Level 3 and 4 laboratories in Boston's South End

- 51.4 { Although the 1700 page draft report appears to have been produced by large and presumably expensive research and consulting effort, it fails to provide a complete estimate of the potential risk associated with operation of the already constructed laboratories.
- 51.5 { The current draft includes an assessment of a very limited selection of the possible event-pathogen incidents. The text of the report frequently mentions that the event-pathogen incidents evaluated are 'representative' of the ranges of pathogens to be studied in the laboratory and possible events but this reported representative quality is never seriously evaluated. The authors of the current draft report appear to be unaware that there is a need to add up the risks associated with even the limited selection of event-pathogen incidents studied and then estimate what share of the total risk associated with planned operations of the laboratory is accounted for by the limited set of event-pathogen incidents included in the analysis.
- 51.6 { The lack of such an estimate may have been an intentional omission because the entirety of the potential risk is clearly larger than the risk associated with each of the individual incidents presented in the current draft document. In addition, choosing to analyze a limited set of reportedly 'representative' incidents rather than all of the possible events prevents readers from estimating the totality of the risk based on the analysis included in the current draft.
- The lack of an integrated or summative assessment of risk is a major source of the inadequacy of the current draft report. The potential risk to the community resulting from the operations of the laboratories is the sum of all of the risks from the entire set of possible risk producing incidents. For each pathogen that may be studied in the NEIDL's laboratories, there are a series of risk producing events that may occur and for each of these events there is some potential for members of the community to experience a harmful consequence (including fear, disease, and possibly death). The summation of these possible risks for an individual pathogen is the risk associated with this pathogen being studied in the laboratories and the summation of these pathogen specific risks across all pathogens to be studied in the laboratories is the risk associated with operating the laboratories.

Section II --

The analyses of many of the specific pathogen-event incidents included in the Draft Risk Assessment do not provide the accurate information needed for decision making

The draft report accurately describes that the information available needed to assess both a) the likely human health effects resulting from exposure to many of the pathogens that will be studied in the NEIDL laboratories and b) the likelihood of laboratory accidents and other incidents is severely limited.

Letter 51
David S. Mundel

Overall, the 95% estimate range for the risk of infections among the public resulting from an undetected and unreported initial infection in a laboratory worker following a needlestick event SARS infections is 1 in 760 to 27,000 years (see Table 11-6c), which is a broad range.

- 51.2** As discussed in Section 2.1 of the Draft Supplementary Risk Assessment, there are multiple reviews of NEIDL research protocol, including but not limited to, approvals by the Boston University Medical Campus Office of Environmental Health and Safety (OEHS) and the Institutional Biosafety Committee (IBC). Changes to the NEIDL operational practices that degrade safety are unlikely because of these reviews. See also response to comment 51.1.

Consideration of additional changes that degrade safety beyond those already addressed are speculative and beyond the scope of this analysis.

- 51.3** The inclusion of total risk was discussed with the Blue Ribbon Panel and it was agreed that it is inappropriate to attempt to present total risk for this risk assessment. This risk assessment analyzed scenarios that are expected to pose the greatest risk to the public, but it is not possible to attempt to analyze all possible scenarios. Summing the risk from a subset of possible scenarios and presenting them as the "total risk" incorrectly implies that all scenarios are included. A summation of these scenarios would present a misleading result that we believe would not serve the public interest. However, the large conservatisms used for the MRF earthquake and needlestick analyses means that they are reasonable approximations of the total public risk for direct and indirect exposures.

- 51.4** It is assumed that "complete estimate of the potential risk" refers to total risk. See response to comment 51.3.

- 51.5** Please see response to comment 51.3.

- 51.6** Please see response to comment 51.3.

51.7 { Nevertheless, the authors have presented their conclusions regarding these likelihoods with relatively narrow confidence limits (i.e., levels of uncertainty). In many cases, the extent of the reported ranges of uncertainties often appear to be based on small samples of observations and/or opinions although it is widely known that small sample studies are unlikely to provide any reliable information about the tails or extremes of the distributions.

51.8 { The limited accuracy of the uncertainty ranges reported for the pathogen-event incidents is particularly apparent in the assessments that rely on the dose-response estimates derived from the Delphi Technique process used in surveying the opinions of a small number of experts. Given that human effects research studies that provide valid data about these estimates are essentially non-existent and the centering bias resulting from the repetitive surveying of a small number of experts, it is incorrect to conclude that the range of the final opinions expressed by these experts represents the actual extent of the uncertainties involved.

51.9 { Furthermore, the authors often appear to mistakenly believe that the 'lack of available evidence' about human health effects and laboratory events indicates that health effects do not exist and laboratory events have not occurred. Given that most of the research needed to estimate potential human health effects has not been conducted (for good reasons) and the reporting of laboratory events has never been reliable, the reported 'lack of available evidence' solely indicates that evidence is not available, not that if it were available it might indicate something.

Section III –

Many of the needed assessments of the impact of possible pathogen-event incidents on vulnerable populations are either missing or inadequate

In many cases, populations that are likely to be more vulnerable are simply omitted from the analyses even though information about these populations is readily available.

For example, the NEIDL laboratories are located close to the Boston University Medical Center hospital, outpatient clinics, and physicians' offices. Many sick individuals are served in these facilities and the hospital provides a large share of the medical services needed by many lower income, minority and medically compromised Boston residents.

51.10 { In its attempts to secure public support for its general operations, the Medical Center has frequently provided data about the number, scope, and importance of the services it provides to these populations and the number of patients who are served. In spite of the availability of these data, the Draft Risk Assessment does not include any analysis of the potential health effects that might be experienced by members of these vulnerable populations as a result of the pathogen-event incidents that included in the draft.

51.11 { In addition, the current draft report provides no evidence that the authors even considered assessing the potential impact of laboratory-based, pathogen-event

Letter 51**David S. Mundel**

51.7 Please see response to 51.1.

51.8 Please see response to 51.1.

51.9 Please see response to 51.1.

51.10 The health effects on medically vulnerable populations are summarized in Section 11.7.4. of the Draft Supplementary Risk assessment. Differences in vulnerability are addressed Appendix H, the composition of vulnerable subpopulations at the three sites are addressed in Appendix I, and the differences in risk are presented in Appendix L.

51.11 Please see response to comment 5.10. Consideration of the impacts of potential operational impacts on other facilities is beyond the scope of this risk assessment.

51.11 { incidents on either: a) the operation of these vitally important urban medical facilities or b) the willingness of otherwise, underserved populations to use these facilities given their fears of contagion and disease.

51.12 { In addition, the report does not include any analysis of the potential health impacts of a possible incident on inmates and staff of the correctional facilities located near the NEIDL laboratories. Many of these inmates have medical conditions that may either increase their susceptibility to released pathogens or that will be exacerbated by these pathogens but these impacts were not assessed. In addition, the fact that these inmates are unlikely to be evacuated in the event of any pathogen-event incident and the staff members working in these institutions are unlikely to be allowed to leave their positions is never mentioned in the report.

In other cases, that draft assessment includes analyses of the potential impact of pathogen-event incidents that are both inadequate and incorrect.

For example, the draft report specifically excluded individuals with asthma from its analysis of medically vulnerable subpopulations. This exclusion was based on the following assessment -- “Those with asthma were excluded as there is no known direct association of asthma with increased susceptibility to infections from the pathogens considered in this RA. (see page I-3 of the Feb 2012 Draft)

But the lack of a “known direct association” is probably an indication that this knowledge does not exist because there has been little or no research directed toward understanding this potential association.

51.13 { Given that readily available information indicates that the rates of asthma in the communities surrounding the NEIDL’s laboratories are high (as are the rates among the patients using the nearby medical facilities), the apparent ease with which the authors of the report decided to exclude asthmatics from consideration is, to say the least, disturbing.

51.14 { The authors do, however, admit that there is likely to be an association between respiratory diseases resulting from infections from the pathogens that will be studied in the laboratories and the severity and rate of asthma conditions and attacks (see page I-3). Many other sources also describe that a clear connection between respiratory infections and the health status of individuals with asthma exists.

This means that the health status of individuals with asthma is likely to be disproportionately affected by potential pathogen-event incidents resulting from the operation of the NEIDL laboratory. The existence of this effect – even if individuals with asthma are no more likely than others to be infected by the pathogens studied in the laboratories – means that this medically vulnerable subpopulation should be considered in assessing the risk associated with the NEIDL. But, no such consideration occurred.

Letter 51

David S. Mundel

- 51.12** As noted in Section F.4.2.6 of the Draft Supplementary Risk Assessment, the prison population is included in the resident population values. As with all residents, the jail population is assumed to be present at all times. The medically vulnerable subpopulations are addressed in Section 11. 7.4 and Appendices H, I, and L. Also see the response to comment 51.10.
- 51.13** The issue of asthma is qualitatively addressed in the risk assessment with respect to the available literature on the association of asthma with the pathogens studied. (Chapter 3). The potential adverse effect of the pathogens on asthma is also qualitatively addressed in the Draft Supplementary Risk Assessment (Appendix I, Section I.3.3). The risk assessment acknowledges that asthmatics are one of the diverse groups of Medically Vulnerable Sub Populations (MVSP) in the community (see Section I.2). The risk assessment further acknowledges that the diseases caused by the pathogens addressed in the risk assessment, especially those associated with respiratory disease such as influenza, may exacerbate asthma (see Section I.2). The criteria for selecting a specific group within MVSP for detailed analysis for this risk assessment are explicitly stated in Section I.2: (1) the condition should be relevant in a bio-medical sense and confer increased susceptibility to a pathogen, such as those under study for this Risk Assessment (bacteria and viruses); and (2) reliable estimates of the subpopulation should be available from federal, state, and local government sources that could be cited. The objective of performing the MVSP analysis was to generate estimates of initial infections after exposure to a pathogen and secondary spread in the community. The consequences assessed for the MVSP were infections and deaths and no evidence was found to warrant assuming an increased infection rate or an increased death rate for asthmatics exposed to or infected with pathogens under consideration. Based on review of the existing literature on asthma and the pathogens studied in this Risk Assessment (see Chapter 3), there is no known direct association of asthma with increased susceptibility to infections from the pathogens considered in this Risk Assessment. Thus, based on criteria described above, asthma was excluded from a detailed quantitative analysis.

51.14 Please see response to comment 51.13.

Section IV –

The text of the current draft is subtly and dangerously biased

Throughout the document, evidence and opinions that reflect positively on the proposal to allow the Level 3 and 4 laboratories to begin operations are placed early in paragraphs and sections. But, evidence that reflects negatively or describes the large extent of the uncertainties involved is placed much later.²

- This type of bias may not indicate that the Draft Risk Assessment is technically incorrect because each individual sentence may, in fact, be true. But, this textual style clearly represents a biased attempt to present evidence to readers, particularly those who are confronted with the task of reading a 1700 page document.

A second type of bias is evident from the repeated statement that the assessments presented in the draft report are intended to be “conservative” – i.e., representing a higher level of risk than is likely to occur.

- Some of these statements of ‘conservatism’ may be accurate and others may be inaccurate but the report is amazingly consistent in omitting any analysis which demonstrates the validity of these statements. Again, the intent is all too clear – the authors of the this 1700 page document would like to leave the overburdened reader who lacks the time to read the document fully and carefully (and probably lacks the strength to hold the document during such a reading) with the impression that the described risks are higher than any reasonable person would expect.

The extent and the subtlety of these repeated textual biases are extremely dangerous and prevent the current draft from being transparent, as required by the Environmental Protection Agency’s “RISK CHARACTERIZATION HANDBOOK” (December 2000), a handbook which the authors of the current draft reported they were following. (see Chapter 1 of the Draft Risk Assessment)

Section V –

Although the limited availability of data and information has a major impact of the credibility of the Draft Risk Assessment, it is disturbing to note that a very important review of three of the most significant of these limitations is buried on the last two pages of this 1700 page document

The last two pages of the final chapter of the 1700 page report (Chapter 11, pages 32 and 33) highlight three important factors that significantly limit the validity of the reported conclusions regarding the potential risks facing members of the public who live, work, shop, receive medical services, and travel near the NEIDL laboratories.

² See for example the paragraph beginning with the statement “There does not appear to be any evidence of risk of direct person-to-person secondary transmission” page 11-31.

Letter 51
David S. Mundel

51.15 { The first factor (reviewed in one paragraph that begins at the bottom of page 11-32) is the lack of reliable operational data from other Level 3 and 4 laboratories – data that could, if available, provide some insights about the occurrence rates of potential risk-inducing events. The authors report that they used a wide range of occurrence rates that were based on conservative assumptions that tended to overestimate the frequencies of these events. But, given that little, if any, reliable operational data exist and the available data are based on processes widely believed to result in the underreporting of events, there is no basis for the authors’ opinion that the “wide ranges” ranges of event frequencies encompass the actual occurrence rates. Similarly the authors’ opinion that the rates used in the analysis are ‘conservative’ is not supported by any analysis.

The authors may be correct that the results “are generally considered to be conservation (i.e., overstate the risk)” but it is likely that these ‘considerations’ are entirely those of the authors, themselves.

51.16 { Given the lack of reliable occurrence rate data, an unbiased analysis would have clearly stated that the occurrence rates may be either higher or lower than the boundaries of the assumed ranges of uncertainty and it is essentially impossible to assess the actual values of these occurrence rates.

The second factor reviewed in these final pages is the impact of uncertainties in the opinion-based assumptions regarding the consequences of human exposures to infectious pathogens resulting from potential pathogen-event incidents (see page 11-33). Again, the authors report that they obtained what they regard to be a wide range of estimates (based primarily on available, animal exposure research studies and the opinions of a small number of experts) and that the used “conservative assumptions”.

51.17 { The authors report that “the estimates of the overall risk are sensitive to those estimates” but they do not report that the conducted any analysis that suggests that these animal-based and expert-opinion-based ‘estimates’ (or more correctly, ‘assumptions’) encompass the full range of the potential uncertainties.

In addition, the authors fail to acknowledge that the report does not include any estimate the ‘overall risk’ of operating the NEIDL laboratories.

The third factor reviewed on the final page of the Draft Risk Assessment relates to the possibility of changes in the operations of the Boston University Medical Center NEIDL laboratories.

In the last paragraph of the last page of the Draft Risk Assessment, the authors state that “Changes in the operation of the NEIDL relative to the bases used for this (Risk Assessment) will affect the outcomes accordingly and could invalidate the conclusions of this (Risk Assessment) if such changes were substantial.”

51.18 { Throughout the current draft, the authors of the risk assessment have described these operational plans in glowing terms, stating that the these plans would reduce or prevent the occurrence of risk-causing, pathogen-event incidents and mitigate the health risks resulting from such incidents if they did occur. The effectiveness of these plans and the standard operating procedures (SOPs) that were going to result from their implementation were

Letter 51

51.15 Please see response to 51.1.

51.16 Please see response to 51.1.

51.17 Please see response to 51.1 and 51.3.

51.18 Please see response to 51.1. Equipment failures and personnel errors were considered in detail in the analysis for each scenario.

51.18 {

never questioned. The sensitivities of the predicted risks of the individual pathogen-event incidents to changes in the laboratories' operating practices were never evaluated. The meaning of and the potential for 'substantial' changes in operating practices were never discussed.

Nevertheless the final sentence of the Draft Risk Assessment states that if these changes occur the conclusions of the assessment could be invalid.

The validity of this statement is obvious.

One can only guess as to why this paragraph was placed at the end of the Draft Risk Assessment. Perhaps, the authors hoped that no one would read this last page. Perhaps, the authors realized that they had never addressed the possibility that the operating practices described elsewhere in the report might not be implemented consistently and they wanted to make sure that somewhere in the report such a possibility was discussed. Perhaps, the editors of the report were so tired when they reached the last of the 1700 pages that they forgot to remove this paragraph.

Subject: NIH risk assessment comment

Panel Members:

I offer my comments as an active member of two organizations in Boston: Pax Christi Boston and Alternatives for the Community and the Environment (ACE). Both groups focus on issues of environmental justice.

52.1 { The Environmental Justice (EJ) community designation for Roxbury, MA is the focus of this comment. In the Commonwealth, an EJ community warrants enhanced protection rather than equal protection from environmental impact. Therefore, all of the analysis presented in the risk assessment to indicate that the three communities of Peterborough, Tyngsborough, and Roxbury would be equally effected by the Level IV lab is irrelevant. There is an operating premise for considering the siting of environmentally sensitive projects. An EJ community cannot be considered an option because it has already been disproortionately impacted by the siting of past projects. While it may be unreasonable to expect that existing projects be relocated, it is clearly possible to avoid additional ones from compounding the environmental threats. This is an instance in which equal is not adequate.

52.2 { One further comment on the disparity between the three sites. As I understand the emergency plans, there would be a quarantine of the immediate area surrounding the lab enforced by the US military. This would absolutely not be a comparable event for all three sites. The immediate area surrounding the Level IV lab includes an extremely dense swath of humanity including an entire prison and bus terminal as well as the neighborhoods. The same measured area surrounding a lab in Tyngsborough or Peterborough would likely include grass, ants and dandelions.

Sincerely,

Susan P. Harden

Letter 52
Susan P. Harden

52.1 As discussed in Sections 10.2, 10.3, and Appendix M of the Draft Supplementary Risk Assessment, the Environmental Justice analysis was performed consistent with federal and state requirements. The Risk Assessment acknowledges that the Commonwealth of Massachusetts Executive Office of Energy and Environmental Affairs (EEA) has an Environmental Justice policy. The state criteria for environmental justice populations are those segments of the population that EEA has determined to be most at risk of being unaware of or unable to participate in environmental decision-making or to gain access to state environmental resources. They are defined as neighborhoods that meet one or more of the following criteria:

- The median annual household income is at or below 65 percent of the statewide median income for Massachusetts; or
- 25 percent of the residents are minority; or
- 25 percent of the residents are foreign born, or
- 25 percent of the residents are lacking English language proficiency.

Neighborhoods, as defined by the Environmental Justice Policy of the EEA are U.S. Census Bureau census block groups (Massachusetts EEA 2002). The Draft Supplementary Risk Assessment addressed and analyzed demographic data per the state Environmental Justice guidance in sections: 10.6.1.2; 10.6.2.2; 10.6.3.2; 10.7 and Appendix M.

The Massachusetts Executive Office of Energy and Environmental Affairs (MEEA) provides the following definition of environmental justice:

“Environmental justice is the equal protection and meaningful involvement of all people with respect to the development, implementation, and enforcement of environmental laws, regulations, and policies and the equitable distribution of environmental benefits.”

MEEA requires enhanced public participation and enhanced analysis of impacts and mitigation under the Massachusetts Environmental Policy Act, but it does not address enhanced protection of Environmental Justice communities. The actions undertaken to ensure enhanced public participation are addressed in Section 10.5.5 and these actions include public meetings held in the Roxbury community to ensure that their opinions are heard.

Letter 52

Susan P. Harden

52.2 In the unlikely situation in which a quarantine would be required, the decision would be the responsibility of the Boston Public Health Commission, or alternatively the Department of Public Health, at the State level, and not that of the military.

May 1, 2012

TO THE NIH BLUE RIBBON PANEL

I am writing on behalf of Watertown Citizens for Peace, Justice and the Environment, an organization that has worked for these goals for 34 years. We have been concerned about Boston University's proposed NEIDL since its inception, as evidenced by our testimony at each hearing and written comments on each document throughout this long process.

The new 1700 page document does nothing to alleviate our concerns. This appears to be more of a public relations document than a serious attempt at analysis of the potential dangers of siting such a facility in the midst of the most densely populated and low income neighborhood in a major city. We continue to believe that NIH should be adhering to its policy as stated in a 2004 NIAID memo, that a BSL4 lab should be well removed from major population centers in order to reduce the possibility of an accidental release of an organism leading to a major public health disaster.

There are innumerable manners in which such an accidental release can occur, which are either entirely ignored or at best inadequately examined in this report:

- 53.1 { - Escape of infected research animals; the Risk Assessment analysis of this possibility has been criticized by the National Research Council panel as inadequate.
- 53.2 { - Accidental releases of pathogens during transport to laboratories; there have been documented cases of such occurrences, and the transportation analysis is particularly weak. No details are provided on routes, background checks on drivers, or impacts of commuting patterns.
- 53.3 { - Infected lab workers unknowingly carrying a disease out into the community; this, for instance, was the origin of some of the SARS outbreaks.
- 53.4 { - Intentional acts by rogue scientists or malevolent actors; indeed, the anthrax incidents of 2001 are now claimed to be caused by exactly such an act by an internal researcher. However, this report deals with this issue only by stating: "It would be speculative to attempt to provide an estimate of the consequences of malevolent scenarios involving the removal of pathogens from the facility." No analysis is given of the probabilities or consequences.
- 53.5 { - Sloppy practices leading to major safety violations; a number of reports in the past few years have documented missing vials, unauthorized employees working with select agents, improper disposal of research animals used in select agent experiments, unreported exposure of researchers to pathogens, researchers carrying out unapproved experiments, and other serious problems. Given the history of problems in BU labs, there is no reason for confidence in the "culture of safety" which the NRC has stressed as being so important.
- 53.6 { There are many other reasons that BSL3 or 4 level research should not be allowed to proceed in this laboratory. The proposed use represents a diversion of public health dollars into biodefense research. According to congressional testimony in 2007 (to the Subcommittee on Oversight and Investigations of the House Committee on Energy and Commerce), the rapid proliferation of laboratories handling biological weapons agents in the last decade far exceeds our national needs as well as posing significant risks to the public. Instead, the biolab should follow the Alternative Vision for the Boston University NEIDL which was prepared by Lynn Klotz and other scientists working with the coalition opposing the

Letter 53

Ernesta Krackiewicz

53.1 Chapter 4 of the Draft Supplementary Risk Assessment discusses the potential for infected animals to escape and Chapter 7 addresses the potential consequences of an escape.

53.2 In its review of the Draft Supplementary Risk Assessment, the National Research Council concluded that “The committee believes that the chapter on transportation is thorough and has no concerns with the content.” The routes taken to deliver shipments to the NEIDL are dependent upon the origin/destination for the shipment(s).

53.3 The centrifuge aerosol release and needlestick events, described in Sections 4.2.2 and 4.2.3 of the Draft Supplementary Risk Assessment, analyzed the potential for infected laboratory workers to inadvertently expose members of the general public. All 13 pathogens under study in the risk assessment, (including SARS) were analyzed.

53.4 As discussed in Section 6.8 of the Draft Supplementary Risk Assessment, the risk assessment followed the recommendations of the Department of Energy (DOE) NEPA Guidance (DOE 2002), which states:

“Analysis of such acts poses a challenge because the potential number of scenarios is limitless and the likelihood of attack is unknowable.”

“[T]he consequences of an act of sabotage or terrorism could be discussed by a comparison to the consequences of a severe accident because the forces that could result in a release of radioactive or hazardous material would be similar to those considered in accident analyses.”

Consistent with this guidance, a frequency estimate is not reported for these malevolent acts and the consequences are estimated by comparison to accidents. The risk assessment states that the consequences of malevolent act scenarios are expected to be less than the consequences of the Maximum Reasonably Foreseeable earthquake event.

53.6 ↗ biolab.

Use of this lab for BSL 3 or 4 research will provide little long term economic or public health benefit, but will pose a risk of public health catastrophe in the case of a release of a lethal, contagious and incurable disease.

Sincerely,

Ernesta Krackiewicz

From: Cornelia A. Sullivan

April 30, 2012

Re: Boston University's NEIDL Level 3 & 4 Biological Research Laboratory

To: Whom It May Concern:

As a resident of Boston I am deeply troubled by the lack of respect we, The Coalition To Stop The BU Bioterrorism Lab have received from NIH, The Blue Ribbon Panel and Tetra Tech. For almost 10 years I have been following this issue. The local scientists I trust have made it perfectly clear the this type of research should not be done in the center of Boston which is a densely populated area and in fact question the wisdom of it being done any where. On 4/14/2004 the Boston Globe reported, "Academic stars join a push against plan for bioterrorism lab. This included two Nobel Peace Prize recipients from Harvard, Dr. Eric Chivian and Dr. Bernard Lown. Dr. Lown was quoted as saying of the lab, "This could become a lab for developing new instruments of death." On 4/20/2004 David Ozonoff, MD, MPH, Professor of Environmental Health testifying before the Boston City Council stated among other concerns that the research proposed in this lab does not have a public health agenda. At the same hearing Professor Patricia Hynes also from the same department at BU testified that this lab "represents the growing militarization of public health, a parasitical trend that is leaching the life out of it." More recently this month Lynn Klotz, Ph.D, a Senior Science Fellow at the Center for Arms Control and Non-Proliferation suggested that the word health be removed from the title of NIH because the research proposed has nothing to do with health.

In March of 2005 over 750 NIH Scientists certified to do research on these deadly organisms wrote an open letter to the Director of NIH Elias Zerhouni, MD stating, "The diversion of research funds from projects of high public health importance to projects of high biodefense but low public health importance represents a misdirection of NIH priorities and a crisis for NIH supported microbiological research." You have lost our trust and the inability of Tetra Tech to present a credible Draft Risk Assessment increases our concerns.

Although I am retired I was employed as an RN for over 50 years, 30 of which were spent working at the old Boston City Hospital and as a School Nurse in the Boston Public Schools. I earned a BS, MS, MA and was certified as a School Nurse Practitioner by the American Nurses Association. I believe this qualifies me to comment on the issue of Environmental Justice. I worked with children and their parents in this area of Boston and saw the devastating effects poverty has on children's self esteem and there ability to achieve in their studies. There is a much higher rate of asthma in this neighborhood which leads to frequent hospitalization, absence from school and anxiety that the fear of not being able to breath causes. Eight trash-transfer stations, substandard housing which contributes to elevated lead levels in children, along with higher levels of unemployment creating further stress are just a few of the problems with which the residents in the neighborhood struggle.

In Massachusetts an Environmental Justice (EJ) community warrants enhanced protection rather than equal protection. All the analysis presented in the risk assessment to indicate that the three communities of Peterborough NH, Tyngsborough MA, and Roxbury MA would be equally effected by the lab are irrelevant. Roxbury, which is already designated as an EJ community can not be considered an option because it has already been disproportionately impacted by the existing projects. While it may be unreasonable to expect that existing projects be relocated, it is clearly possible to avoid additional ones compounding the environmental threats. This is a case in which equal is not adequate.

Letter 54

Cornelia A. Sullivan

54.1 As discussed in Sections 10.2, 10.3, and Appendix M of the Draft Supplementary Risk Assessment, the Environmental Justice analysis was performed consistent with federal and state requirements. The Draft Supplementary Risk Assessment acknowledges that the Commonwealth of Massachusetts Executive Office of Energy and Environmental Affairs (EEA) has an Environmental Justice policy. The state criteria for environmental justice populations are those segments of the population that EEA has determined to be most at risk of being unaware of or unable to participate in environmental decision-making or to gain access to state environmental resources. They are defined as neighborhoods that meet one or more of the following criteria:

- The median annual household income is at or below 65 percent of the statewide median income for Massachusetts; or
- 25 percent of the residents are minority; or
- 25 percent of the residents are foreign born, or
- 25 percent of the residents are lacking English language proficiency.

Neighborhoods, as defined by the Environmental Justice Policy of the EEA are U.S. Census Bureau census block groups (Massachusetts EEA 2002). The Draft Supplementary Risk Assessment addressed and analyzed demographic data per the state Environmental Justice guidance in sections: 10.6.1.2; 10.6.2.2; 10.6.3.2; 10.7 and Appendix M.

The Massachusetts Executive Office of Energy and Environmental Affairs (MEEA) provides the following definition of environmental justice:

“Environmental justice is the equal protection and meaningful involvement of all people with respect to the development, implementation, and enforcement of environmental laws, regulations, and policies and the equitable distribution of environmental benefits.”

MEEA requires enhanced public participation and enhanced analysis of impacts and mitigation under the Massachusetts Environmental Policy Act, but it does not address enhanced protection of Environmental Justice communities. The actions undertaken to ensure enhanced public participation are addressed in Section 10.5.5 and these actions include public meetings held in the Roxbury community to ensure that their opinions are heard.

MR. KURILLA: Good evening, ladies and gentlemen. I'm Michael Kurilla, the Director of the Office of BioDefense Research Affairs at the National Institute of Allergy and Infectious Diseases at NIH, which has been responsible for the oversight of the federal funds that partially contributed to the construction of this project that we are here to discuss tonight. I would like to welcome you all to this public meeting.

The purpose of this meeting is to listen to your comments on the recently released draft supplementary risk assessment regarding the National Emerging Infectious Diseases Laboratory at Boston University. As you can see from the agenda, we will begin this evening with a short, very short presentation from Dr. Adi Gundlapalli, which will summarize the methods and approaches that were used towards

this risk assessment, as well as highlight the general conclusions in that assessment.

Following the presentation we will begin a public comment portion of the meeting.

My colleague, Ryan Bayha, will be moderating that session. Ryan will review the rules for commenting when we begin the public comment portion. Before I begin though I would like to emphasize that this meeting has not been structured as a question and answer format, we are here to listen to you. Your comments are a crucial element that allow us to finalize the draft supplementary risk assessment and we look forward to hearing them, as well as any written comments that you have and you may potentially submit following this meeting.

Ryan will describe that process and also outline the time frame for receiving comments that will be addressed in the final risk assessment. With that, I would like to introduce Dr. Adi Gundlapalli, who will be

presenting an overview of the risk assessment, as well as the results. He is a member of the independent contracting team who conducted this risk assessment, he is an Assistant Professor at the Department of Internal Medicine Pathology, and Biomedical Informatics at the University of Utah.

MR. GUNDLAPALLI: Thank you, Dr. Kurilla, and good evening, everyone. We appreciate the opportunity to present an overview of the risk assessment of the National Emerging and Infectious Diseases Laboratories, NEIDL, at this meeting. The purpose of the risk assessment of NEIDL is to estimate the human health risks and impacts to the environment resulting from loss of biological containment from potential accident or malevolent action, which then would expose laboratory workers and members of the public to pathogens being studied in the lab.

The second task was to determine if

NEAL R. GROSS

COURT REPORTERS AND TRANSCRIBERS

the risks would be different if the facility were to be at an alternate site. So the risk assessment was designed to address three questions: What could go wrong at the lab? What are the probabilities and likelihood of those events occurring? And if those events occurred, what would be the consequences? The consequences studied were exposure to pathogens and also infection and fatalities resulting from the pathogens.

The risk was addressed at three levels; for laboratory workers, for members of the public and for the three different sites, namely the urban Biosquare Research Park site, a suburban Tyngsborough, Massachusetts site and the rural Peterborough, New Hampshire site. So the methods are based on established procedures. The risk assessments used data that were available from published scientific literature.

These data were supplemented with

NEAL R. GROSS

COURT REPORTERS AND TRANSCRIBERS

expert judgment as needed and when the desired data for certain analyses were not directly available from published, scientific peer reviewed literature, assumptions were made using relevant, real world experience, related data and expert judgment. In all such cases, values were used so as to over-estimate the risk and not minimize the likelihood of events occurring or the resulting consequences.

Four essential principles were followed in the context of this risk assessment.

Transparency was achieved by providing details of the approach, the assumptions used, the basis for those assumptions and uncertainties in the available data. The risk assessment used qualitative analyses throughout and when sufficient data were available, qualitative analyses were supplemented by quantitative assessment. Clarity was achieved by conveying the methods used and results clearly in the main document while providing technical details in

the appendices.

For consistency, the risk assessment followed established guidance and methods and, for reasonableness, the analysis relied on best available scientific information and was based on realism and real world experience. Thirteen representative pathogens were studied. Of these, seven are classified as BSL3 and six are in the BSL4 category. From the large number of possibilities of events that could occur at NEIDL, four representative events were chosen that represent the greatest risk, in terms of the frequency of occurrence of those events and the consequences.

These four events are needle stick, which is an example of human error; centrifuge release, which represents equipment failure; an earthquake, as an example of a natural disaster, and transportation accidents. The assessment focused on those events that could lead to the greatest consequences. For example, for needle sticks and centrifuge

releases, these are undetected and/or unreported events.

For each event the risk assessment analyzed the risk of exposure to pathogens from that event, the subsequent risk of infection from exposure to that pathogen from that event and, finally, resulting fatalities, if any, from those infections. In all cases the risk refers to a combination of the likelihood of how often the event occurs and the consequences resulting from that event.

Here is an overview of the process that was used to conduct the risk assessment.

The first part of the assessment involves the event sequence analyses. As mentioned in the previous slide, a large number of possibilities were considered and representative events were selected that represent the greatest risk. These were then analyzed in detail to provide estimates of the frequency, number and extent of exposure to a pathogen from those events.

Health effects were the focus of the

NEAL R. GROSS

Letter 55
Public Meeting Transcript

second part of the assessment. Here, infections and fatalities resulting from exposure to the pathogen from the particular event were analyzed. First, initial infections among those exposed to the pathogen were estimated. For most events, this involved laboratory workers. Then, in certain cases, if the pathogen can be transmitted directly from person to person, the numbers of secondary infections that could potentially occur among the public were estimated using quantitative modeling methods.

Finally, the estimates of exposure, infection and fatalities were combined to categorize the risk associated with NEIDL operations. For this presentation, the results are shown as a combination of the likelihood of that event occurring and the resulting infections as the consequence of that event. This is represented as the risk of infection from exposure to a particular pathogen from a particular event.

The first risk consideration of the laboratory workers at NEIDL, they are considered to be at the greatest risk of exposure to and infection from pathogens during NEIDL operations. For example, as a result of a needle stick event that is undetected and/or unreported, the risk of one or more infections to a lab worker is estimated to be once in one hundred years to once in ten thousand years. This is a broad range, as this includes the risk for all 13 pathogens in the BSL3 and BSL4 categories.

For a centrifuge event, there were no realistic events identified that would pose a risk from BSL4 pathogens. The risk of one or more infections to lab workers as the result of a centrifuge event that is undetected and/or unreported was considered plausible only for BSL3 pathogens. The risk is highest for Rift Valley Fever Virus with one or more infections estimated to occur with an average frequency of once in one hundred years. The risk is lowest

for *Yersinia pestis*, the bacteria that causes plague. Here the risk of one or more infections is estimated to be a one in five million risk.

The greatest risk to the public is from close contact with an infected lab worker who has experienced an undetected and/or unreported needle stick injury. The risk of one or more infections among the public from secondary transmission is estimated to occur with an average frequency of less than once in five hundred years. The risk is greatest for these four pathogens listed; the SARS associated Corona Virus, the 1918 Influenza Virus, *Yersinia Pestis*, the bacteria that causes plague, and the Ebola Virus.

The risk of a hundred or more infections among the public as a result of this event is estimated to occur with an average frequency of less than once in fourteen hundred years. Here the risk is greatest with the SARS associated Corona Virus and 1918 Influenza Virus. There is potential for direct exposure

Public Meeting Transcript

to and infection from pathogen among the public from an earthquake event that's severe enough to demolish the building. Here the risk of one or more infections is estimated to occur with an average frequency of less than once in ten thousand years to less than one in one million years. The estimated, here, range again is broad, as this includes results for all the 13 pathogens, both in the BSL3 and BSL4 categories.

There also exists the potential for direct exposure to and infection from pathogens among the public from malevolent acts. A number of scenarios were considered and analyzed under this category, none of these scenarios resulted in consequences greater than those estimated from the earthquake scenario that was described in the previous slide.

With regard to transportation accidents, NEIDL operations call for special packaging to be used for shipping and receiving pathogens. These packages are expected to withstand any realistic vehicle crash.

Public Meeting Transcript

Therefore, the risk of one or more infections in the public resulting from pathogen release from a transportation accident is estimated to occur with an average frequency of once in more than one million years for all the 13 pathogens studied.

With regard to site differences, the risk to laboratory workers is estimated to be the same at the urban Biosquare Research Park site, the suburban Tyngsborough, Massachusetts site and the rural Peterborough, New Hampshire site, as NEIDL operations are assumed to be identical at all three sites. The risk assessment estimated differences in risk from the earthquake event. This is an estimate of risk of infection from direct release of pathogens from the facility as the result of a massive earthquake.

The overall risk of infection among the public from such an event is less than one in one million years at all three sites for 12 of the pathogens studied. There is a difference

NEAL R. GROSS

COURT REPORTERS AND TRANSCRIBERS

Letter 55
Public Meeting Transcript

noted with regard to Rift Valley Fever Virus, the risk of infection from this pathogen is greater at the -- estimated to be greater at the urban site and this is estimated to occur with an average frequency of less one in ten thousand years.

The greatest risk to the public is from an infected lab worker in whom the infection is either undetected and/or unreported. If this were to occur, the analysis shows that there is no substantial difference in overall secondary infections among the public at the three sites. High commuting rates among the three sites offset the population differences at the three sites. It's important to note that for this analysis, higher social contact rates were assumed for the urban site as compared to the suburban and rural sites.

The risk assessment also addressed aspects of environmental justice. EJ communities were identified near the urban and suburban sites. With regard to risk of direct

NEAL R. GROSS

COURT REPORTERS AND TRANSCRIBERS

Letter 55
Public Meeting Transcript

exposure to pathogens, EJ communities may be exposed as a result of direct release of a pathogen from NEIDL due to an earthquake event.

This was noted only for the urban site, the Biosquare Research Park. As noted earlier, the greatest risk to the public is from secondary transmission of a pathogen from close contact with an infected lab worker.

In the event of exposure of members of the public from an infected lab worker, the likelihood is not based on the location of the facility. Rather, it's based on the potential that the infected lab worker leaves the facility and transmits the pathogen to close social contacts. In the event that this occurs, second transmission of pathogens may occur in EJ communities. However, in both the direct release and infected lab worker scenarios, it's important to note that the risk of exposure to the pathogen is estimated to be similar for all persons at all sites, regardless of their EJ status.

NEAL R. GROSS

Apart from EJ communities, the risk assessment also addressed medically vulnerable subpopulations. For this assessment, five categories were analyzed, namely those below age five, those over age sixty-five, those with diabetes, those with HIV AIDS and pregnant women. In looking at the risk of infection and secondary transmission among these groups of people, there were possible differences noted in susceptibility to some pathogens in each medically vulnerable group. At the community level, however, the risk assessment estimated no overall substantial difference in risk among the three sites. Asthma was also considered.

There were no known associations of asthma with increased susceptibility to infections from pathogens studied in this risk assessment.

So, in summary, the risk assessment was conducted using established methods, available data were used and when the desired data for certain analyses were not directly available in published, scientific, peer

MR. BAYHA: Good evening, ladies and gentlemen. My name is Ryan Bayha and I will be moderating this public comment session. As Adi just mentioned and as you see behind me, there is a slide up on the screen that shows the mailing address, e-mail address and telephone number for our office. You can use this information to either request a copy of the draft supplementary risk assessment with reader's guide or to submit your comments on the draft supplementary risk assessment.

As a reminder to everyone in the room, the end of the public comment period is May 1, 2012. For your convenience, so you are not trying to scratch this address down while I'm talking, we are going to leave this slide up for the remainder of the evening. Before we begin with the public comment portion of our meeting, I would like to briefly go over how the session will run. Prior to the beginning of this meeting there was a comment or sign-up sheet in the registration area. If you have

not signed up to speak but wish to, please do so now.

For those who have already signed up, I will call four names at a time. When you hear your name called, please proceed to the microphone closest to your seat. Some other information that you are going to want to know.

These proceedings are being videotaped and a written transcript of everything said is being recorded. We do have a fair number of people that have signed up to speak, so I request that you limit your comments to no longer than three minutes so that everyone here who wishes to speak has the opportunity.

I'll be keeping track of the time up here and I will alert you when the three minutes have passed. I respectfully ask that you adhere to this three minute limit so that all of your neighbors have an opportunity to be heard. If we do reach the end of the sign-up list and there is still time remaining, we will give those individuals who wish for more time

an additional three minutes, as time permits.

Finally, before we get started, I just wanted to reiterate, as Dr. Kurilla noted earlier, that this meeting is not structured in a question and answer format and NIH is here tonight to listen carefully to all of your comments. All of the comments you give either through oral testimony here or any comments submitted to our offices will each receive a response in the final supplementary risk assessment.

With that out of the way, we can now begin the public comment session. I want to apologize in advance if I mispronounce anyone's name. I have a last name that is somewhat strange to pronounce as well and I know how frustrating it can be, so I do apologize in advance, but I will do my best. I ask that the following people proceed to the microphone nearest their seat; Kevin Norton, Laura Mazlow-Armand, Jennifer Rushlow and Tia Panna.

Kevin Norton?

MS. ALLEN: I just want to say welcome to everyone that is here. My name is Claire Allen, I'm a community organizer for the Roxbury-

(Applause)

I just wanted to say thank you very much for coming out and I know the presentation might have been a little complicated, but be glad you didn't have to go through this document right here, the 1,700 pages, to figure out what was going on. I just want to let folks know that this has been a very long issue, we have been working very hard on it, but we still haven't received -- NIH and Tetra Tech have not been able to prove our question from the beginning in terms of what is going to happen, so we haven't gotten that information yet.

I want people to know that you do not have to be a scientist in order to speak tonight.

A lot of technical stuff was up here but, still, we have concern about transportation, we have

concern about releases, we have concern about evacuation. We have concerns about different things, so let the scientists handle the science and let's speak up, speak out, let them know that this is not fair and we don't want this thing in our community. They have not proved that it's safe for it to be in our community and we won't stand for it to be in our community.

(Applause)

MR. BAYHA: Mr. Norton?

MR. NORTON: Hi. My name is Kevin Norton and I would like to go on record as saying I feel the facility has the potential to do life saving research and therefore I am in favor of it. Thank you.

(Applause)

MR. BAYHA: Laura Mazlow-Armand?

MS. MAZLOW-ARMAND: Hello. I'm a staff attorney at the Lawyers Committee for Civil Rights and Economic Justice and I represent, with others, the plaintiffs in the federal and state cases. I have three quick

points; bad faith, environmental racism and civil rights violations. Bad faith; this is an after the fact risk assessment, it was not a risk assessment of the possibilities to this community before the building was built or the grant was allowed.

The problem here is that the uncertainty in that 1,700 page document is tucked away. It's disguised as expert opinion when there is lack of knowledge and something that defies reason is the alternative -- is the comparison of sites, Boston, or Tyngsborough or Peterborough. How could anybody think it's safer to have a building working on select agents in Downtown Boston with a population density of 12,200 per square mile as opposed to Tyngsborough or Peterborough?

55.1

And NIH thought this also because when the BSL4 was built in Hamilton, Montana, where you have a population density of 1,000 per square mile, they said that's perfect because if there should be an escape or an

- 55.1** Laboratories in and around the city of Boston, including those at Boston University have safely conducted research with Select Agents for many years. The possession, use, and transfer of Select Agents is regulated by the Centers for Disease Control and Prevention (CDC). Additional oversight is provided by the Boston Public Health Commission.

accident, there would not be a public health disaster. Second point; environmental racism.

President Clinton signed an Executive Order in 1994 condemning the environmental racism of the past. This is a throwback. The community was not consulted, has not been informed, their opinions are not taken into account.

This is just like it used to be, dump it in Dixie or just dump it on the poor, nobody cares. They were not consulted and this sham of a community liaison committee that BU has created, which does not include any public participation, is simply further proof that there is no community dialogue, in violation of NEPA as well. And, finally, let's look at the population in which this is located, and I'll be finished quickly.

55.2

To say there's an equal risk of exposure is one thing, but what about the consequences of exposure? This community in which the building is located has 40 percent, at least, living below the poverty line. They

55.2 To address the public, state and federal courts interest in the demographic and health information regarding the community surrounding the NEIDL and how it relates to environmental justice populations, apart from the demographic data, this risk assessment addressed additional considerations such as health disparities among populations surrounding the urban and suburban site and access to healthcare at urban and suburban NEIDL sites. The available literature recognizes that large proportions of environmental justice communities suffer from health disparities (e.g life expectancy, morbidity, risk factors, quality of life). The literature also shows that environmental justice communities most often are comprised of individuals that have a lack of access to health services. The analysis for this Risk Assessment therefore considered factors and available data regarding environmental justice communities and access to services in the state of Massachusetts and New Hampshire.

have the highest rate of all Boston neighborhoods of diabetes hospitalization, heart disease hospitalization, tuberculosis rates and infant mortality. It's not a community that is equivalent to the community that would be in Tyngsborough or Peterborough.

Thank you.

MR. BAYHA: Thank you.

(Applause)

MR. BAYHA: Ms. Rushlow?

MS. RUSHLOW: Thank you. I'm Jennifer Rushlow, I'm an attorney with the Conservation Law Foundation. I would like to start out by pointing out that there are a number of elected officials in the room that have not been acknowledged yet tonight. If they could all stand up so we could thank them for attending?

(Applause)

MS. FOX: Let me just say that my position on this project has not changed. I've stated before and I believe then and now a level

NEAL R. GROSS

four biolab built in the heart and soul of the most densely populated part of the City of Boston, not just the community of color, but the entire city. So we feel they have not proven that our concerns have been resolved.

(Applause)

MS. RUSHLOW: Overall, I am greatly concerned by the shortcomings of the draft risk assessment. NIH is required by law to evaluate the risks associated with this facility. There are dozens if not hundreds of places in the 1,700 plus pages that NIH reaches the conclusion that there is insufficient data to determine the risks associated with a particular pathogen or how a pathogen might affect medically vulnerable sub-populations, such as the EJ community in Roxbury, and by EJ I mean environmental justice.

In other words, NIH has admitted that it doesn't know what the risks are, so my message to the agency is this: If this is the best you can do, then this draft risk assessment has made one thing extremely clear, the NEIDL

NEAL R. GROSS

COURT REPORTERS AND TRANSCRIBERS

must not operate in this location.

(Applause)

MS. RUSHLOW: NIH must accept that it cannot make an environmental justice community the set of its experiments with risks that we can't even quantify. That being said, I would like to offer a few specific comments on chapter three of the draft risk assessment which deals with pathogens. First, this chapter focuses on seven BSL3 and six BSL4 pathogens. This list is described as representative. In other words, you have not committed to limit your research to the pathogens on this list.

Other pathogens that are not addressed in this risk assessment will be tested in the NEIDL, if it's allowed to proceed. EIRs and EISSs, pursuant to NEPA and MEPA, can't just skip over significant aspects of a project. The risk analysis of a project of this scope and impact must be comprehensive and an incomplete list of pathogens won't do.

55.3

Letter 55

Public Meeting Transcript

55.3 Chapter 3.3 of the Draft Risk Assessment explains that the thirteen agents were selected because they encompass broad categories “to describe the general nature of risks from infectious pathogens to laboratory workers and to the public at large, and to describe in broad terms the range of potential effects from the release of such pathogens.” Therefore, any existing or new agents would present risks that are similar to one of these 13 agents under study and would not require additional risk assessment because the consequences are within the bounds of the agents and accident scenarios studies under the Draft Supplementary Risk Assessment.

55.4

Second, in many areas of this chapter you state that there are no published reports regarding transmissibility or effects of a given pathogen in medically vulnerable sub-populations and you leave it there. You make no attempt to draw inferences from similar diseases or knowledge of the effects of known symptoms on those sub-populations. For

example, in the discussion of SARS, you say that there are no published studies on SARS's differential impact on lower socio economic groups, yet we have seen it transmit rapidly in several low socioeconomic areas of the world.

To drop the analysis on the basis that you couldn't find any published studies is irresponsible, in light of the real world information that we all have. In the section

55.5

about the Nipah Virus, this section concludes with a statement that the possibility of transmission is low because it requires, and I quote, close contact that may be culture and region specific, yet the risk assessment

NEAL R. GROSS

COURT REPORTERS AND TRANSCRIBERS

Letter 55

Public Meeting Transcript

55.4 Medically Vulnerable Subpopulations (MVSP) are addressed throughout the Draft Supplementary Risk Assessment where appropriate, including.

- Chapter 3 addresses “Disease in Medically Vulnerable Subpopulations” for each pathogen.
- Section 8.6 addresses the initial infection in MVSP for each pathogen.
- Section 9.3 14 addresses secondary transmission in MVSP for each pathogen.
- Section 11.7.4 provides the risk characterization for the MVSP.
- Appendix I provides detailed information for the analyses of MVSP.

55.5 Regarding Nipah virus, the full statement in the risk assessment reads “There is a possibility of person-to-person transmission of Nipah virus via respiratory secretions; however the risk is low and requires close contact that may be culture- and region-specific (Luby, Hossain et al. 2009).” The statement of low risk is supported by the evidence cited in the same section that person-to-person transmission rates were found to be low (no sustained person-to-person transmission despite many separate introductions) in endemic settings, specifically in Bangladesh, a resource-poor setting with extremely limited infection control practices. An assumption of different cultural or regional practices at the three NEIDL sites compared to Bangladesh is not required to conclude that the risk of person-to-person Nipah virus transmission would be low. Site characteristics are addressed in Appendix B. Differences in characteristics of populations at the three sites with respect to contact rates were addressed in Appendix L (Appendix L.2, L.2.9, L.3.14).

55.5

includes no analysis as to how families in Roxbury or the South End might share the cultural characteristics of communities afflicted by the virus, for instance, large households or cultural practices that could encourage close contact.

These are just a few of the examples of the ways in which the draft risk assessment starts to characterize the specific risks of siting the NEIDL in Boston but then drops the ball and leaves the analysis incomplete. Ultimately, under NEPA, the purpose of this risk assessment is to help you to decide whether the risks of going forward with this project are justifiable. NIH is supposed to be the ultimate force in protecting America's health. Siting a facility with risks that are clearly unknown in a medically vulnerable community is hardly a protective action.

This draft risk assessment tells you everything you need to know, which is that it is not safe to proceed with it. Thank you.

and was successful in being one of the three teams picked.

Subsequently we, the community, stepped up and one of the things that I want to point out is that the mayor does not have any power if this place is implemented, or responsibilities. The first call goes to the Governor, then to the President's office. If this level four is opened up, it also can be -- it's managed by Boston University but it's controlled by the Federal Government, Department of Development, Department of Defense and the CDC.

Anyone also with enough money to rent enough space and time that they want to do their research can get in there, so the opportunity for individuals with negative indiscretions towards anyone and everyone is there. I think we the people feel that the place is not right and the impact would not be right, and it's too close. Our primary hospital, Boston City Hospital, is in the quarantine zone.

If anything happens within that area, within a mile area everything would be quarantined. That means you would not be allowed to leave.

You would not be able to jump on the expressway, that would be locked down. If you ask to see the mandated plans of security, they shut down the expressway all the way in Quincy, and towards Malden, if I'm not correct, and Medford, so we will not be able to leave if this thing is implemented in our community. One of things I want to let everybody know is this.

There was \$220 million spent to build this, \$69 to \$70 million is provided every year for 20 years, and there was not one dollar considered for the first response of City of Boston Police, Fire or anything else socially applicable to respond to a negative situation.

I don't think anybody thought about us and I don't think we should think about them.

The Developmental Neighborhood Coalition votes to reject the level four proposition. God bless you.

55.7 Boston University, in conjunction with the Boston Public Health Commission, has provided extensive training for City of Boston emergency responders, including Boston Police, Boston Fire and Boston EMTs. These training sessions have familiarized the emergency responders with the specifics of the NEIDL facility as well as the general response protocols for biological laboratory emergencies which could occur in any one of the hundreds of such laboratories located in Boston. In addition, Boston University provided a \$200,000 grant for training programs coordinated by the Boston Public Health Commission to bring in outside trainers with national expertise on responding to biological laboratory emergencies. Boston University will offer ongoing training and support to the City's first responders so that they continue to be prepared to respond In the event of an emergency.

MR. BAYHA: Thank you, sir.

(Applause)

MR. BAYHA: Sandy Eaton?

MR. EATON: Yes, thank you. I would like to point out that there are other elected officials here and I would like to yield to them, if they want to say a word at this time.

They are Senator Chang-Diaz and Counselor Jackson at least I know are here, I don't know if there are others. Representative Byron Rushing also.

MR. JACKSON: Thank you, sir. My name is Tito Jackson, I'm the City Councilor for District Seven and I stand with my community, in defense of my community, against this project. It is very simple; our community will no longer get dumped on. We have an expressway, we have all of the trash transfer that occurs in the city in that area and we also have a prison. We do not need Ebola or any other potentially airborne or non-airborne agents in our community.

In addition, within a mile, as Mr. Walker brought up, within a mile of that area is the largest and busiest bus terminal in the State of Massachusetts in Dudley Station with over 35,000 riders who move through there every single day. It scares me beyond no end, and I went through the tour and the tour scared me even more because I saw folks who were in suits and even if they had a heart attack they would still have to go through the decontamination unit, even if they were in medical distress.

That is not -- those are not the type of agents that we need, want or desire in our community and with the amount of money that was spent here, we are not going to see the down flow of jobs that we would normally see from a \$200 million facility. So I stand and I represent 72,000 people in District Seven and I am not for this. It's something that our community does not need. We need opportunities, but this is not an opportunity, this is dumping on our community. Thank you.

55.8

making that pledge and I think that's going to be a critical pledge because there remain a lot of unanswered questions for the community, and I would just like to log one question in particular. In addition to the concerns the attorney from CLS expressed earlier about all the places in the report that say that insufficient data was available, I also have a question about the assumption put forth in the report that the life of this facility would be 50 years and would not be expected to stay in the community past the 50 year life span, and I'm wondering how that number was arrived at and why 50 years. Thank you.

MR. BAYHA: Could you state your name for the record, please?

MS. CHANG-DIAZ: Sorry. Again, my name is Sonia Chang-Diaz and I represent the Second Suffolk District.

MR. BAYHA: Thank you very much.

55.8 The timespan of 50 years is not the expected lifetime of the facility, but rather the time period that the analysis of the Risk Assessment is assumed to be relevant. The Risk Assessment makes the assumption that in the intervening 50 years of operations, improvements, modifications, technological advances, and evolution of laboratory technique and practices is likely to be sufficiently different from present day.

It is expected that the facility will last more than 50 years, but that with continual upgrades it will be a substantially different facility with even greater controls and redundancies in place. We would also expect that after 50 years, many of the agents proposed for study at the NEIDL are likely to have both vaccines and therapeutics available, such that lab workers (the source of the greatest risk to the public) will be at reduced risk for laboratory acquired infections.

MR. EATON: Thank you very much.

My name is Sandy Eaton, I retired in January after 48 years working at the bed side in a variety of facilities. Most of that time it was a critical care -- as a critical care registered nurse. I want to speak particularly to concerns raised by my clinical colleagues regarding what they are expected to do if there is a breach, particularly the nurses and their colleagues at Boston Medical Center with whom I have had a dialogue throughout this whole process.

They are very concerned that there has been no education, no training. The physical facilities are not adequate with only two negative pressure rooms on each unit, meaning no more than twenty in the whole facility, and the fact that the institution is going through one reduction in force after another and the churn of personnel, which make education and preparation even worse. I can

think of three possible scenarios that were

55.9

55.9 Boston Medical Center is a key part of the emergency response network for the City of Boston and has facilities to accept and treat individuals with unknown or potential infectious diseases including decontamination and negative pressure treatment areas located both in the ER and inpatient units. As a facility that responds to and treats issues involving infectious diseases the hospital supports, works, exercises and trains with first responders from the City of Boston and has developed detailed protocols for how to deal with a variety of pathogens including many that will be studied at the NEIDL. Responding to a potentially exposed person from the NEIDL is significantly easier than most cases because there is specific information immediately available about agents the person was working with, symptoms of the disease and how to respond to an individual who may have been exposed.

In addition to the joint drills and training with the City of Boston responders, Boston University infectious Disease staff is available to the Emergency Department staff at any time to help respond to and coordinate an event. The overlapping responsibilities of Boston Medical Center hospital epidemiology and NEIDL occupational health which includes the expertise of Infectious Diseases clinicians and the ongoing training of fellows on first response contribute to a high level of preparedness.

touched on in the report but I want to bring them out particularly from a clinician's point of view.

If there is a known accidental breach, back in December of 2004, when we in the Massachusetts Nurses Association realized that the Bush Administration and BU were planning to site a level four bioterror lab in the middle of gridlock city we had great concerns. We summoned the folks from BU and invited the folks from the Roxbury Safety Net to come to our headquarters in Canton. We intended to have everybody in the room so we could have an intense dialogue and real time exchange of facts and opinions and ideas among everyone present.

The folks from BU refused to be in the same room with the Roxbury folks and we thought that was very inappropriate and set the tone for our whole approach going forward. In January of 2005 we passed a very strong resolution opposing the siting of this lab in

NEAL R. GROSS

Public Meeting Transcript

this community at this time and raising questions about the validity of the whole program, nationally and globally.

And in that presentation in December of '04 the folks from BU, among other things, showed us slides of what looked like a \$100,000 coffin on wheels, that if there was a known breach affecting a worker within the plant, within the facility, they would be put into that and wheeled -- presumably wheeled down Albany Street to the Emergency Department at Boston Medical Center. Well, what the heck are the nurses supposed to do then?

The second scenario is if there is an accidental breach that isn't known, a needle stick or whatever, and someone goes out into the community and subsequently folks show up sick. Fever of unknown origin is a very frequent diagnosis, what do you do? Our courageous colleagues in Toronto several years ago, many of whom died, were faced with the SARS epidemic. They used universal precautions, as

Letter 55
Public Meeting Transcript

they were supposed to. They did the right thing, to their knowledge, and it took a while to bring that under control.

55.10

And the third and scariest scenario, it would be of a deliberate malicious breach by an individual or group, even with suicide as being a potential vehicle for carrying out a breach. I don't think that is adequately addressed.

The document is over 1,700 pages long, I have it in my iPad. I have looked at it frequently and I've tried to get through it as much as I can, and I'm only a college graduate, so my reading comprehension isn't quite up to par.

I could get from the front to the back of the Bible more easily and quickly than I can through this 1,700 page document, so I just don't know. There are a couple of other scenarios.

55.11

We are situated on the largest earthquake fault on the East Coast. Does anybody realize that? We also -- the lab is also situated near the apex of a funnel of the

55.10 A threat assessment was developed as a separate component of the Draft Supplementary Risk Assessment in response to concerns raised by the public regarding the capability of the facility's security systems inclusive of security/law enforcement personnel, electronic systems, policies, and procedures in place to prevent, withstand, or respond to a malevolent action (e.g., disgruntled or unbalanced lab worker, insider threats, terrorist action) against critical systems and assets at NEIDL that could result in the exposure of personnel or release of a pathogen into the community. (Chapter 6, Section 6.1.1) Because the analysis contains sensitive information, the threat assessment is a confidential/official use only document. Additionally, a threat assessment for select agents requires the plan must be reviewed annually and revised as necessary. Drills or exercises must be conducted at least annually to test and evaluate the effectiveness of the plan. Both Boston University and NIH security personnel have reviewed the analysis and conclusions of the threat assessment

55.11 The maximum reasonably foreseeable (MRF) event involves a total loss of all biocontainment features, so it envelopes the consequences that may result from any magnitude earthquake that may occur. Because all biocontainment features are compromised, the MRF earthquake also envelopes the potential damage to the facility that may result from hurricanes, floods, tsunamis or other natural disasters. Natural disasters such as hurricanes and strong winds would result in lower exposure levels because the higher air velocities result in lower pathogen concentrations. Natural disasters involving water, such as flooding, result in lower exposures because the public will not ingest large quantities of contaminated water.

55.11

Four Point Channel, on a flood plain through lower Roxbury and Back Bay. They don't call it the Back Bay for nothing, so there's water as a or a tsunami as a possible situation also.

So, anyway, MNA took this position a long time ago, we haven't changed that position. We have attended every possible hearing and studied every possible aspect of this and our opposition has maintained itself.

And I have to say this, as someone who has been a practitioner at the bed side in all kinds of scary situations starting from the beginning of the HIV epidemic, I am not afraid of germs, I am afraid of arrogant bureaucrats. Thank you.

MR. BAYHA: Thank you.

(Applause)

MR. BAYHA: Ms. Steinitz?

MS. STEINITZ: I am one of the coordinators of Cambridge United for Justice and Peace and we have been involved in this struggle since the beginning. The reason why we have been involved in this struggle is that

we saw this as an example of the war at home.

We are not just concerned about wars abroad, we are also concerned about the wars at home and wars perpetuated on low income communities like the community where this lab is proposed to be sited.

55.12

Also, the dual impact of the pathogens that are going to be studied, we are told over and over again that it's illegal to do offensive research in this country, but we also know the United States has really not been a party to signing off on international treaties about biological weapons, so we are concerned about that.

I think that history is important here, the ten year history of the struggle against this lab and the reasons why there is so much suspicion and so much distrust have a lot to do with that history.

55.13

And I think the distrust is about the neutrality of NIH in this process. NIH is going to be judging the results. As part of the mutual process, they will be judging whether

55.12 Please see response to comment 55.6.

55.13 The Blue Ribbon Panel and the National Research Council Technical committee were both independent bodies consisting of national expert in a wide range of fields. The advice and guidance provided by both committees, as well as members of the public, helped guide the process for this risk assessment. Meetings between the Blue Ribbon Panel and the National Research Council committee were open to the public, and accessible through webcast.

55.13

this risk assessment is adequate. At the same time they have been coaching Tetra Tech for the last couple of years with blue ribbon panels and the NRC, so we really worry about this being a done deal or the effort to make this seem as a done deal.

A few specific comments relevant to that. Jenny talked about the 13 pathogens selected for study. In the 1,700 page document there are a lot of claims made about community involvement in the process, a list of all the meetings that the community was invited to. Well, I happened to be at the ones where the pathogens were being discussed and it was in the basement of a Roxbury church and we were presented with the task of deciding which pathogens we in the community wanted studied.

That was the assigned task.

55.14

Well, nobody in the room wanted any pathogens to be studied and this has been counted as community involvement in the process of selecting the pathogens. The question that we

NEAL R. GROSS

55.14

have, and Jenny raised it as well, is what happens if some other pathogens are researched? Will there be a risk assessment to decide whether they are problematic? Will we be told?

Transparency was on the list of the four criteria by which this risk assessment was done, but we still have no idea of what the plans are for research in this laboratory. We don't know what will be studied, by whom, etcetera.

55.15

Another specific point that I want to raise is about some of the comments the NRC, National Research Council, panel, which advised at a number of points, wrote a letter raising some questions about the 90 percent risk assessment, which is the 1,700 pages. It may be 2,000 by the time it becomes a hundred percent and one of the things that it said throughout the document is that every estimate is a conservative one, yet the NRC letter suggests that the number of needle sticks is a low estimate, it's not a conservative estimate.

This has not been addressed in the

55.15 Based on the National Research Council letter report from the November 2, 2011 meeting, Section 4.2.3.3.1 of the Draft Supplementary Risk Assessment was revised to be responsive to the NRC's concern and now reads: "Needlestick events in BSL-3 that are not promptly detected and reported are assigned to frequency category B (1 in 100 to 10,000 years). This frequency category assignment is appropriate and even conservative because: (1) the historic estimate is on the boundary of frequency categories A and B, (2) historic values likely overstate the value for current facilities due to enhanced practices, equipment, and facilities (see Section D.1.1 of Appendix D), and (3) the NEIDL is expected to have lower incident rates due to its attention to sharps safety (see Appendix F.7.2.1) and the enhancement of safety (see Section 2.1 of Chapter 2). Appendix F.7.3.2 of provides additional details."

document thus far and this, given that needle sticks are the largest frequency of possible negative events, seems to be rather critical.

Similarly, and here's something which I've learned -- I'm not a scientist. I'm a social scientist, I'm a psychologist, but I've learned a lot about biology through these years, but one of the things that gets talked about a lot is the fomite carry out risk. So what are fomites?

55.16 {

I Googled it last night and discovered fomites are the surfaces on which infectious diseases pathogens can be settled, lab instruments, lab coats, and the concerns is about the fact that in this risk assessment there has been no independent analysis of the risk of fomites carrying out pathogens out of the lab and what would happen to those.

MR. BAYHA: Ma'am, I respectfully request that you wrap up your comments.

MS. STEINITZ: Okay. Just another point that I want to raise, biological pathogens

are distinctly living organisms with no shelf life. They reproduce and they mutate often in unexpected ways. No governmental agency regulates or enforces with the public exposures to biological agents. This lack of oversight and the lack of uniform regulations on biological agents in particular is very worrisome for all of us. We worry about risk of infection and are skeptical of oft disputed the claim that secondary transmission is so unlikely it's not to be worth consideration. Thank you.

MR. BAYHA: Thank you, ma'am.

(Applause)

MR. BAYHA: Mr. Mundell?

MR. MUNDELL: My name is David Mundell, I'm a resident of the South End and I've been working on this since 2004. I did have gray hair when it started. I have not read either the Old or New Testament in its entirety, but I have read all 1,700 pages twice.

55.17 Unlike the chemical and nuclear industry, there are no explicit occupational or public exposure limit values for biological agents. However, this does not mean there is not oversight of the research operations proposed for the NEIDL. More specifically, The Boston Public Health Commission regulates the use of all BSL-3 and BSL-4 agents within the City of Boston where the NEIDL is located. This oversight is mandated under the Biological Laboratory Regulations that established the criteria for the registration of the laboratories and approval of research projects. The Boston Public Health Commission also has the Disease Surveillance and Reporting Regulation that mandates a medical surveillance and reporting program. The biological Laboratory Regulations provide specific worker protection which states “any employee absent from the work place due to illness. Section 1.3 of the Draft Supplementary Risk Assessment described the entities that would regulate the research operations taking place at the NEIDL.

MR. MUNDELL: The NRC letter, I have listened to all of the sessions with the NRC and I have some comments about the risk assessment itself, my colleagues, my friends, the elected representatives, of the risk assessment, the 1,700 pages that I've read. I do want to apologize. My mom told me throughout my life, and those who know me can sure understand that I didn't always follow my mother's advice. I want to deal with three important flaws in the risk assessment, and I advised the representatives from Tetra Tech that I would talk about these flaws. First, this is not an assessment of the risk of the lab.

55.18 {

The risk of operating the lab is the combination of all of the possible events from all of the possible agents or pathogens. This is an analysis of a supposedly representative subset of events and subset of pathogens, it is not an analysis of the risk of this lab.

(Applause)

MR. MUNDELL: Second, with regard

NEAL R. GROSS

Public Meeting Transcript

55.18 The inclusion of total risk was discussed with the Blue Ribbon Panel and excluded from this risk assessment because not all potential scenarios were analyzed. Summation of the frequency for those events that were analyzed would present a misleading perspective that we believe would not serve the public interest.

to the text of the 1,700 pages, the current draft and the companion reader's guide are subtly and dangerously biased, they are not, if this is what is meant by transparency, you have failed transparency. In many instances the positive views are placed early in the paragraphs where someone who doesn't want to read the entire paragraph can then skim to the next sections with negative views. Sections with qualifiers are put later.

In fact, the summary from Adi this evening never used the word uncertainty, never used the word uncertainty either verbally or in the text of the slides. With regard to the exclusion of asthmatics, now, again, my mom was an asthmatic, so I lived through that. The reason asthmatics were not studied was because there was no known association. There are no known associations for almost 900 percent of the events in this lab.

55.19

In fact, on page I-3, if I am correct, it does say although there are no known

NEAL R. GROSS

Public Meeting Transcript

55.19 The issue of asthma is qualitatively addressed in the Draft Supplementary Risk Assessment with respect to the available literature on the association of asthma with the pathogens studied (Chapter 3, individual pathogen descriptions). The potential adverse effect of the pathogens on asthma is also qualitatively addressed (Appendix I, page I-10, section I.3.3, Impact of Pathogen on Underlying Medical Vulnerabilities, lines 11-19). The Risk Assessment acknowledges that asthmatics are one of the diverse groups of MVSP in the community (see page I-3, lines 4-5). The Risk Assessment further acknowledges that the diseases caused by the pathogens addressed in this risk assessment, especially those associated with respiratory disease such as influenza, may exacerbate asthma (Page I-3, lines 25-26 and page I-10, lines 11-19). The criteria for selecting a specific group within MVSP for detailed analysis for this risk assessment are explicitly stated in lines 10-13 of page I-3. The objective of performing the MVSP analysis was to generate estimates of initial infections after exposure to a pathogen and secondary spread in the community. The consequences assessed for the MVSP were infections and deaths and no evidence was found to warrant assuming an increased infection rate or an increased death rate for asthmatics exposed to or infected with pathogens under consideration. Based on a review of the existing literature on asthma and the pathogens studied in this Risk Assessment there is no known direct association of asthma with increased susceptibility to infections from the pathogens considered in this Risk Assessment. Thus, asthma was excluded from a detailed quantitative analysis.

55.19

associations of susceptibility, the asthmatics will be more -- are likely to be more seriously affected by the organisms that affect the lung functions. This is bias. And, third, there

is no clear, accessible and accurate summary.

The NRC said there should be a summary, the blue ribbon panel said there should be a summary.

There should be a summary of the entirety and there should be a summary of the individual sections.

The only part which appears to present a summary is the so called reader's guide, which we were directed, purposefully, I would say, not to comment on. Frankly, I think there is a reason why we were asked not to comment on the reader's guide because the reader's guide is a biased, incomplete and inaccurate summary.

It is transparent in its avoidance of mentioning uncertainty, other than one mention of some uncertainty.

This document is not a qualified, adequate risk assessment. It is better than

NEAL R. GROSS

the other ones, but that is faint praise, given the inadequacies of the previous risk assessments. I suggest that this risk assessment doesn't have ten percent more work to be done, this risk assessment needs to be revised, it needs to be a complete assessment and it needs to be an unbiased, accurate assessment of the potential risk associated with this lab.

MR. BAYHA: I respectfully ask you to wrap up your comments, sir.

MR. MUNDELL: I respectfully will do so. In an attempt to be helpful, with regard to the summary, I wrote down a summary. "Based on available evidence and insights, it is difficult to adequately or accurately predict the level of risks potentially associated with the proposed facility." That one sentence is in fact a summary of the 1,700 pages.

(Applause)

MR. MUNDELL: And I guess I would always add another one, I would say "although

NEAL R. GROSS

it is unclear whether these risks are likely to be large, moderate or small, it is very clear we do not now have the data or understanding that allows us to predict them adequately." If this risk assessment were presented to the community before this lab was built, it would never have been built. Therefore, the high containment labs ought never to be allowed to operate. Thank you.

MR. BAYHA: Thank you, sir.

(Applause)

and I know a fair amount about infectious disease because of my biosecurity work. The first thing I want to say is NIH must not like you very much, putting you up there as the target of all our anger, but there you are.

MR. BAYHA: They thought I had the best smile.

55.20 { DR. KLOTZ: Anyway, when I started reading this risk assessment, and I'm going to bore in on one thing here, which is SARS. When I started reading the risk assessment I was surprised to find out that the risk assessment used the same hypothetical calculations to calculate the risk of SARS that it did in the 2010 risk assessment, and this was despite the fact that the NRC wrote a scathing criticism of the 2010 risk assessment and one of the things they focused in on was the fact that that risk assessment totally ignored three SARS escapes from laboratories, from BSL3 laboratories.

So I expected to see in the calculations for the risk assessment the actual

NEAL R. GROSS

www.nealrgross.com

Letter 55

Public Meeting Transcript

55.20 The three historic SARS incidents referenced in the comment were considered in the risk assessment (see Table D-6 of Appendix D); however, these foreign incidents were not used to estimate the laboratory-acquired infection (LAI) rates for the NEIDL because they are not directly applicable for SARS research at the NEIDL. The Beijing incident is not applicable because it did not occur in a BSL-3 or 4 laboratory, which would be the case at the NEIDL. The Singapore incident involved a worker with “minimal training”, which is not consistent with the training and certification requirements at the NEIDL. There is insufficient information on the Taipei incident to determine whether their protocol were similar to those of the NEIDL. It should be noted that the recent Centers for Disease Control and Prevention (CDC) study of LAI rates also excluded these and all other foreign data from its evaluation.

The risk assessment analyses were performed on the basis of NEIDL-specific biocontainment features (see Appendix F.2), while considering the potential for equipment failures and personnel errors. These NEIDL-specific protocol (e.g., use of hooded Powered Air-Purifying Respirators for all BSL-3 activities) dramatically affect the outcome of mishaps and must be considered for a relevant the analysis. Use of data that are based on different biocontainment features would result in results that are not predictive for the NEIDL.

use of that data, which they didn't use. So, as a mathematician, I went ahead and did my own risk assessment based on those three escapes and to get a probability of escape at each lab per year I found out roughly how many labs have been working on SARS, live SARS, over the last seven years. And you add all that up and you divide that into the number of three escapes and you get a probability of an escape in a single year in a single lab.

Now, the only reason I'm saying this is, as I'm sure the people from Tetra Tech know, once you have that there are all kinds of things you can calculate, if you have the probability.

So I went ahead and said okay, given the 50 year life time of this facility, which Tetra Tech uses and has also been used for the NVAF and other facilities, I asked myself, with my probability of escape in one year, what is the probability of escape in the 50 year life time of this facility?

So I found out there's a 50 percent

NEAL R. GROSS

COURT REPORTERS AND TRANSCRIBERS

1323 RHODE ISLAND AVE., N.W.

Letter 55
Public Meeting Transcript

probability of escape and about a 20 -- of at least one escape and a 20 some percent probability of at least one escape with secondary infections. Well, why is that important? SARS I think has tremendous pandemic potential. Just to give one example, there was one woman during the one natural outbreak in 2003. The woman was infected, she flew from Hong Kong to Toronto and in Toronto, even though they knew about SARS in Hong Kong at that time, in Toronto she seeded 400 and some infections and 40 deaths. So SARS can kill.

Does it have pandemic potential? Well, I compared it with the 1918 pandemic flu virus and if you look at the so called reproduction number, in other words, the number of victims that a single infected person can infect, SARS and the 1918 pandemic flu are about the same, but SARS in some ways is worse than the 1918 pandemic flu because the 1918 pandemic flu only killed between 2 and 2.5 percent of its victims, SARS kills closer to 10 percent.

NEAL R. GROSS

(202) 234-4433

www.nealrgross.com

Letter 55
Public Meeting Transcript

So SARS, in my mind, has as much potential for a pandemic.

Well, if you know you are working with something with a pandemic potential, and all the people who work on SARS, I'm sure the risk analysis here was just based on BSL3 labs, you ask yourself well how can big can a pandemic be? Well, the 1918 pandemic flu was 40 million people it was assumed died, so I just took, to be conservative, 10 million people. Then I asked myself a question, and the mathematicians and scientists in the room understand what this is, is what is the likelihood weighted number of victims and number of deaths?

So this facility, if they end up researching SARS, if the NEIDL ends up researching SARS, has a likelihood weighted number of fatalities over its 50 year life of something like 20,000 victims and over 2,000 deaths. That's much too high for any facility and even though they dismiss a pandemic, and I won't read the quote, in the risk assessment,

NEAL R. GROSS

Letter 55
Public Meeting Transcript

clearly the pandemic potential is there. And I just took -- I just said well let's suppose only one in a thousand escapes with secondary infections would lead to a pandemic.

Now this part is pure speculation because nobody really knows, but my intuition tells me if we had a thousand escapes of SARS from different laboratories, that one of them would result in a pandemic. So my bottom line on all this is no SARS research in BSL3 or BSL4.

I think all the safety, the safety that is touted in BSL4s isn't exactly right. There have been three escapes in BSL4s and NIAID has missed one, there was a 1990 escape in Russia that they missed where the worker went out of the lab.

So BSL4 labs aren't as safe and I think to work on these things we have to take the same kind of precautions that we do with smallpox, which is worked on only in two facilities in the world, by international regulation, and those two facilities do it in BSL4. Smallpox is not as dangerous in developed

countries because there is a vaccine. There is no vaccine, no anti-viral for SARS. SARS, to me, is a big danger, as is the 1918 pandemic flu, and also the potentially contagious and human Asian Bird Flu Virus.

I would say those three should not be worked on in any BSL3 or BSL4 facility without even additional precautions, which I won't get into today, but I'll send my whole analysis and everything to you.

MR. BAYHA: Thank you, sir.

(Applause)

MR. BAYHA: Ms. Griffin, to accommodate the council member's schedule, would you mind if he went before you?

MS. GRIFFIN: I would be delighted to yield to the council member.

MR. BAYHA: Council Member Yancey?

(Applause)

COUNCILLOR YANCEY: Thank you very much. I will be very, very brief. First of all, I just want to be very clear and unequivocal

NEAL R. GROSS

COURT REPORTERS AND TRANSCRIBERS

that I stand with the people of Roxbury and
Dorchester, Mattapan, the South End and the
Greater Boston Area in opposing the operation
of a level four biolab here in the City of Boston.

(Applause)

COUNCILLOR YANCEY: And I oppose it
because over the past seven years of my
twenty-nine years on the Boston City Council
we have held a series of hearings and
informational sessions at Boston City Hall, and
I did testify back in October, October 23rd of
2006, when NIH convened a so called community
meeting to get some input and my position
unfortunately hasn't changed over the years and
over the actual construction of the facility.

Because the basic question I have
to answer as a member of the Boston City Council,
where I am responsible for the lives of visitors
and residents of Boston, is this: If, for
whatever reasons, one of these pathogens were
to be released, what is the city's response?

NEAL R. GROSS

55.21 The containment of an infectious disease relies on early diagnosis and treatment and reducing the spread of the infection by preventing contact between the infected individuals and the community. This is accomplished by asking those with an infection to stay in their homes (sometimes referred to as quarantine or shelter-in-place). Evacuation or a city-wide quarantine is not part of a typical public health response to an infectious disease. The Boston Public Health Commission's Infectious Disease Bureau is the public agency that makes decisions about management of infectious diseases. The Office of Emergency Management (OEM) is responsible for coordinating all emergency management programs for the City of Boston.

55.21

Commission, there may well be a response from the United States Military instituting a quarantine. The risks are far too great, the rewards are doubtful and dangerous.

And I can't understand why a United States agency would select a densely populated area like Boston, particularly this section of Boston, adjacent to hospitals and hundreds of thousands of residents. Why do it here? I say don't do it here, use that facility for some other purpose and I go on record as being opposed to the level four biolab, and thank you so much for yielding. Thank you.

(Applause)

MR. BAYHA: Ms. Griffin, thank you very much.

MS. GRIFFIN: No problem. Good evening. My name is Christine Griffin, I am one of the attorneys representing the community members in the federal and the state litigation and I work at Anderson & Krieger in Cambridge, and I specifically want to address the

NEAL R. GROSS

alternatives analysis that's been included in the risk assessment. The risk assessment aggressively attacks this question as one of the focuses of its analysis, it announces in the opening chapters that it will be one of the focuses.

It was the focus of one of the slides that was presented this evening and unfortunately, although there are a lot of conclusory statements made in the risk assessment about the alternatives analysis, there is not a lot of actual analysis provided in that document. Now, as a number of people have noted, there are other locations that are possible places where BU could locate this lab, a suburban location and a rural location, Tyngsborough and Peterborough, New Hampshire.

Beyond those locations, there are a million other locations where this lab could also be located but, focusing just on those three, it's important to look behind the conclusory statements that are made throughout

NEAL R. GROSS

the risk assessment about the fact that they have considered whether or not the different locations have an impact, and they have looked at the map and in fact the different locations would not have an impact. Whatever map or analysis they are relying on to reach those conclusory statements is not provided in the risk assessment and if that map has been done, if there is data that they are relying on, that data needs to be provided in much more specificity.

Part of the problem in reaching these statements is that the biolab has been built and as a number of people have pointed out, we are here discussing whether or not it is safe to build a building that is already sitting several blocks away, fully built. And, therefore, the fact of the building, as it exists, is incorporated as an assumption into the entire risk assessment, if you were to build a level four biolab in a suburban location or a rural location, there is no reason to believe

that the building would even look exactly the same as it looks sitting in Boston.

55.22

The building sitting in Boston, as it was built, was built to be on that site. It is a tall building with a narrow footprint. If it were located in a rural location, it would probably be a much lower story building with a broader footprint. It would present a different target for malevolent attacks if it were located in a different location.

Unfortunately, it is far more likely that a building located in a dense, suburban area that has a tall, highly visible frame -- sorry, in a dense, urban area that has a tall, highly visible frame would be the subject of a malevolent attack than a building located in a rural location.

There's also a lot of discussion in the risk assessment about the fact that the percentages of people who have susceptible immune systems or who fall into communities and populations that are more at risk is the same

55.22 The analyses do address external differences such as population and meteorology, so the only differences not addressed are the building and its operations. There is no basis for assuming that operations within a facility would be different solely because of its location, so operations (e.g., standard operating procedures, personal protective equipment, etc.) are assumed to be the same for all three sites. Differences in the building design would have negligible effects on the results of the analyses because of the nature of the analyses. The centrifuge and needlestick analyses are only effected by the operations inside the facility, which would likely be identical. The MRF earthquake analysis would be unaffected because: 1) it assumes a total loss of biocontainment features so design differences are not relevant, 2) it assumes a ground-level release so building height differences are not a factor, and 3) the facility design would adjusted for potential site differences in seismic hazard. The frequency of an aircraft crash would be affected by a different design, but this analysis was performed solely to demonstrate that the MRF earthquake bounds it and this conclusion would not be altered. Therefore, because the alternate design information is not available or producible, and because it would not significantly alter the results if it were available, the facility design is assumed to be the same for all three sites. The Risk Assessment addresses the effect of commuting on potential secondary transmission for the three sites (see Section 9.3.14).

55.23

percentage of the population that it would be in many other locations. But the risk assessment plays a little bit fast and loose with its term using percentages and actual numbers. Obviously, even if the percentage is the same here as it would be in another location, the number of people who would be affected is much higher because the population is much denser.

55.24

So the risk assessment also needs to take into account how many people would be impacted, not just the percentage of people that would be impacted. Another issue that the risk

55.25

assessment repeatedly says that it has considered is the nature of the commute and the traffic patterns surrounding the location. At this point, there are people who are actually employed by Boston University who work in the biolab on the lower level BSL pathogens. We have actual data that could be collected about where those people commute from, what modes of transportation they take.

55.23 It is true that even if the percentage of medically vulnerable individuals were the same at the three proposed locations, there would be a greater number of medically vulnerable individuals located near the urban site due to population density. However, MVSP were addressed extensively throughout the Draft Supplementary Risk Assessment. Information regarding the analysis of MVSP can be found in the following locations:

- Chapter 3 addresses “Disease in Medically Vulnerable Subpopulations” for each pathogen.
- Section 8.6 addresses the initial infection in MVSP for each pathogen.
- Section 9.3.14 addresses secondary transmission in MVSP for each pathogen.
- Section 11.7.4 provides the risk characterization for the MVSP.
- Appendix I provides the detailed information for the analyses of MVSP.

55.24 Please see response to comment 55.23

55.25 Section 9.3.14 is a summary of the site differences from the secondary transmission analyses, for which extensive detail is presented in Appendix L. Data from the U.S. Census on commuting patterns of residents and workers at the three sites were incorporated in several different simulations of secondary transmission among the public. Details can be found in Appendix L.2.5 and Appendix L.3.14.

55.25

It doesn't appear that any of that actual data was considered in calculating whether or not the surrounding community would be more likely to be affected in this urban location and the fact of the matter is that

Boston is an old city with old infrastructure.

There are bridges and tunnels, there's tremendous traffic gridlock. A lot of people commute to and from work on public transportation. Those characteristics of the City of Boston are different not just from an urban or a suburban location but they are also different from many other urban locations that you could have chosen to locate this lab.

These aspects of the location also impact the transport of the pathogens and the emergency response to any accident that would take place at the biolab. So, in closing, I would urge NIH in editing the risk assessment to provide us with much more data and a much more rigorous analysis of why this urban

location is, in NIH's eyes, no more dangerous than any other location because this is a unique space and it does not appear to this community that they have properly evaluated this unique location. Thanks.

MR. BAYHA: Thank you.

(Applause)

MR. BAYHA: Mina Makarious.

MR. MAKARIOUS: My name is Mina Makarious, I represent -- that's all right, it's not the first time that has happened. Along with Christine Griffin, I represent the plaintiffs in the federal and state lawsuits involving the biolab. I want to start by noting that the RA refers to public input dating back to 2004 throughout the document. It's not clear, however, what this public input includes or how it informed the analysis, which is a key point to consider in the public input.

55.26 {

Details as to how the RA evolved as a result or as influenced by the public comment would not only have been helpful but would be

Letter 55

Public Meeting Transcript

55.26 Throughout the course of the project NIH has held extensive consultations with the Boston community. During the drafting of the Environmental Impact Statement for the NEIDL, public input was sought and considered multiple times before the report was finalized. For the Supplementary Risk Assessment, the NIH Blue Ribbon Panel has held several public meetings to hear the concerns of the community and to solicit feedback on what scenarios and agents the community wished to see analyzed in the document.

55.27

essential to know that the comments were listened to. An appendix containing prior public comments could have been considered or should be considered in the future. In addition, the plaintiffs and other members of the Roxbury and South End communities have raised serious concerns with the openness and transparency of the community input process throughout this time between 2004 and now.

55.28

These include the inaccessibility of NIH meetings and materials and the community's interaction with the CLC, which has been referenced before tonight. In addition, the chart in the risk assessment of public involvement opportunities included several meetings held in Bethesda, Maryland where it would be very difficult for many members of this community to travel to on a regular basis. These were not accessible to members of the Boston communities, the materials from these meetings were not accessible in advance, in most cases, and in some cases even the telecast was

NEAL R. GROSS

Public Meeting Transcript

55.27 Public comments made on previous risk assessment documents are available to the public upon request. Comments made on the Draft Supplementary Risk Assessment, as well as the NIH response to those comments appear in full in Appendix O of the Final Supplementary Risk Assessment.

55.28 NIH has actively and extensively engaged the community and has sought community input throughout the Supplementary Risk Assessment process. All meetings of the NIH Blue Ribbon Panel, many of which occurred in Boston, were open to the public and videocast for those who could not attend in person. The videocasts of those meetings were placed on the NIH Blue Ribbon Panel Web site for those who wished to view the meetings at a later date. Meetings were widely advertised on the NIH Blue Ribbon Panel web site, local Boston newspapers, and the Federal Register. Each meeting included a portion of time for public comment. Finally, all materials discussed at these meeting are accessible via the Blue Ribbon Panel web site.

55.28

difficult to access for those who had computer access to begin with.

55.29

Further, the brief descriptions in the risk assessment of public input include things such as "members attended and provided comments on", and then in parentheses the subject of the meeting. This does not capture what influence, if any, the public involvement has had on this risk assessment or the previous risk assessments. So, to phrase some of the

concerns that have been raised in the past, one, although NIH and BU have been urged by members of the Boston community and the state court to focus on specific sites at issue, very little of the risk assessment actually does focus on the placement of the NEIDL within Boston or the two alternative sites, as my colleague just mentioned.

55.30

Instead, the bulk of the risk assessment draws on generic medical and sociological data without analyzing specific social patterns, commuting patterns or,

NEAL R. GROSS

Public Meeting Transcript

55.29 NIH has actively and extensively engaged the community and has sought community input throughout the Supplementary Risk Assessment process. The input from the Boston community assisted NIH in scoping which agents and which scenarios would be studied in the risk assessment.

55.30 The Draft Supplementary Risk Assessment considers differences in social contact rates for urban populations due to increased population density as compared to the urban and rural sites (Appendix L.2.9.1). Estimated differences in contact rates between residents at the urban, suburban, and rural sites were applied in the secondary transmission analyses, as described in Appendix L.2.9.1. The contact rate estimates were based on demographic data about homes, places of work, and service locations near the three sites. The effects of these site differences on the overall results were summarized in Section 9.3.14 and quantitative details can be found in Appendix L.3.14. Use of public transportation was not specifically addressed because assessment of potential links between public transit ridership and risk of acquiring infection is an open area of research and no clear correlations were found in the literature that could be used to support any further adjustments in assumed site-specific contact rates.

55.30

frankly, any other population characteristics, aside from the medically vulnerable subpopulations within the potentially affected communities. Second, there's been a lot of

mention of the potential for creating jobs and yet within the categories of potentially exposed populations there is the category of laboratory worker, which is used to describe scientists and lab technicians who are likely to have received some training in the safe handling of pathogens, and a separate category of facility workers, which is assumed to include only administrative staff with no access to laboratories.

55.31

This categorization fails to include maintenance staff, janitorial staff or any other staff that may enter laboratory spaces on a regular basis, especially at times when other lab workers are not there. This omission is especially problematic given the fact that such workers are more likely to live in environmental justice communities and more

NEAL R. GROSS

Letter 55

Public Meeting Transcript

55.31 Section 4.1.2.2.3 of the Draft Supplementary Risk Assessment included facility workers as a “potentially exposed group.” Maintenance and janitorial staff are also included in this group. All support staff, including maintenance and janitorial staff, will receive the appropriate training prior to their entry into the BSL-3 and BSL-4 areas. Section A.4.3 provides a training matrix that shows the appropriate training for administrative staff, visitors, vendors, service personnel, community members, operations and maintenance staff, Institutional Biosafety Committee (IBC) and the Institutional Animal Care and Use Committee (IACUC), NEIDL emergency response team, and public safety emergency responders. In addition, due to access controls, it is unlikely that maintenance or janitorial staff would come into contact with pathogens in the course of their job.

55.31

likely to commute using public transportation, given their socioeconomic status.

Second, the risk assessment references the conclusion of a blue ribbon panel on bioterrorism and its implications for biomedical research as one of the reasons for the need for the lab. That panel was convened in 2002. We all remember that the world was a very different place in 2002 and at that point that analysis said an insufficient amount of BSL3 and BSL4 spaces existed to protect the United States from bioterrorist attacks. That conclusion, even if accurate, is outdated.

55.32

The risk assessment does not include an up to date statement of the need for additional BSL3 or BSL4 space that takes into account the advances of scientific research, the changing nature of terrorism risks and the proliferation of high level labs since that time. Finally, I would like to focus on something that has been brought up a few times, which is the way the risk assessment handles

55.32 NIH still concurs with the 2002 panel recommendations. While scientific advances have been made in the past decade, the need for this type of facility continues to be essential towards the development of effective vaccines, therapeutics and diagnostics against emerging or reemerging infectious diseases or agents that could be used against the United States for the purpose of bioterrorism.

the risks of malevolent attacks.

55.33

The risk assessment assumes that risks caused by malevolent attacks can be analyzed through comparison to earthquake risks and other natural disasters. This is unpersuasive. Malevolent attacks would target the NEIDL, they would be intentionally targeted at the NEIDL or specific populations. Earthquakes don't do that.

55.34

In addition, some risks that would be created by malevolent attacks that don't include the release of pathogens, such as fire, building collapse or violence used to obtain pathogens are not discussed at all.

In fact, fire is used as a great fact that may allow some pathogens to be killed off.

These are unlikely to occur in an area absent the placement of a target for malevolent attacks and that analysis hasn't been studied for any of the sites, whether the urban, the rural or suburban sites. Thus, the additional risks of

55.35

these other non-biological risks should be

NEAL R. GROSS

Public Meeting Transcript

55.33 As discussed in Section 6.8 of the Draft Supplementary Risk Assessment, the malevolent act releases are expected to be less than the MRF earthquake releases because the inventory is less, the release fraction is less, and the release is likely to be discharged out the stack.

55.34 Please see response to comment 55.10.

55.35 The inclusion of total risk was discussed with the Blue Ribbon Panel and it was agreed that it is inappropriate to attempt to present total risk for this Risk Assessment. This Risk Assessment analyzed scenarios that are expected to pose the greatest risk to the public, but it is not possible to attempt to analyze all possible scenarios. Summing the risk from a subset of possible scenarios and presenting them as the "total risk" incorrectly implies that all scenarios are included. A summation of these scenarios would present a misleading result that we believe would not serve the public interest. However, the large conservatisms used for the MRF earthquake and needlestick analyses means that they are reasonable approximations of the total public risk for direct and indirect exposures.

55.35

analyzed and should be presented to the public so that a full assessment of the risks can be given, as Mr. Mundell pointed out earlier, not just a piecemeal assessment of different risks.

Thank you.

MR. BAYHA: Thank you, sir.

(Applause)

MR. BAYHA: Mr. Orareo.

MR. ORAREO: Excuse my back, Brian, but I am going to address the people who matter here.

(Applause)

MR. ORAREO: My name is Richard Orareo, I live on the Fenway, just a ten minute walk on the other side of the tracks. I've lived there for 40 years and I've gone to every one of these meetings at Cathedral High School and Hibernian Hall, and two of them here, and I state to you with every affirmation that I can drum up that our voice has no influence, no authority, no control, that this thing is going to happen in spite of us. And I think it is so politically

NEAL R. GROSS

what we have learned is that in spite of us, it is built. In spite of us, they are doing research right now, and I think that we have to go beyond our simple voices in speaking out in opposition, that we have to go storm City Hall, occupy City Hall.

(Applause)

MR. ORAREO: Confront Tito Jackson to take a position. Let me tell you the story of why the Fenway, not even close to the South End, is affected by this. One would think that City Hall would have learned from this experience, that the lawsuits that are involved in the blue ribbon panel, that they would not make the same mistake again. Well, they have made the same mistake again and it's right now in process. Northeastern University, across the street here, in Tito Jackson's district, has had a chemistry laboratory compromised with cyanide being taken right out of the building in a suicide attempt.

There was an incident, another

NEAL R. GROSS

suicide incident at Boston University just a couple of weeks ago. There was a suicide incident at Dana Farber. Where are the protections? Where are our safeguards? When that Northeastern suicide took place it was investigated by the fire department and the investigation said, and I quote, from the *Boston Globe* reporting, the firemen who investigated the living quarters of the suicide person said there was enough cyanide there to take out a neighborhood.

If you know cyanide, there's very little that's required to commit suicide. Any institution that cannot control its controlled substances cannot be trusted.

(Applause)

MR. BAYHA: Before anyone starts, I would just like to remind people to adhere to the three minute limit. We have a lot more people that want to comment tonight. So that we can get to everyone, I respectfully request that you adhere to the three minute time limit.

Thank you. Mr. Chinich?

MR. CHINICH: Hello. My name is Ian Chinich, I'm a graduate student at Boston University. I came to offer my support and support of a lot of students who have been working for a lot longer at the university than I have in opposing this lab. I'm showing solidarity with the affected communities, particularly in the areas around where the facility has been built, but also in the rest of the city which would be affected in the case of any kind of contamination.

And one of the questions that we often hear on campus for support of it is, well, you know, it's located in the position it is because of its location to the medical facility. What that means is ease of transportation and what that actually means is cost. So essentially the facility has been located in the area that it is because of the cheapness factor in locating it there, rather than the safety factor in preventing any kind of

NEAL R. GROSS

contamination.

So mostly this is about profit. This is about profit for the facilities that are making this, this is about profit for the scientists who are working on it and this is essentially one long chain in subcontracted defense spending by the United States Government.

What we have also found out is that this facility is now one of approximately 15 or 16 facilities across the country, 15 or 16 facilities that are all testing diseases that actually have no real human effect in this country or in most portions of the world and that what they will be testing on is weaponized forms of these.

55.36

(Applause.)

MR. CHINICH: Since we all know that terrorist attacks by weaponized forms of these agents are very infrequent, as it takes years and scientists working on them, we can only expect that what they really mean is weaponized forms by governments. So for us, what this

NEAL R. GROSS

Public Meeting Transcript

55.36 Research conducted in the NEIDL will also be carried out on pathogens that are major threats in the US, such as tuberculosis, but also on infectious diseases that impact the populations of other countries so that the nation can be prepared against new threats.

No bioweapons research will take place at the NEIDL. The production of bioweapons is prohibited by Article 1 of the *Biological Weapons Convention* of 1972.

Research at the NEIDL will be performed for scientific research and biodefense purposes (i.e. developing effective vaccines, therapeutics, and diagnostics). All research at the NEIDL will be conducted in accordance with applicable federal, state and local regulations. Information on the purpose of the NEIDL was presented in Chapter 1.1 and Chapter 1.3 of the Draft Supplementary Risk Assessment.

means is that our country is building a giant facility and framework for stockpiling what they call defensive biological weapons but could actually be offensive biological weapons which, as has previously been stated, is illegal under our own laws.

Furthermore, they are going to be testing and creating agents that don't actually exist in reality, weaponized forms, which are more deadly than the actual versions of these diseases, all because of the reason and rationale that they have to test them. So what this means is that we are going to be stockpiling even more dangerous forms, which could have an even greater effect than the natural diseases which they have actually been testing in this framework.

And, as has previously been stated, there's no actual list of any of the pathogens that they are going to be testing, only alleged forms or certain forms of potential pathogens that they could be testing. And, as we all know,

NEAL R. GROSS

the only case of domestic biological weapons that have ever been used on this country was by a scientist leaving one of these facilities and actually using it on our population. So by creating and proliferating more of these facilities, we are actually making a greater danger for it domestically, we are giving more chances for more scientists to have more access to these pathogens.

And so not only am I opposed to having this facility in this city, I am opposed to it in the country and I think that by trying to save money we are putting our citizens at risk. Thank you.

MR. BAYHA: Thank you, sir.

(Applause.)

MR. BAYHA: Ms. Creary?

MS. CREARY: My name is Gwen Creary and I'm a long time resident of Roxbury and I just had one comment. I wanted the NIH blue ribbon panel to explain, nobody has explained why the NEIDL or the building is a couple of

55.38 Please see response to comment 55.25, 55.30, and 55.34.

55.39 Boston University requires a number of shipping safeguards, including use of qualified carriers, background check requirements on drivers, two drivers with each vehicle and others, such as the use of GPS. These practices were detailed in Chapter 5 of the Draft Supplementary Risk Assessment. These practices are currently in place with BSL-3 Select Agent shipments and involve City of Boston Response Agencies during shipment planning and are part of the protocols submitted to the Boston Public Health Commission for permitting. The carrier selected to transport select agents to the NEIDL will subject their drivers to security background checks as part of the employment process and NEIDL public safety officials will be provided proof of these checks. Also, there will be two cleared drivers for all Select Agent transports to and from the NEIDL. The transport vehicle and package will be monitored by GPS tracking and NEIDL public safety officials will have, in advance, the drivers' names, photo ID and clearance information. Upon arrival at the NEIDL the drivers ID and information will be verified and the truck and packages will undergo inspection prior to entering the perimeter.

this is an unlikely occurrence. Really? Love that self-assuredness. How about what happens in all of our bridges, tunnels or during rush hour? And what happens when first responders are affected? They leave the scene unknowingly, possibly infecting others with a potentially lethal virus. There are just some more pieces in a puzzle that is completely inadequate and an insult to the community's intelligence.

Please remember we've been at this for ten years. Maybe you've had children grow up in this period of time who might live near a site as dangerous as this and who could be in danger of a great and hideous death. Do we deserve this danger? No. Does anyone deserve this danger? No. I oppose any BSL level four labs and hope that we would like some answers, and stop this lab. Thank you.

MR. BAYHA: Thank you, ma'am.

(Applause.)

City of Boston, particularly Mayor Menino, won't seem to give up on this lab, so I get to continue to hang out on my campus. I had heard about the lab here and there as a student at BU, but then I went to a forum, and I heard Claire Allen speak and I got the facts, and I don't know really what else we need to hear here.

This is a blatant form of environmental racism, it has failed all the risk assessments. The community has been opposing it for over nine years now. It's extremely dangerous, extremely unnecessary and, as my good friend, Ian, was saying, in order to test these things, you also have to create them, which is extremely concerning. During my time at BU, I was editor of an independent student newspaper there and I did some reporting on the biolab, but it just got to a point where I couldn't be doing objective reporting on something that was so blatantly wrong and I needed to be out there at the protests and the different rallies that have been held.

If you just do some research on the history of how my former university approached the Roxbury community, that in itself is just extremely upsetting, and overall this just seriously embarrasses me as an alumna of Boston University. There are so many different questions that have not been answered here, but I think the most pressing is just why should this lab ever, ever open in the community of Roxbury? Why should a level four biolab ever open, but particularly in the community of Roxbury? That question will never be answered.

So I just want to say the community opposition is only going to continue. The BU student and alumni opposition is only going to continue and we aren't going to let this level four lab open.

(Applause.)

MR. BAYHA: Thank you. The next four speakers are Katie S., Lisa Cain, Walter Newman and Kristen Martin.

Katie, I'm from Allston and in May I graduated from Boston University, which is one of the creepy and unaccountable institutions behind the building of the bioterror lab. So I would just like to say shame on BU and on the NIH for building this unsafe, environmentally racist bioterror lab and for attempting to open it over the wishes of Roxbury residents. It's unnecessary because it does not purport to research diseases that have impact on the lives of Roxbury residents.

It does research that is being done elsewhere and safer and you don't need live viruses to do this. It doesn't require a BSL4 lab and it doesn't need to be in a densely populated urban area that has repeatedly told you for years and years that it does not want you here. So, in conclusion, as an alum and as a concerned citizen, I am going to do whatever I can to support the students who are fighting the fight on the campus and the folks from Roxbury Safety Net who are opposing this lab

and just do whatever I can to help them make sure that it does not open.

MR. BAYHA: Thank you.

(Applause.)

MR. BAYHA: Lisa Cain?

MS. CAIN: I would just like to say that history is really replete with examples of groups of people discerning a horrendous event coming, and naming it and cautioning people, and then becoming victims, and this is -- the number of peoplehours that have gone into these ten years of meetings and people preparing in all kinds of different ways to come here and say their most earnest -- in their most earnest way this cannot happen, and yet this is a tragedy because -- look at the person next to you.

This is the last meeting tonight, and where does it go from here? It's over, so what's going to happen? This is the last scheduled meeting of all and I just would say that use your own head to just convince yourself that this really -- it can't happen and there

NEAL R. GROSS

have to be ways beyond these kinds of meetings to have things change, because I've seen panels here looking down and talking, looking down at and talking down to people in the audience, and I've seen numbers that make absolutely no sense at all.

I'm sure that a lot of people in this room are unconvinced by figures that say this is a one in ten million chance that this could possibly happen.

(Applause.)

MS. CAIN: What is that? We all know that there are other level four labs that have had problems with people walking out of the lab with some sort of contamination. These figures just -- they are just not real. So I would just like to say that the National Institute of Allergy and Infectious Disease really needs to look at itself for even thinking of allowing something like this to be in any kind of a populated area and you really wonder why they have to be at all.

Jerry Frank.

MR. RORLICK: Hello. My name is David Rorlick, I'm a member of the Massachusetts Green-Rainbow Party which has consistently opposed this project over the years and still opposes it. I'm also a resident of Boston and a BU faculty member. There are a lot of things to comment on this so called risk assessment but I will focus my comments on one slide of the presentation, the slide that refers to the possibility of malevolent action.

Now, there are numbers that appear on that slide and on all the slides, those are numbers like one event in ten thousand years, one event in a hundred thousand years, one event in a million years. I want to talk about something that occurred less than eleven years ago and the fact that it's not even mentioned on that slide about the possibility of malevolent incidents puts the entire report in a -- it makes the entire report lose credibility.

It's so egregious, that slide, among

NEAL R. GROSS

COURT REPORTERS AND TRANSCRIBERS

1323 RHODE ISLAND AVE., N.W.

WASHINGTON, D.C. 20005-3701

(202) 234-4433

Letter 55
Public Meeting Transcript

others, but I'm going to focus on that slide, it's so egregious not to mention it that the entire credibility of the presentation is lost.

What am I referring to? It's been mentioned, it's been alluded to by one speaker. Less than eleven years ago there was a biological terror incident in this country, five people died, several others were injured. Millions of people were afraid to open their mail.

The fall of 2001, do you remember it?

I bet everybody in this room remembers it. There was an investigation by the top law enforcement authority in this country, the Federal Bureau of Investigation, under the auspices of the Department of Justice. A lot to say about the investigation, mighty unprofessional, but it is the last word of the Department of Justice, of the FBI, so let's take it at face value. It concluded that a crime was committed, first of all, and it identified the person who it said was responsible for the crime, a man by the name of Bruce Ivins who

NEAL R. GROSS

COURT REPORTERS AND TRANSCRIBERS

Letter 55
Public Meeting Transcript

conveniently committed suicide before he was actually charged.

He was, well, there's a lot to say there. And it also identified where the anthrax bacillus emanated from, so Bruce Ivins, the alleged perpetrator, the anthrax bacillus from a specific source. What was the conclusion of the FBI? Bruce Ivins, an employee of a federal bio safety lab in Ft. Detrick, Maryland, and the source of the anthrax bacillus was a lab in Ft. Detrick, in the bio safety lab itself.

For you to mention a million years, five million years, one incident, is an insult to the intelligence and to the historical memory of the entire audience here.

(Applause.)

MR. BAYHA: Mary Krotte?

MS. KROTTE: I'm Mary Krotte, I'm a nurse attorney with the Massachusetts Nurses Association and, as Sandy Eaton testified earlier, we have taken a position opposed to the biolab and have worked strongly to oppose

NEAL R. GROSS

COURT REPORTERS AND TRANSCRIBERS

1323 RHODE ISLAND AVE., N.W.

it for several years now. I also want to say I think we should commend those people, David Mundell and others, who waded through the 1,700 page document that people here were expected to read.

(Applause.)

MS. KROTTE: And note that it's kind of interesting timing. We heard from our Supreme Court Justice, Antonin Scalia, a couple of weeks ago that certainly no one could expect him to have read all 2,000 pages of the Obama health care law that he was to rule on, so I think there's a point that we need to sit and think: what are we asking of people? We understand, just to step back a moment in time, as our last speaker did, the 25,000 nurses of the Massachusetts Nurses Association understand where this all came from, in the hysteria, the aftermath of 9/11, the search for weapons of mass destruction, the feeling that something had to be done.

55.40 {

Where we are lost though is how this

defend it, but it doesn't have to be used for the purposes it was designed for. It can be used to support badly needed research in the area of antibiotic resistant infections, drug resistant TB, flu, things that are really, truly public health risks.

(Applause.)

MS. KROTTE: I think that's what we should be looking at. Just to stick strictly to the risk analysis that was done, Chapter 2.6, the risk analysis says that the facility, that the site here in Boston is appropriate because of its -- because it's on a BMC campus. That's just stunning. That's the last place you want to put a facility. You really don't want to wipe out one of your major downtown teaching hospitals and there simply is no -- there is no capacity. There is no new isolation facilities that are being built at Boston Medical Center.

Boston Medical Center in fact is \$70 or \$80 million in the hole year after year.

We have people that are stacked up in emergency rooms right now waiting for hours to be seen.

We have psychiatric patients that are waiting days to be seen that are -- we have homeless that are sleeping in some of our downtown teaching hospitals for days at a time. We have no extra capacity to handle any surge that would happen if there is an incident in the lab.

(Applause.)

MS. KROTTE: We also, as an aside, have no confidence in the siting. I want to point out to the group, and I don't believe I heard it mentioned tonight, another biolab was built in Galveston, which is a hurricane barrier island. That's the kind of thinking and strategy that's gone into the siting of these labs. The absurdity just stuns us. That lab flooded also a few years ago when a hurricane hit Galveston and a couple of our nurses from MNA were down there at the time working and were not told about the flooding in the lab. They were put at terrible risk.

We see people, there was severe flooding in Northeastern Massachusetts a few years ago. The *Boston Globe* had pictures of old people sitting in grocery carts because hospitals weren't prepared to accept them when their senior citizen and nursing homes flooded because Medicare hadn't approved them for temporary housing. Year after year, we have storms that hit Central Massachusetts, we have poor residents of Worcester that are left without heat, without power for weeks at a time.

I, of course, don't need to remind you about all the people of color that were left sitting on rooftops after Katrina, and yet we are led to believe that Boston is better situated to handle a disaster? We just don't buy it.

MR. BAYHA: Ma'am, please wrap up your comments.

MS. KROTTE: All right. I would like to strongly encourage you, to get back to my earlier point, to think about alternative appropriate uses for this laboratory.

MR. BAYHA: Thank you.

(Applause.)

MR. BAYHA: Mr. King?

MR. KING: The gentleman from the Fenway said what I think is as significant about this as anything. And, for me, the issue starts with the dishonesty in the initial granting of the funds by NIH to BU. The court session in Cambridge where it was first brought clearly showed that as the judge asked questions to BU and the state, where they answered no. Did you try any other place? Did you do any analysis? No. What made you believe that -- no answer. And he said that it was arbitrary and capricious.

And I sat in the court and I thought about black folks whose -- when the court said you don't have any rights that white people have to respect and I sat there and I said this is exactly what the judge was saying about the people in the South End, that we had no rights that BU or the state, at that point, had to

NEAL R. GROSS

Letter 55
Public Meeting Transcript

respect. And NIH went along with that, even knowing that the court had said that the decision for it to go forward was arbitrary and capricious.

Since then, and now as a member of the plaintiffs in the federal court, we've had the court say go back and do due diligence. Your last one, the group came back and said was a sham, and so you are going back again, and what we have again here is a sham. If you heard what was said about the anthrax stuff and how this was just a little while ago, as I looked at those numbers up there where they talked about one in a million, ten thousand years or whatever, I said that's cuckoo.

We have people being affected by things daily, daily, and it doesn't seem to matter. Listen, to me it's very simple. If you respect the rights of people, then you will tell the NIH folks that this is not the way to go about it. The report, all those pages, who would you expect to do that? Do we know whether

NEAL R. GROSS

there are any people on this group who had a different point of view? Is there a second opinion from anybody else?

Even with the Supreme Court, they at least have a way that the other justices who don't agree with the first part are able to come and say why they don't think the decision by the majority works. We don't even have the benefit of that because we know that you didn't want to hear from scientists who would have had another opinion and that is because you are lockstep into trying to make this thing happen.

And, folks, it's one thing to go after NIH. I think there are some local folks, the mayor, for example, and Governor Patrick, that we have to go after as well.

(Applause.)

MR. KING: We have to go after them, and it may take some demonstrations, it may take stopping traffic and a lot of things around the hospital, but we are going to have to do it, if we are serious about protecting the interests

of a lot of people here. Understand this, if all the communities around us have passed laws preventing bio -- I mean level four labs in their communities, why is it that we are the butt of it? Why is it that we here in Boston have to be subject to what all the communities around us say uh-uh, not in our back yard. This shouldn't be in anybody's back yard. Thank you.

(Applause.)

MR. BAYHA: Jerry Frank?

MS. SKYE: I'm going to face the audience too. I'm taking Jerry's place. I'm Beverly Skye, I'm on the Board of the Union Park Neighborhood Association. We do not dispute that this research is important for humanity, we object to the fact that it will be conducted in our humanity. In a densely populated area next to a major highway, all we need is one deranged person to fill a van with explosives and pull over on the expressway during rush hour and set it off. That would be the equivalent of a major earthquake that would damage this

NEAL R. GROSS

glass building.

This research puts out entire city at risk. One in a million, once in two thousand years, once in two million years, these are the risk assessment numbers we are being offered by this huge risk assessment study. Don't they sound reassuring? What are the odds? Much like the possibility of winning a Megabucks lottery, someone does win. Unfortunately, in this case, if BU wins, we all lose. Corporations with a great deal of money to be made on government grants and funding will say everything is safe until disaster occurs and then it is too late.

Let us not forget Fukushima, Fukushima, Fukushima. All the scientists said it was safe to build a nuclear power plant there too. Where are they now? No doubt they are very busy checking their risk assessment numbers again. At the last public forum the NIH panel indicated that nothing would be approved that did not have community support. Does that

NEAL R. GROSS

facility to be in this community with our leaders, all of who have stood in opposition, and everyone in this room? Is there anyone in this room that supports this idea and, if so, where are you and why aren't we hearing from you?

Why aren't they hearing us and why do we have, ten years later, been speaking to the NIH about something that has nothing to do with health but which has to do with catastrophes? It sounds like a haunted building being placed in the middle of a community unlike something that any city has ever heard of before. This is a haunted building, it's full of ghosts of diseases and ghosts of the flus and the vaccinations that they are supposedly working on to protect our health.

This isn't a health facility, this is a bioterror facility and it's putting us on the front lines of a war that may never get fought except for in our community when there is a slip

a non-negligible risk. The risk of winning the March 30th MegaMillions lottery was, and that jackpot was \$650 million, but the risk of winning that lottery was 1 in 176 million. Not much of a chance. Certainly far less of a chance than one in a million, yet there were three winners.

(Applause)

MS. GALLAGHER: Do not play the lottery with human life. Thank you, sir.

(Applause)

MR. BAYHA: Alice Kitter?

MS. KITTER: I'm Alice Kitter from Watertown, Massachusetts. I come here because people in my church in Cambridge are very concerned about this and I remember that the United Church of Christ some years ago raised up the issue of environmental racism and we are very concerned about that. I think that the risk assessment doesn't say that if you don't build it, there is no risk.

(Applause)

MR. BAYHA: The next four speakers are Susan Hardin, Cornelius Roddick, Virginia Pratt, and I can't make out the last name on this last one but the first name is Prascinan. Sorry.

MS. HARDIN: Hi. My name is Susan Hardin. I have one question and two points, maybe three. First of all, the question I would like to have on record is an analysis of the locations of all of the bio level four labs in existence and on the planning boards and in terms of the positioning of this one in this kind of neighborhood and place, how does it compare to all the ones that exist and all the other ones that are on the drawing board? So I would expect to get an answer to that, thank you.

First of all, I've got to say that there is no doubt that this is political, political, political, on top of being financial, financial, financial. But I recall that about the same time that we were meeting two years ago at Faneuil Hall the senators from the State

of New York determined that placing a bio level four lab at the tip of Long Island, not the closer tip to Manhattan but the opposite one, was much too close to Manhattan, to a populated area, and so that ended any discussion.

About that same time I found the opportunity to come face to face with the Mayor himself, His Honor Menino, and I said, Mayor Menino, there are many of us that are citizens of this city that are greatly concerned about this bio level four lab and he said that is a done deal, it is a done deal, it is a done deal.

He repeated it three times to make sure that I knew that two years ago it was a done deal.

If that's not political, I don't know what is.

Thirdly, I would like to compare this, the situation of siting this lab here and the lab itself to something else that is of a level four, and maybe more than a level four, as we know now, and that's siting any kind of nuclear facilities. On the one hand you can come down, go down and look at the big battle

that's going on with Yankee, Vermont Yankee, and the one that's happening in Pilgrim Power Plant, and you may not be aware that our communities to the south, at every one of their town meetings, is asking that the re-licensing of these power plants not happen until we find out and implement the safety measures from Fukushima.

So there is a lot of -- but if you look at one of the nuclear power plants, if you go to it, you can't walk in the front door, you can't walk out the back door and get on a subway.

It's in an isolated area, there's fencing all around and there's a huge perimeter of open land.

Not so with this. However, on the other hand, I mean, there's another place that I'm familiar with and that's Livermore Lab where they do research, and that's in California. Let me tell you when you are doing research like this there are armed guards at the gate, barbed wire, fences. You don't even see the building from the outside, from the road.

We've got land in this country, if you really want to do something like this. It doesn't belong in the middle of a city. The other point I want to make though is that I'm sorry to be finding out that the National Institute of Health is no better and maybe fits into the same category as the Nuclear Regulatory Commission which still insists that we should license our nuclear power plants even though we are right now, as we speak, still in threat, being threatened by the Fukushima nuclear fallout.

It's going across the country. It's been measured on the West Coast and it's coming here. All of the damage that they said would never happen and don't worry about it, it's happening, it's really happening right now.

So NRC, NIH, you are supposed to be working for us and it doesn't seem like that's happening at all. Thank you.

MR. RODDICK: Hi. My name is Cornelius Roddick, I live in Roxbury. I'm one of the ten Roxbury residents who complained about this lab initially, going back ten years, and I want to reaffirm what the gentleman said, going back a little bit, which is we just don't trust you, we just don't trust you, I can not help it. The older I get, the less I trust, especially in terms of the politics that I see going on today.

So, anyway, the Big Dig thing and the biolab, they strike me as being very similar.

The Big Dig was supposed to be very straightforward and all of that and look what a boondoggle that turned out to be, so I'm confident that that's something that will happen also with the biolab, that those germs are going to get out, that there is going to be somebody who is going to be pissed off one day and he is going to be like a Timothy McVeigh or some dude out there who kills 73 people and he decides he is going to off folks because he's got some

political situations on his mind.

55.43

So I know, I can feel it, I know that that's what's going to happen here, there is no question about it. And, also, I want to say that me being one of the ten respondents was up on the web site, myself and others who oppose this lab, our names have been taken out. I would like to know why that was. I think that was the wrong thing to do. Also about the Mayor, I voted for His Honor. I voted for him year after year after year after year, but I see that let Borders Book Store close.

Although that doesn't seem to be related, to me it represented a spot where people of color could go and do their own research. They didn't have to go to the library, they could have gone to Borders. He could have done something about that and I'm very upset over that. And in addition to that, now he wants to raise the rates so that people can't even get around. So I'm saying that the attitude of the people who are in power towards the people

who live here, I think it's really a terrible thing.

I know that these germs are going to get out, I know it. Somebody is going to do that, some so called terrorist, but he is going to consider himself to be a patriot, and one day we are all going to regret doing this here.

(Applause)

MR. BAYHA: Virginia Pratt?

MS. PRATT: Thank you. I'll identify myself as being with the Women's International League for Peace and Freedom, the Boston chapter, and for ten years we've been going to the meetings. We have had representatives at all of the meetings and it's been a long struggle, and I share the sentiments of everyone in the room who has said the most serious issue here is that there is no credibility or trust. I really appreciate a lot of the big thinking that people have done and I also want to say that I'm very glad that

people have said that they are opposed to a bioterror lab, they are opposed to development of bioweapons.

That's something that we have seen as a moral issue. It's also coming on the heels, and this was mentioned, of Fukushima and the hubris that's proposed by the NIH is just so striking, the idea that there couldn't be an incident or that we should just simply be reassured or the best minds have worked on this.

I guess I have to say that I've been thinking more simply and I've been thinking, okay, like what's in a laboratory? There are specimens, there are animals who probably are going to be injected with all these horrible things.

There are people like janitors who have to clean up, and we live in a city that has a lot of people who English is not their first language, and a lot of times the people for whom English is not their first language are doing jobs that are very dangerous and also not getting paid very well. So I think about

55.44 All spill clean-up at Boston University laboratories is conducted either by the trained researchers with appropriate personal protection, Environmental Health and Safety (EHS) Staff or trained contractors supervised by EHS. No janitorial or housekeeping staff is allowed to perform such tasks.

55.44

like, well, you know, if there are animals and there are specimens, what would be a likelihood that somebody who is a cleaning person would become infected? Probably there is some likelihood of that.

55.45

What about if they have to wash something and there's water? Water is something that is a finite resource I've recently learned, like all the water that's on the planet is the same water that's always been on the planet, and water is becoming increasingly contaminated. So if they have to wash something in the lab, where does that go when it goes down the drain? Does it go to the Deer Island Treatment Facility? Does it go to Malibu Beach where I like to swim in the summer?

I hope not.

What about the fact that with any type of environmental clean up, clean up is a relative term. Like if you look at a super site, these things are never really completely clean, it's a relative kind of clean. So what about

55.45 Section 2.1.5 of the Draft Supplementary Risk Assessment addressed waste management at the NEIDL. Section 2.1.5.1 described the management of biological waste including the effluent treatment and decontamination procedures. Section 2.1.5 also described the processes used in sterilization of effluents before they are discharged into the sanitary system, after which they can be treated as any regular discharge into the system.

the fact that people who work in the lab have to wear these suits and they have to suit up?

So what does that mean? It means it's really dangerous. So we don't have suits and we are not going to have \$2,000 suits, nor do I want to live in a city where I feel like I need to have a respirator and a suit on.

There's a report out today that one half of the people in this country are in poverty, 50 percent of the people in this country are in poverty. Why are we spending, not we, why is it being shoved down our throat to spend an astronomical amount of money to manufacture bioweapons to kill people and to terrorize people when, as was stated earlier, we've got homeless people sleeping in the hospitals because they don't have another shelter to go to?

55.46

Our dear Felix Arroyo, Sr. was at one of these hearings one time and he said they talk about jobs and how there are going to be jobs if we build this thing. He said, for my

money, we could build a supermarket and we could have the same number of jobs probably and especially the same number of jobs for people in the community, and the pay would probably be about the same.

And I just want to say that as a member of WIPF, as a Boston resident, no, no, and no to the bio level four lab. There are so many ways that we could reinvest this money and we, the U.S., the most belligerent country on the planet right now, should be toned down and not gearing up for more war and weapons. Thank you.

(Applause)

MR. BOTHEARTI: Hi everybody. My name is Prascinan Bothesarti. I live in Newton, Mass and for ten years many of us in Newton, Massachusetts, which is about five miles from here, have opposed this lab. And I'm happy to say that our former mayor, David Cohen, who was mayor when the lab was proposed, and the Board of Aldermen also came out in public in opposition

to this facility.

(Applause)

MR. BOTHE SARTI: So many of us who live in the area stand with the residents of Roxbury and the South End who are going to bear the brunt of this facility. Now I just have two questions for Tetra Tech that I would like them to take up when they do revisions on their risk assessment. The first is a number of speakers have talked about what are the various probabilities of various events happening.

55.47 {

I mean I don't think we can actually attach very good probabilities to a lot of these events, we don't have that much data to go on,

but I think a more important or another important question is what level of risk is acceptable and how do you determine that level, the level that's acceptable? I mean, why should we accept what Tetra Tech, NIH, BU, the level of risk that they say is acceptable? What about the community's perspective? So how do we deal with

55.48 {

these differences? That I would like them to

NEAL R. GROSS

55.47 As discussed in Appendix F.1.2 of the Draft Supplementary Risk assessment, this analysis is consistent with the National Environmental Policy Act (NEPA) regulations and with the Department of Energy (DOE) NEPA Guidance for implementation of those regulations. Consistent with the requirements of 40 CFR 1502.22 (the requirements for dealing with incomplete and unavailable information), this analysis identifies the limitations of the data used, discusses the options and significance of assumptions made, and provides a basis for use of these assumptions and data. The results presented herein reflect the uncertainty in both the data and the models used for this evaluation. The analyses consider the variability and uncertainty of the data and models in each phase of the analysis.

55.48 This comment is outside the scope of the Draft Supplementary Risk Assessment.

55.48

address in this risk assessment. I mean, it's not enough just to tell us, oh, the risk is this, but why is this an acceptable level?

The second question is a number of speakers have talked about accidents, Lynn Klotz talked about three cases of SARS released from level four labs. There have been accidents in BU laboratories in the time that this laboratory, this BSL4 facility has been debated.

There was the famous incident of the Tularemia infections, which BU tried to cover up. They did not follow the proper reporting procedures.

So when NIH or BU officials wonder why there is such a lack of trust in this audience, look at yourselves, look at what you have done. Look at what you have funded, NIH.

Look at the record. Now, given this history of accidents, someone looking at risk assessment from the outside, like me, would say why should we not adopt a precautionary principle? Why, if the risk of accident is not zero, why place

NEAL R. GROSS

this lab in a place where accidents could lead to great disasters, like the center of Boston?

55.49 {

So where is the precautionary principle in the Tetra Tech risk assessment? That seems to be an essential part of trying to understand risk and coming up with strategies to deal with risk and it was ignored in this risk assessment. Thank you.

(Applause)

MS. CRUSTADO: Hi. I want to address the public too because my heart is pounding. I feel infuriated. I feel that there's people that have no conscience, that put money before and profit before life and that you decide what you want to do with your life, but I don't respect anybody who talks back, I'm sorry. And I want to say that we should take this time to realize that for nine or ten years we've been talking about this, we've been trying to be rational. We've been trying to convince them because we believe that they can be convinced, that they can be rational human

55.49 The Risk Assessment analysis was conducted in accordance with the DOE NEPA Guidance, as discussed in Section 4.1.1 of the Draft Supplementary Risk Assessment. A key element of the DOE NEPA Guidance for the accident analyses is the application of a sliding scale. The sliding scale allows for adjustment of the level of detail of an accident analysis in accordance with the frequency and consequences of the accident and the level of information available. While realism is important, the DOE NEPA Guidance also supports use of *bounding* (i.e., analyses based on conservative assumptions that envelope potential factors) when its use is consistent with the sliding scale approach. Bounding approaches can have several potential benefits including streamlining the analysis and potentially being more defensible than more rigorous approaches because they are unlikely to underestimate potential accident consequences.

beings.

But the fact that some people put profits before lives, it's a reality. Let's face it, we are not going to continue, they are not going to give us any more information. You can present all day, most specific scientific information to them that says that this is wrong to do and they are not going to come up with anything. Ten years is enough, let's try to do something different.

55.50 {

We have to change our tactics because this is what's happening, the lab is functioning at a level three already.

Ten years of explaining, ten years of asking them for change, it's not going to happen.

Let's save our energy and not try to convince them anymore but use our energy to focus on a different tactic to stop this. We have to stop it.

MR. BAYHA: Ma'am, could you state your name for the record, please?

MS. CRUSTADO: My name is Yvonne Crustado, and I am not a scientist, I'm sorry,

connected to facilities, but you are not going to answer me, so I'll take that as a yes.

MR. BAYHA: This is not a question and answer format, sir.

PARTICIPANT: You are still talking to me though, I appreciate a little interaction.

Well, now that you've shown us a great presentation of facts and figures that prove you have taken every precaution to eliminate risk, now I want to talk to you about an uncalculatable risk, human error. This is actually pretty relevant with a recent story at BU that has to do with police conduct actually that has resulted in some unfortunate unveilings that occurred with a hazing incident.

At my ACA meeting a police officer handed out a completely unredacted report on the recent hazing. Five men naked, duct taped to each other, covered in various condiments and sauces is not considered sexual assault, even if they were beaten with an iron pipe and forced to drink out of it. Now I know the

NEAL R. GROSS

victims' names because I have this report because BUPD on the scene -- well, okay. The hazing is complete, now that I know the names.

This wouldn't have happened if the people in power labeled this as a sexual assault. BPD and BUPD were on the scene.

Human error comes from inconsideration, I think, mislabeling, failing to identify the truth. The results are accidental, unintended. The officer that handed out the report had good intentions. The reporting officer from BU had good intentions, to let the victims believe that they weren't sexually assaulted. Unfortunately, that label would have saved them privacy from the record the police keep forever. I believe you could be doing this with good intentions possibly defending the lab for the premise of national security.

Again, this lab is unprecedented.

In the 1950s, New York had the decency to put their lab on Plum Island, far removed from the

NEAL R. GROSS

Public Meeting Transcript

city. Now this lab is actually being moved to Manhattan, Kansas. Have you ever heard of that town, sir? If you can drive a truck through it, it's not safe. The threat of the BU lab needs to disappear, it does not need to be there.

Again, this is considerate of every possibility.

From my allegory about BUPD's bad decision, people in power can not evaluate the risk because, yes, well, I'll say it again, the people in power can not evaluate the risk because the police are scathed against college tourists puking on their door step, because BU can have the convenience of bringing their dirty business in our city for their profit. There are 15 level four labs, 9 on military grounds, 1 that's privately owned by a non-profit, and one doesn't need to be in this city at all.

(Applause)

MR. LEWITT: My name is Dave Lewitt, I'm from the Alliance for Democracy. I'm co-chair of the Campaign on Corporate Globalization and Positive Alternatives. I think that the risk assessment panel was narrowly composed or narrowly instructed.

55.51

There were four criteria that were under examination; needle stick, centrifuge, earthquake and traffic accident or transportation. These are all accidents. What was missing, it seems to me, was the elephant in the room, not accidental release but controlled release. How can that be?

55.52

I would like to know what the interest of the Pentagon and the CIA have been in this biolab, particularly the level four lab.

The Pentagon was certainly largely responsible for Nagasaki and Hiroshima, and also Dresden and Pyongyang, which were fire bombed dreadfully, weapons of mass destruction. And here we have the Pentagon moving into Africa, having already devastated large parts of the

The 2001 mailing of letters containing *B. anthracis*, and other events of this type, were discussed in Appendix D of the Draft Supplementary Risk Assessment.

55.52 This facility is partially funded by NIH and owned and operated by Boston University. The Pentagon and the Central Intelligence Agency have no role in the operations of this facility.

Middle East, Africa, where Ebola was said to have arisen, which might make an interesting cover for an outbreak of Ebola, which is one of the level four pathogens.

So those populations, the populations at risk there are far more numerous than just the Boston area and somebody has to speak for those populations. So I would simply ask the panel to be clear about the interests of the CIA and the Pentagon and that level four research and development of new varieties of pathogens should not go forward in any laboratory. Thank you.

(Applause)

MR. BAYHA: We still have a few more names to go through on the list but if there are more people that wish to sign up, I would encourage you to do so now. The next speaker, I can't make out the name, but it's Riverview Avenue in Waltham, I believe.

PARTICIPANT: Thank you. I'm going to go by the name of Jane Doe, and I think

it's fitting because I would like to speak for the 99 percent of the people who could not come tonight and who are clearly not being heard in this country anymore. I am very ignorant about this issue. For many, I understand it's the last panel. For me it's my first. I came simply to be a body, to be in solidarity with a campaign that I know has been going on for ten years, and I remember people in this room asking me to come to meetings ten years ago and I didn't.

And part of what strikes me here is how incredibly reasonable all the speakers have been. They care about the security of their community, about their job, about their kids going to school, about where people are working.

People are being totally reasonable, but I feel like this is another public hearing that is a total sham. I feel like Mel King said it right, the word is sham. I feel like we, the 99 percent, are being held in contempt increasingly by the people who hold power, whether it's our

government, the CIA, the Pentagon or the corporations, and including you all.

Even the notion that people can only stand here for three minutes and then they are cut off to me is absolutely disgusting. These are people who are talking about safety and lives and I feel like we are being treated in contempt, and I think it's time that we, we are clearly powerless. I am struck here tonight again about how powerless we have become to determine anything about our future and our communities and I think what's happening is that we are going to have to work to regain our power.

What you all are doing by continuing not to listen is to radicalize the American population and at some point, whether it's the biolab or it's a nuclear plant or the latest, being able to be stripped and searched for being stopped for a traffic violation, is that the American public is going to get sick and tired of being reasonable, and I welcome that day.

(Applause.)

MR. BAYHA: There are five names remaining that I'm going to read out. Mark Pelletier, Michael Cote, David Roald, Claire Allen and Akila Manna.

MR. PELLETIER: My name is Mark Pelletier, resident of Boston. I'm also a molecular biologist with 25 plus years of experience in medical research. I've reviewed every one of the risk assessments that have been put forward since 2004, I think there's been five or so iterations of that, so we'll just get to some specifics on this one. So

specifically in Chapter 6, on the risk assessment or the threat assessment, there was omission of historical data, as well as important scenarios.

So, particularly the point that one speaker mentioned before me, that there is no mention of the Bruce Ivins attack. The only

mention, when you search through these whole 1,700, almost 1,800 pages, the only mention of those attacks are as a reason why we need to

The 2001 mailing of letters containing *B. anthracis*, and other events of this type, were discussed in Appendix D of the Draft Supplementary Risk Assessment.

build one of these labs, because this attack happened. But yet there is no connection between the fact that, as the speaker pointed out very vocally, and I'm totally behind him, this came from one of these labs. This was a respected and career scientist who had been working at a U.S. Government lab for 30 years and he decided to sneak material out and use it for bioterrorism.

55.55

So there was no modeling of that anywhere in the report, and this is an incident that is the basis for supposedly needing these labs, a huge omission.

So how would you possibly model something like that? I think that it was conveniently left out because it was obviously very difficult to model. They

55.56

also, at the same time, downplayed that there was an anthrax attack from a government lab in Russia in 1979 and that was only referenced as not relevant to the NEIDL situation, so here's another escape from a government-funded lab that killed some citizens, not really relevant to

55.56 {

this analysis.

55.57 {

Further in that section, Chapter 6, they mention that if you want more information on why they chose the scenarios that they did or didn't, they said go to Section G10-2.2. If you look for that in the document, it's not there, it doesn't exist. Also, in that same

chapter there's also where they talk about another scenario, there was a loss of a pathogen that they were supposed to model and they said that there was no similar event that happened in the past that they could use to model this on.

I guess they forgot about the 9,000 vials of various specimens that turned up missing from the Ft. Detrick lab, that was probably about three or four years ago. So some of that they are not sure, it may be clerical error, but there's 9,000 unaccounted vials from a government funded weapons lab. Furthermore, as several people pointed out, there was no discussion about how the lab-borne tularemia

55.58

infections that happened at the BU Medical Center, how those happened, and this is in light of -- and that was in 2007.

55.59

In 2009 there was a similar lab-borne infection of *Neisseria meningitidis* at the BU Medical Center, no mention of that in their analysis. So here is an incident that

55.60

they should be modeling in the facility that they should be modeling it in and that's not even mentioned. That is somehow deemed as not relevant. So as the speaker mentioned before me, this report has no credibility. They choose to focus on hypotheticals, as opposed to focusing on incidents that actually happened and things that we could maybe learn something from.

Especially if you want to understand how it happens to prevent something from happening, the same thing from happening again, maybe even worse because now BU Medical Center is applying to work with even more dangerous infective agents, and so they can't even figure

out how it happened with the less pathogenic organisms. So, as we said, the lab report has -- this risk assessment has no credibility. This is really a political process, not a scientific one.

Let's look at who is conducting the risk assessment. So it's Tetra Tech and, in particularly, Dr. Adi Gundlapalli. So Tetra Tech, if you go to their site, they have no experience, they have nothing on bio safety.

Their knowledge center, which they highlight there, has no bio safety experience. There is no mention of bio safety in any of their featured projects. If you search for bio safety or BSL on their web site, there are zero hits, so Tetra Tech has zero experience that we can see studying these types of problems.

Dr. Gundlapalli, if you go to PubMed and look at what he has published lately, he publishes a lot on medical -- on communication of medical records and medical communications.

He has no publications on these types of

55.61 Tetra Tech has core competencies in the preparation of environmental analyses and a wide breadth of technical expertise, particularly in the areas of Biosafety/Biocontainment Laboratories. Tetra Tech has prepared hundreds of human health and ecological risk assessments for the Department of Energy (DOE), Department of Defense (DOD), Environmental Protection Agency (EPA), NIH/NIAID, and other federal agencies involving biological, chemical, and radiological materials. Tetra Tech has performed similar analyses for other BSL4 laboratories, such as the National Bio and Agrodefense Facility, Rocky Mountain Laboratories, and the Galveston National Laboratory.

diseases, on working on any high containment laboratories. Even I would say the laboratory experience, the wet lab laboratory experience looked like it happened back in the mid '90s, that was kind of my read from the published report.

So of all the scientists and all the people in the United States, these are the best people to have picked to study the possible risk posed by this lab? There's an obvious -- well, let's look at why they possibly were picked. Now, if we look at where Dr. Gundlapalli works, he works at the NIH funded Rocky Mountain Center for Excellence in Biodefense and Emerging Infectious Disease Research. So here he is, he is an employee of NIH who is contracted by NIH to study a lab that NIH has already sunken a lot of money in pride to build.

55.62 {

On top of that, Tetra Tech has been paid by NIH to assess any risk that this lab could possibly pose to the community. This is all very reminiscent, if we all remember the

55.62 Dr. Gundlappali is not an NIH employee. He is currently a faculty member at the University of Utah, School of Medicine, one of ten institutions that comprises the NIH-funded Rocky Mountain Regional Center of Excellence. Dr. Gundlappali has no personal or financial interest in the outcome of the Supplementary Risk Assessment.

financial meltdown that happened where the rating agencies were paid by the financial institutions to rate the securities that they were selling, and of course they were like, oh, these are great, sell them, yeah, thanks for the money. Doesn't this all seem very reminiscent of that? And then what did we get for that? We got the financial meltdown.

MR. BAYHA: Sir, please wrap up your comments.

MR. PELLETIER: Thank you, I will.

So obvious conflict of interest. And so I guess over 1,700 pages, looking at that, it really reminds me of something that we thought about back in high school when we were writing our essays, it's like, I don't really know what to say, so I'm just going to write down a bunch of stuff. You know, and the old saying was, if you can't dazzle them with brilliance, baffle them with bullshit. The volume, this is a work of volume, this is not a work of quality and believe me, I am a scientist, I work science,

able to sort of go through and really show how absurd the math was, but I wasn't able to do that so much this time because there's almost no formulas anywhere in this report, anywhere for you to be able to look at, the way in which the slides are presented in the report, in order to see whether or not the way in which these slides are put together are illogically consistent.

55.63 { It's really bad. In fact, I would call attention to the fact, and I can't remember the exact page number, I think it's about 20 or 30 pages in, but there's one page where you can tell that there used to be a formula there at one point because the text goes on and on, and then it drops down significantly, and then there is a gap, and then there is a word, and then there is another gap and then there is a period. It clearly looks as though at one time

NEAL R. GROSS

55.63 This comment could not be authenticated. Applicable formulas related to the modeling performed were presented in the Draft Supplementary Risk Assessment for public review.

55.63

there was a formula there, but that formula isn't there anymore.

55.64

And it looks as though an effort was seriously made to go through this report to remove any possibility of being able to computer model anything that's presented in this report independently in order to verify that it exists.

And one of the things that this report definitely relies on, and people have raised this point before, is that it's -- I can't say that I understand this report 100 percent, I haven't read this report.

I haven't read every single word in this report, I apologize, but I have looked at every single page and it literally is to the point to where if you want to be able to understand any of these slides, you have to have access to all the footnotes and to be able to see the footnotes and then be able to go back to whatever report or whatever science peer-reviewed journal published those original reports in order to find out whatever

55.64 Information regarding the modeling methodology is contained throughout the Risk Assessment such that it can be reproduced and verified.

55.65

information that underlies the slides. Because all the stuff, any sort of computer modeling, any sort of formulas, probabilities, statistics that was there in the previous version of the report, it's all gone, it's not there anymore, and I don't understand how that could happen.

I mean I understand that the last time we were here I pointed out the fact that the number of times that absolute zero was used throughout the report was statistically impossible, you couldn't have that, that kind of stuff doesn't happen in a real life scenario.

And so I would like to -- I mean I know I'm getting into dangerous ground talking of any kind of sports metaphor, but this is literally like reading a report that says the Boston Red Sox are better than the New York Yankees, and looking at the paperwork and not being able to find a single example anywhere where the absolute best player on the Yankees is better than the absolute worst player on the Boston Red Sox.

It is so biased that it's unbelievable. There is -- one of the things that I just found absolutely totally absurd when I got to it was there was the discussion about what would happen about plane crashes. There was examples of what are the odds that a plane would actually crash into this building and cause the possibility of a breach, and they were talking about the possibilities of what would happen if the plane crashed in New Hampshire and what would happen if the plane crashed in Tyngsborough and what would happen if the plane crashed in Boston as though they were equal probabilities.

But they weren't taking into consideration the fact that planes land in Logan Airport in Boston. I mean the planes come down right over this site in order to land and that doesn't happen in Tyngsborough and it doesn't happen in Peterborough, New Hampshire in the same way that it happens in the vicinity of Logan Airport, and so there were underlying

Flight patterns were included in the analysis of aircraft crash risk for the urban site (see Section F.9.3.1.1). The risk of aircraft crash is likely to be lower at the suburban and rural sites, but the conclusion of the analysis is valid for all three sites. As reported in Section 9.3.3 of the Draft Supplementary Risk Assessment, the frequency and consequences of an aircraft crash are less than or no greater than the frequency and consequence of the MRF earthquake .

55.66

assumptions that are just absolutely absurd in the way the connections are made.

The whole presentation is stripped of any -- I mean it's heavily footnoted, I will commend you on that.

It's heavily footnoted and it's finally using fractions and percents and all that, which wasn't there before, but some of the underlying assumptions, unless you have access to a full medical library in order to research like every single footnote on the bottom of every single page, there's no way that you could determine whether or not this thing is realistic or not.

55.67

And so the absence of any sort of formulas in there in order to be able to verify the logic underneath some of the math that was used in some of these things, like saying that this has a one in ten thousand year or this has a one in one million year probability of occurring, none of that's there for us to be able to actually see it.

We are having to be able to take it on face value and the fact that that gap exists

but I got here and I can see that it's important to speak up on this occasion, so I would like to say that before the formation of the so-called United States of America in the 17th and 18th Century, the founders of the Colony of Massachusetts, the leadership of the British colonists used biological warfare, deliberately giving smallpox-infected blankets to the indigenous people in Massachusetts so that the British colonists could steal every inch of land here.

And since the formation of the United States of American, the Federal Government, the Government of the United States has constantly been perpetrating wars of aggression, racist wars of aggression, including biological warfare, against people on this continent and people on every continent of the world. And today the United States is perpetrating wars of aggression against people all over the world, including oppressed communities right here in Boston.

presentation that was done earlier. I just have a problem with not knowing who I'm speaking with, so I was just wondering if there's any NIH, NIAID, BU folks, can you raise your hands so we know who you are? Be proud. There you are.

Okay, thank you very much. Now I know who you people are, okay.

So, anyway, I just wanted to see who folks were. And I think that I just want to say to NIAID and NIH and Tetra Tech, I think that this process was really messed up. And I know that we have been working with you all at least eight years and have also been fighting you for ten years and all we have spoken about is community process and transparency. I really think that it's very, very, very unfair that the whole purpose of having a Boston meeting was because Maryland meetings were being held with the NRC and other experts around the table.

Residents were unable to attend the Maryland meetings.

So we did fight to have a Boston

NEAL R. GROSS

meeting so that we were able to speak about our comments and have discussions as well. For you to come into our community once again with this ten year history of wanting to present what you have to say and then not having a discussion with us is very rude and very ignorant and I really don't appreciate that.

(Applause.)

MS. ALLEN: And so I don't think it's a fair process that you have created. I think that we should be able to have discussions, I think Tetra Tech should be able to stand up and represent the work that they have done, and also be able to answer some of our concerns. As far as our comments are concerned, usually we see our comments at the end of the document.

I have not seen any of our comments implemented in any of the document risk assessments that have come out.

We still have a concern about the risk assessment. And one of my major concerns is our question has always been the lab may not

NEAL R. GROSS

have an accident, I know that that is possible, that that is a probability, but it could. And the fact that our higher powers, our Federal Government and the entities that are experts in this field have to go for a third time to do a risk assessment to prove your statement that there is no risk to our community is what makes you fail constantly. You are experts, you are the people that we are supposed to look up to and when we say prove to us that there is no risk to us, you have three attempts.

This attempt, you have heard our experts, who are experts from around the country, say you have done a poor job once again.

That's scary. The other thing is that in the risk assessment when we ask if there is a release, what is going to happen, when there is a release in Boston. I'm not really looking at the figures and how you came about that, that's for the experts to talk about. But when there is some sort of incident, why isn't BU in the risk assessment? I don't understand why

NEAL R. GROSS

they aren't saying what their role is going to be because whatever you put in that book they are going to have to implement.

So it's BU, the Boston Public Health Commission, Mayor Menino, Bio Square. Where are these entities that we are supposed to go to to get answers and questions? I'm sorry to say that I really did not agree with the BU tour.

I understand that Mayor Menino has been trying to get this lab open for ten years or eight years, or however long. I understand that. I understand he wants to go down there and showboat and do his thing, that's fine. I just don't understand how NIH, how NIAID can say to me and also the energy office can say to me, well, Claire, that's up to BU, you go talk to them.

You are bringing people, BU, literally, and Mayor Menino I just found out brought over 300 people into that high risk federal facility, cameras going. They are showing backup systems, they are showing this, they are showing that, they are showing this

55.68 {

and they are showing that. No wonder you haven't included malicious intent in your risk

assessment. It makes no sense to give a tour.

Let's not forget 9/11. Two people came from Mission Hill and boarded that plane.

Boston is not off the map and to have a tour done with whomever, because residents were asked to come. You had a 24 hour check, birth certificate and Social Security, that's it. You don't know who you let in that lab. Who do we speak to? If we are supposed to speak to someone when tours and things like this that don't make any sense, who are we supposed to speak to? NIAID told me that I'm supposed to speak to BU. NIH says I'm supposed to speak to BU. I speak to BU and they say, well, this is what we are doing.

If there is an incident in this community it will affect everyone within a ten mile radius. We need answers, we need for BU to be accountable. You need to make BU accountable and the risk assessment, I just want

from the community members because I don't think we can do anything about extending the time.

MS. MANNA: Good evening. My name is Akila Manna and I actually just found out about the meeting, unfortunately, and it wasn't well publicized, but I guess you know that and it was intentional, most likely. And I still take issue with the fact that we only have three minutes and no one else will be able to -- people that we had, more eloquent than myself, who weren't able to discuss the problems. I'm an Army brat. You can see the scarf, don't pay any attention to the scarf, that's a religion.

I'm an Army brat, I was raised going on and off of Army bases with my dog tags and my ID card, and we didn't have any bioterrorist facilities when I was growing up. I mean we just had trucks, and people running in and out, and different countries and stuff like that, but I'm sure it wasn't anything this dire. We had, like they have around the prisons with those barbed wires and the fences so high, and then

we had police and -- I mean, not police, we had the MPs with the "halt, who goes there" and what not, and they are not going to have that.

Obviously they don't have it and they are not going to have it, and why not? And, plus, I mean why put it in a glass facility?

What are they joking? Glass? I mean, at least the World Trade Centers were concrete and they didn't have a chance in hell. Why would they put something like that in the middle of this city, in such a populated area, and everyone said this already. I'm not the only one with these feelings, I'm just going to be heard. I have to put my two cents in because I'm a citizen of Boston, I've been here for the last 42-43 years after my father retired from the services.

I knew nothing except for government. I learned that everything the government says, don't believe it. That's what I learned as an Army brat. Whatever they told my father was a lie. He gave his life for the

United States of America, and we stood up and saluted at Taps and when the flag was being lowered and raised on the base we stopped what we were doing and paid attention to that flag, but what do they do for the people? Not a thing.

They take your money.

I love America, this is my country, this is my native language. I speak one language. Well, I speak a few, but this is my natural place of being and I don't want to go anywhere else. No, I don't want to move out of Boston because these unfeeling, callous people want to put a life-threatening facility here for me to die. I mean, I don't particularly feel like dying when you are finished with your money making facility. I just want to know who is in whose pockets. I can't figure out whether it's the government in BU's pocket or BU is in the government's pocket.

I can't figure out who is making -- somebody has got something to do with something that's more than lives in the City of Boston.

I mean what could be worth all of these millions of people? How much are they making in order to put this up and actually have no -- take into consideration all of these lives? I mean, no matter what ethnicity, we are talking about ethnicities across the board. Forget all the poor people and our homeless people and the derelicts in the middle of the city right here taking advantage of Boston City Hospital, whatever they call it today.

Forget all these people, but don't forget you've got all of these other folks that are making money, and don't forget the millionaires and the little brownstones down here in the South End. We've got money up in here, and we have other money ten miles out. I mean, you said Newton, you said Wellesley, you said Cambridge. You are talking ten miles out. This is not a bunch of little people like you can step on like a cigarette butt and forget about us.

Every single person that you will

annihilate when this thing does escape finally, because it most likely will because it is so well publicized. The meeting wasn't publicized but the event -- I mean but the facility has been, everyone knows it's there. And like she said, put it on television for everyone to see how it's done. The intelligent people can pick it apart, or they will find another way to get in there and find exactly how to find what they need, or a way to get in or whoever is at the head of what in order to get a job there, even if it's only cleaning the floors.

And you don't have to be an immigrant to clean floors in a biolab. I mean, I know that amount of money that they are going to be putting in, it's well worth someone's contract.

The contractors that are going to -- I mean the people that are going to get the contract to clean that place, they are going to be making millions and millions. I know they will because that's the kind of facility that you are getting, that you are talking about.

So you don't have to get little, uneducated immigrants to clean that lab, but you will be able to get anybody else that wants to do harm to us in there, anybody with a high intelligence level that knows what to do with these things. I don't know what to do with them, I'm just an RCC graduate. I went to a few other colleges around, I went to BU, I went to Suffolk, but I still wouldn't know what to do with that anthrax, and I was a bio major, I still wouldn't know what to do. Put it in the paper and I'll look at it, I wouldn't know what to -- I'd run from it, I know that.

I have enough sense to know to get away from it, but the people that are making this thing happen seem not to be aware that it is too much for us to actually settle for. They absolutely positively will have blood on their hands, without a doubt, it being in such a -- I'm sorry for the loss of words, I'm having a senior moment, but such a very detrimental area. First of all, you are looking at the public

news every single night of all over the planet earth.

All over the planet earth you see -- what are those car bombs?

MR. BAYHA: Ma'am, I need you to wrap up your comments.

MS. MANNA: I will, thank you. You see car bombs, you see the people that drove into the thing. You see people doing sneaky stuff, sneaking in, sneaking out, doing this and this. You've got people -- what do you call that, shoplifters. I mean all of this in a city, illegal, whatever, goes on here. A highly

educated group of people could easily do horrible things to us with this facility being so close and so easy to access. And believe me, being where it is, you may think it's not easily accessible, but it can't help but be easily accessible.

Please do not let them put -- let them know that we, this small amount of people represent a larger amount and we do not need

it here, do not want it here, and how many people will die? Thank you.

(Applause.)

MS. MARTINEZ: Good evening, everybody. My name is Donna Martinez and I actually came out tonight -- I received my first flyer, but then I had been hearing about it through the news, but I'm very uniformed about all of this. And I've heard some disturbing comments about this not being a venue where people are feeling that they are being heard, so I would like to say to the people that are here representing to continue the biochemical site that you are planning in turning into a level four site, do you really hear? Is the decision really made?

And, as for myself, I appreciate all the comments from everybody in this community, but I have to say because I live in Roxbury and I have all of my life, my two children are here with me tonight. It may have been the wrong venue to bring them to, but they are here with

me. I would like to say how did you come about this without really informing the residents that the sites are closest to? And there's a lot of disparities in this area, health disparities, economic disparities, and I feel insulted because I feel as if the organizations that are in control of this event are actually not considering the people that are going to be most affected by it.

That's my children, that's my family, that's all the people in my community, which is Roxbury, where I live. I did not see a lot of people of color here today, so I wonder again, when people talk about racism, is it because you bank on ignorance? And shame on you, shame on you because the only thing -- I'm going to make this short. I would ask every single one of you if these were your kids, would you allow this biochemical plant to open up next to your home? And I doubt that very much, I doubt that very much.

You don't live here, so I would --

but, listen, now you are talking, why? Because I touched you, because you know you are lying.

Nobody has talked to anybody in this room tonight but I'm going to make it real for you because that's what it is for everybody here.

Everybody here does not have children, everybody here has been very polite. That's bull. The politeness needs to go out the window, this is your community. There will be an accident. Probabilities? That's a bunch of crap. There will be, nobody is perfect. People are fallible.

We live in a world where terrorism is real. I bet you there is a terrorist sitting in this room trying to figure out how they are going to get into that plant and cause some trouble. Are you going to teach me how to explain to my kids how to protect themselves if something does happen? Say yes to that because then at least you will be being honest.

Thank you.

MR. BAYHA: The final speaker of the evening will be this gentleman in the front row.

I don't think I have your name on the list so when you begin your comments, if you could state your name for the record, I would appreciate that. There's a mic right behind you.

MR. VELOTTI: My name is Frank Velotti and I've lived in Quincy and Roxbury and Dorchester and Cambridge all my life, I'm 67 years old. But I was a manager of the facility of the Bahai Center across the street from the biolab all the way up to recently I was still at the place taking care of the facility with some other people. And I've watched -- I've had two strokes in the course of the building of this facility and every -- I've never heard anyone say they were for the facility.

And every time I've thought about the facility I've thought how ridiculous it is to put a facility like this in a place like that.

I mean I would think that you would put a place

like this in Nevada where they test nuclear -- I mean in a mountain five or six flights down so it can't hurt anyone. I mean these Ebola, anthrax, the names I heard, and I heard a few other, four or five other names comparable to Ebola and anthrax.

At the Bahai Center, the Bahai faith is a religion, we have a Sunday School for children, little, little kids, five, six, seven, ten years old, across the street. No one has ever, I don't think, notified them, but there's kids walking in and out of there all the time, and I'm always there, all hours of the day and night, and there's trucks leaving that plow exchange and coming and going. To flip a truck in there full of explosives, it would be possible to do it any time, no one would notice anything.

The fence is about -- it's a chainlink fence. I mean it shouldn't -- there is no way in the world that we should have the audacity to put something like that there. For the people, for the children around here, for

the next generation, I mean is this something that's going to be open for 60 days or is it 60 years? Is it a research -- I mean what are we researching things like this for? We should be working for peace, not creating anthrax and other diseases we can't even control, creating things we can't control.

How can we have the audacity to create and let loose in the environment something we can't even control? It's like building a nuclear plant there and we can't even control the waste. People talk about nuclear, we talk about it, no one ever mentions that the waste doesn't dissipate for thousands of years.

What about the next generations? Who are we to do this? Do we have any responses? Is there any formal response coming at the end of this?

I haven't heard one person say anything in favor of this. Can you say something in favor of this or you just stand there and smile? And these other guys? I mean it's a big joke and then when you get out of

here, then you just forget about it, go have a cup of coffee and have a few laughs and that's the end of it? I've been watching for what seems like eight years anyway, but it might be ten, you are talking ten, but I've watched the building go up and it's an absolute -- it would have to be a person with rocks in their head that ever decided to put something like this right there, right in the heart of Boston.

It's the crossroads of the city, the Mass Pike, everything right there. I mean what is it? I mean I don't know what to say really, I mean it's -- I can't believe that you are doing it or trying to do it. And I hope the resistance escalates.

(Applause)

MR. VELOTTI: I really hope the resistance escalates, I mean it's got to, it's got to escalate. I mean this has been very polite, as you've said, people are very -- it's amazing it's gone this far. Like I said, I've been in comas twice and come through, and my

head has cleared out a bit and I hear that the meeting is still going on. I mean it's an eight story building, or whatever it is, a six story building. It isn't worth much money really, there's a million other uses for it or at least a hundred other uses for it.

It's right in the middle of a research area. I think two floors or three floors are committed to this use. There's plenty of things it could be used for.

MR. BAYHA: Sir, I'm going to have to ask you to wrap up your comments, we need to vacate the building shortly.

MR. VELOTTI: Yeah, I'd like to wrap something else up, but it doesn't matter. I mean whether I comment for an hour or I didn't come up here and comment because no one is listening anyway. And I'm really, really surprised at the patience of everyone. Really, I'm really surprised. I mean I think you are playing with fire.

MR. BAYHA: That concludes our public comment portion of the evening. I would like to reiterate that all of the comments that the public has given today will be responded to in the final supplementary risk assessment, as well as any comments that are submitted to us via our mailing address or our e-mail address.

There is a link there where you can also get a copy of the document, if you have not gotten one yet. That is also the same information where you can send any of your comments. Again, the responses to those comments will appear in the final supplementary risk assessment.

This meeting will have a written transcript, it will be posted to the web site.

PARTICIPANT: It will be posted to the web site when?

MR. BAYHA: When it is available.

PARTICIPANT: Will that be available before the next--

MR. BAYHA: Sir, I can't speak about when it will be available or not, the meeting
