1.0 Introduction

This *Risk Assessment (RA) Final Supplementary Risk Assessment for the Boston University National Emerging Infectious Diseases Laboratories (NEIDL)* presents the human health consequences of a potential accidental event or malevolent action resulting in the loss of pathogen or biological containment (biocontainment) at the BUMC NEIDL biological research facility. The purpose of the NEIDL is to provide safe and secure laboratories dedicated to the study of disease-causing microorganisms (pathogens) to research the pathogenesis of emerging infectious diseases (including Centers for Disease Control and Prevention (CDC)/National Institutes of Health (NIH) Category A, B, and C pathogens); develop vaccines, therapeutics, and diagnostics for the pathogens; develop animal models for the comparative study of the pathogens; perform preclinical and clinical research in humans; train scientists and related support personnel in the requirements of the area of research; and support a national response if a biodefense emergency occurs. Tetra Tech, Inc., under a contract to prepare this RA for NIH. The NEIDL (Figure 1-1) is within the BioSquare Research Park, adjacent to the BU Medical Center (BUMC) campus in Boston, Massachusetts (Figure 1-2). Construction of the facility began on March 6, 2006, and was completed in the fourth quarter of 2011. The facility is partially occupied and used for administrative and training purposes.

Pathogen

Pathogens are disease-causing microorganisms or biologically derived infectious or toxic materials that present a potential health risk to humans, animals, or plants. Throughout this RA the term *pathogen* is used as a comprehensive descriptor for the purposes of discussion. Where a more specific or limiting definition is required, more precise terms are used (e.g., select agent). Pathogens include the following:

- Bacteria
- Fungi
- Parasites
- Viruses
- Toxins (bacterial, fungal, plant)
- Other infectious pathogens, such as prions (a disease-causing pathogen that is neither bacterial, fungal, or viral containing no genetic material)

Figure 1-1. NEIDL facility 2008.

Several residents and public interest groups filed federal and state lawsuits challenging the adequacy of earlier reviews of the potential environmental effects of the NEIDL and whether those potential risks would vary depending on the location of the facility in an urban or less densely populated area. In addressing the issues raised in those lawsuits and public comments provided during those previous reviews, the NIH sought the advice of a Blue Ribbon Panel (BRP) of experts in infectious diseases, risk assessment, environmental justice, modeling, biosafety, risk communications and other areas. The NIH also sought guidance from the National Research Council (NRC) committee that was critical of the draft of an earlier risk assessment prepared by the NIH.

Figure 1-2. Location of NEIDL in Boston

Because of public concerns and state and federal court direction, this RA compares the frequency and public health consequences associated with potential loss of pathogen biocontainment events in a range of population density areas that represent urban, suburban, and rural environments. The urban, suburban, and rural sites were selected for the purposes of the comparative analysis, including the BUMC BioSquare Research Park, Boston, where the NEIDL has been constructed; the former BU Corporate Education Center in Tyngsborough, Massachusetts; and the former BU Sargent Center for Outdoor Education near Peterborough, New Hampshire (Figure 1-3) (NIH and DHHS 2005).

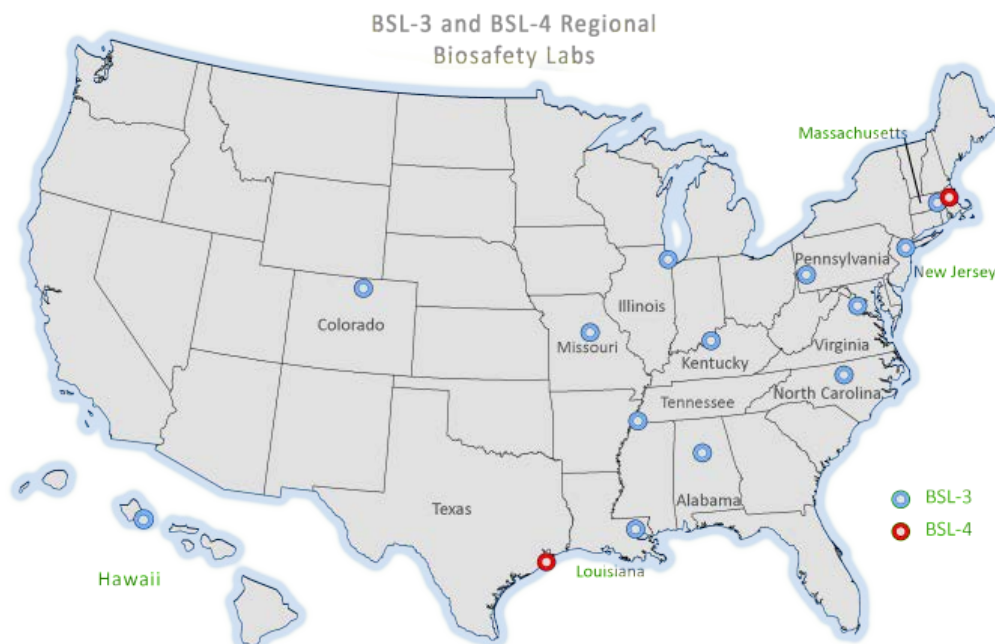

Figure 1-3. Locations of the three NEIDL sites for suitability analysis.

Risk Assessment Chapter Organization

The RA chapters, 1 through 13, are organized to build on the preceding chapter to provide the reader with a basic understanding of the need for the NEIDL; the facility design, equipment, and operations; the environment surrounding the three sites under study; and the RA process and findings. Each chapter's corresponding appendix, as needed, provides detailed and fundamental information, methodology, and analysis. In combination, the RA chapters and their corresponding appendices are designed to provide the courts, scientists, the public and adjacent communities/neighborhoods and interest groups with the information necessary to assess and understand the RA methodology and analysis that is responsive to public concerns and state and federal court direction. Section 1.6 of this chapter provides the organization and brief descriptions of the RA chapters and appendices.

1.1 National and Regional Biosafety Laboratories

The federal government responded to the September 11, 2001, terrorist attacks and the subsequent anthrax bioterrorist attacks with increased focus on and funding for biodefense. In February 2002, NIH convened a BRP on Bioterrorism and Its Implications for Biomedical Research, made up of distinguished scientists representing academia, private industry, and governments to provide guidance to the National Institute of Allergy & Infectious Diseases (NIAID) on its biodefense research agenda. That panel concluded that the insufficient amount of biological safety (biosafety) level (BSL)-3 and BSL-4 laboratory space was a significant barrier to progress in protecting the United States from further bioterrorist attacks (NIAID 2003). BSL designations are differentiated by the degree of protection provided to the integrity of the research, to research personnel, to the community, and the environment when working with infectious microorganisms or biological toxins. BSL-1 requires the most basic level of protection, while BSL-4 requires the most stringent protection (see Section 1.4). The problem of insufficient BSL-3 and BSL-4 laboratory space has been previously documented by the Institute of Medicine of the National Academy of Sciences (NAS) and repeatedly identified in NIAID's strategic planning process (NIAID 2003a). In response, on September 30, 2003, NIAID announced funding for the construction of two National Biocontainment Laboratories (NBLs) and 13 Regional Biocontainment Laboratories (RBLs) to conduct research on biological pathogens that are considered to be of significant research importance. The overall objective of the NBL construction program is to provide funding to design, construct, and commission comprehensive, state-of-the-art BSL-2, BSL-3, and BSL-4 laboratories, as well as associated research and administrative support space. The RBL construction program provided funding for similar facilities containing BSL-2 and BSL-3 laboratories. The NBL and RBL proposals were selected on the basis of multiple factors but primarily on the scientific and technical merit of the applications received from state, university, and private research organizations as assessed by peer review and on the applicant's ability to contribute to the overall NIAID biodefense research mission (Figure 1-4). The biosafety laboratories are also to be available for and prepared to assist national, state, and local public health efforts if a bioterrorism or infectious disease emergency occurs (NIAID 2003).

Regional Biocontainment Labs (BSL-3)

*The Hawaii facility has not begun construction or finalized siting.

BU was selected as an NBL grant recipient in a nationwide competition. The NEIDL is one of only two NBLs in the United States for which the NIAID, an institute within the NIH, awarded partial construction funding in 2003. The other NBL, Galveston National Laboratory (GNL) is at The University of Texas Medical Branch (UTMB) in Galveston, Texas, and is operational. NBLs are designed and constructed to provide comprehensive, state-of-the-art biocontainment laboratories, research support space, and animal facilities to protect public health through developing and evaluating improved diagnostics, therapeutics, and vaccines for protecting against emerging and reemerging diseases, including those that have the potential for bioterrorism.

NBL and RBL activities, operations, and research will be performed solely for scientific research and biodefense purposes (i.e., developing effective vaccines and other countermeasures such as antiviral therapies). No research will occur for developing bioweapons, which is prohibited by international law. The Convention on the Prohibition of the Development, Production and Stockpiling of Bacteriological (Biological) and Toxin Weapons and on Their Destruction, signed in 1972, prohibits the development, production, and stockpiling of biological and toxin weapons (BTWC 2010).

1.2 Federal Agency Roles

A key consideration in the federal government is an increased need for infectious diseases research, as well as for biodefense to address capacity shortages for diagnostic, clinical, and research laboratories.

1.2.1 U.S. Department of Health and Human Services

The U.S. Department of Health and Human Services (DHHS) is the principal agency for protecting the health of all Americans and providing essential human services. DHHS programs are administered by 11 operating divisions, which include the NIH.

1.2.2 National Institutes of Health

The NIH, a part of DHHS, is the primary federal agency for conducting and supporting biomedical research. The NIH is composed of 27 institutes and centers and is the steward of medical and behavioral research for the nation. The NIH annually invests more than \$31.2 billion in medical research to more than 325,000 researchers at more than 3,000 universities, medical schools, and other research institutions in every state and around the world (NIH 2011). Its mission is science in pursuit of fundamental knowledge about the nature and behavior of living systems

and applying that knowledge to extend healthy life and reduce the burdens of illness and disability. The goals of the agency are as follows (NIH 2011a):

1. Foster fundamental creative discoveries, innovative research strategies, and their applications as a basis to advance significantly the nation's capacity to protect and improve health;
2. Develop, maintain, and renew scientific human and physical resources that will ensure the nation's capability to prevent disease;
3. Expand the knowledge base in medical and associated sciences to enhance the nation's economic well-being and ensure a continued high return on the public investment in research; and
4. Exemplify and promote the highest level of scientific integrity, public accountability, and social responsibility in the conduct of science.

1.2.3 The National Institute of Allergy and Infectious Diseases

The NIAID (<http://www.niaid.nih.gov/>) under the NIH conducts and supports basic and applied research to better understand, treat, and ultimately prevent infectious, immunologic, and allergic diseases. To meet the nation's biodefense needs, NIAID, in consultation with other experts in the field, developed a strategic plan for emerging infectious diseases and biodefense research. Key elements of the plan include the following (NIAID 2008):

- Support of medical research on microbes and the human immune response to them;
- Apply such research to the discovery and development of vaccines, drugs, and diagnostic tests designed to protect the general population; and
- Ensure that the United States has enough research facilities to carry out those activities.

NIAID's ultimate goal is to develop new and improved diagnostics, vaccines, and treatments for diseases caused by infectious pathogens. Medical tools such as those can be developed only with a solid understanding of the biology of the disease-causing pathogens and working with the actual microbes or their toxins. Achieving NIAID's research goals requires constructing biocontainment laboratories with facilities and procedures for handling potentially lethal infectious pathogens, including pathogens that have the potential to be used in bioterrorism. Such research must be conducted in special biosafety laboratories and in accordance with the laws, regulations, policies, and well-established guidelines that govern research on those microbes and the design, management, and operation of the laboratories. All the provisions aim to protect not only the laboratory workers, but also the surrounding community from accidental exposure to pathogens (NIAID 2003a).

1.3 NEIDL Owner and Operator—Boston University

BUMC, a consortium of BU and Boston Medical Center, submitted an application to NIAID in response to the NBL Broad Agency Announcement in February of 2003 and, on the basis of the merits of that application, received a grant of \$141 million—\$128 million in 2003 and \$13 million in 2006—to construct the NEIDL. The entity holding legal title to the site is the Biosquare Realty Trust, the sole beneficiaries of which are the Trustees of Boston University, a Massachusetts nonprofit, educational corporation, and Boston Medical Center Corporation, a Massachusetts nonprofit corporation.

BUMC is in the South End of Boston and consists of the BUMC School of Medicine, the BU School of Public Health, the Goldman School of Dental Medicine, and Boston Medical Center.

BU's NEIDL bioresearch operations would be governed by all applicable federal, state, and local laws regulations and guidance. Representative regulatory oversight consists of the following agencies:

Centers for Disease Control and Prevention	Massachusetts Department of Public Health
U.S. Department of Transportation	Massachusetts Department of Environmental Protection
Occupational Safety and Health Administration	Massachusetts Water Resources Authority
U.S. Environmental Protection Agency	Boston Public Health Commission
National Institutes of Health	Boston Fire Department
Nuclear Regulatory Commission	Boston Water and Sewer Commission
U.S. Department of Agriculture	Boston Inspectional Services

NEIDL operations would include the use of select agents, which are biohazardous materials that could pose a severe threat to public health and safety; animal or plant health; or animal or plant products. The Bioterrorism Act of 2002 [U.S. Food and Drug Administration (USFDA) P.L 107-188] requires entities to register with the DHHS or the U.S. Department of Agriculture (USDA) if they possess, use, or transfer select agents or toxins. The DHHS secretary has delegated the responsibility for promulgating and implementing select agent or toxin regulations to the CDC. In addition to ensuring that laboratories safely handle such select pathogens or toxins, the Bioterrorism Act of 2002 requires increased safeguards and

security measures for such select agents, including controlling access, screening entities and personnel (i.e., performing a threat assessment [TA]). Before operating, the NEIDL would be registered with the CDC, and the CDC would register those NEIDL personnel who would work with select agents or toxins. Registration with either the CDC or the USDA allows a laboratory to use select agents, organisms or toxins, regulated by either agency according to the level of facility certification. Additionally, NEIDL will obtain a permit from the Boston Public Health Commission prior to beginning BSL-3 and BSL-4 operations.

Biohazardous materials, such as microorganisms and biotoxins, that are not select agents or toxins will be used in the NEIDL laboratories and handled according to CDC and NIH guidance and requirements. The CDC and NIH guidance and requirements also extend to handling genetically altered microorganisms and recombinant DNA (NIH 2011b).

1.4 Biosafety-Related Information and Practices

Biosafety describes practices and policies that serve to protect the integrity of the research, laboratory workers, facility workers, the public, and the environment from exposure to infectious microorganisms and hazardous biological materials. Protection is provided by using four primary controls: engineering; workplace practices; personnel protective equipment (PPE); and administrative (e.g., security clearances, training and supervision, immunizations). Biocontainment laboratories provide for the handling and storage of infectious microorganisms and hazardous biological materials. The NEIDL facility was designed to protect the laboratory workers, staff, the community, and the environment from harmful infectious agents through (1) primary containment including the use of appropriate safety equipment (e.g., biological safety cabinets [BSCs], centrifuges with sealed rotors), administrative controls, and the use of PPE (e.g., respirators, fully encapsulating suits) and (2) secondary containment systems including unidirectional air flow and high-efficiency particulate air (HEPA)-filtered exhaust systems in the facility design.

1.4.1 Biosafety Levels

Four BSLs of operation define the biocontainment conditions under which infectious pathogens can be safely manipulated on the basis of risk to the laboratory worker. BSL-1, BSL-2, and high-biocontainment laboratories, which refer to BSL-3 and BSL-4 laboratories in the United States, which are designed, constructed, and operated in accordance with guidelines from the *Biosafety in Microbiological and Biomedical Laboratories* (BMBL) manual, 5th edition (CDC and NIH 2007).

Similarly, four BSLs of operation exist for using experimentally infected animals housed in indoor research facilities or maintaining laboratory animals that could naturally harbor zoonotic infectious pathogens (i.e., a disease that can be transmitted from animals to people). Those levels are organized as Animal Biosafety Levels (ABSL) 1 through 4, which correspond with the BSL pathogen classification system (CDC and NIH 2007).

When arthropods (e.g., insects, spiders, fleas, ticks) are used, facilities, trained staff, and established practices must be in place to ensure appropriate safety and the protection of the health and well-being of workers and the environment. Where an arthropod is infected with a biological pathogen, the Arthropod Containment Level (ACL) will be consistent with or exceed the BMBL BSL containment recommendations. Consistent with BSL and ABSL, four levels of ACLs exist (CDC and NIH 2007).

While the BMBL is a set of guidelines, host facilities have also used it to establish requirements for visiting principal investigators for working with biological pathogens requiring higher biocontainment laboratories.

The BSLs are designated by the degree of protection provided to personnel, the environment, and the community. The principal hazardous characteristics of a biological pathogen used to determine the appropriate BSL are the following (CDC and NIH 2007):

- Its capability to infect and cause disease in a susceptible human or animal host;
- Its virulence as measured by the severity of disease;
- The availability of preventive measures and effective treatments for the disease;
- The origin of the biohazardous material—whether indigenous or exotic—for biological pathogens that cause moderate to severe disease; and
- The nature of the work being conducted.

In addition, the mode of transmission, specifically aerosol transmission which is a common mode of transmission, is part of the hazard characteristics of biologic pathogens that are used to determine BSLs. Both the BSL-3 and BSL-4 definitions indicate that aerosol transmission is possible. Each level of biocontainment describes the administrative controls, safety equipment, and facility features for the corresponding level of health risk associated with handling a biohazardous material. For the purposes of this RA, the BSL is referred to as inclusive of those additionally compartmentalized areas such as ABSL, ACL, or other protection categories. As explained in the following bulleted points, BSL-1 requires the

most basic level of protections (e.g., administrative controls, safety equipment, facility features) and BSL-4 requires the most stringent protections (CDC and NIH 2007):

- BSL-1: Practices, safety equipment, and facility design and construction are appropriate for undergraduate and secondary educational training and teaching laboratories and for other laboratories in which work is done with

defined and characterized strains of

viable microorganisms not known to consistently cause disease in healthy adult humans such as *Bacillus subtilis*, *Naegleria gruberi*, and infectious canine hepatitis virus. BSL-1 represents a basic level of biocontainment that relies on standard microbiological practices, a sink for hand washing, with no special primary or secondary barriers recommended.

- BSL-2: Practices, equipment, and facility design and construction are appropriate to clinical, diagnostic, teaching, and other laboratories in which work is done with the broad spectrum of indigenous (i.e., occurring naturally in a region) moderate-risk pathogens that are present in the community and associated with human diseases of varying severity. Hepatitis B virus, the salmonellae, and *Toxoplasma* spp. are representative of pathogens that can be assigned to this biocontainment level. Primary hazards to personnel working within an area requiring BSL-2 controls are accidental exposure via penetrating wounds, through broken skin or via mucous membranes (i.e., nasal passages), or ingestion of pathogens.
- BSL-3: Practices, safety equipment, and facility design and construction are appropriate to clinical, diagnostic, teaching, research, or production facilities where work is performed with indigenous or exotic (i.e., not naturally occurring in a region) pathogens that can cause serious or potentially lethal disease through inhalation exposure. *Bacillus anthracis* (anthrax), *Francisella tularensis*, (tularemia) and *Yersina pestis* (pneumonic plague) are examples of pathogens that can be assigned to this level. Primary hazards to personnel working with such pathogens are needle sticks or cuts resulting from using sharps, ingestion, and exposure to infectious aerosols.
- BSL-4: Practices, safety equipment, and facility design and construction are appropriate for work with dangerous and exotic pathogens that pose a high individual risk of life-threatening disease, which can be transmitted via the aerosol route and for which there is no available vaccine or therapy. Viruses, such as Ebola and Marburg, and those of the tick-borne encephalitis complex

Figure 1-5. Class III BSC.

are manipulated at BSL-4. The primary hazards to personnel working with BSL-4 agents are respiratory exposure to infectious aerosols, mucous membrane or broken skin exposure to infectious droplets, and autoinoculation. All work with potentially infectious diagnostic materials, isolates, and naturally or experimentally infected animals, pose a high risk of exposure and infection to laboratory personnel, the community, and the environment. The laboratory worker's complete isolation from aerosolized pathogens is accomplished primarily by working in a Class III BSC (see Figure 1-5) and in a full-body, one-piece, positive-pressure suit with externally supplied, HEPA-filtered air (see Figure 1-6). In general, BSL-4 facilities are completely isolated zones with complex, specialized, ventilation requirements and waste management systems to prevent release of viable biohazardous materials to the environment (CDC and NIH 2007, NIH 2008).

The ABSL laboratories can present unique problems and hazards not found in standard microbiological laboratories. Animals can generate aerosols, bite and scratch, and can be infected with a zoonotic pathogen. In general, ABSL laboratories have special engineering and design features, and personnel are specifically trained in animal facility procedures and the handling of infected animals.

The ACLs feature specific practices, procedures, biocontainment equipment, and facility requirements to prevent the escape of infected or uninfected arthropods. ACLs are designed in accordance with the American Committee of Medical Entomology (ACME) of the American Society for Tropical Medicine and Hygiene (ASTMH) recommendations for arthropod laboratory work (Mary Ann Liebert, Inc. 2003).

Figure 1-6. HEPA filtration plenum.

High- and maximum-biocontainment facilities (BSL-3 and BSL-4) are located throughout the nation. The U.S. Government Accountability Office (GAO) conducted a survey in 2006/2007 of U.S. academic, biotechnology, and pharmaceutical facilities to better define the location, capacity, and status of existing and operating U.S. laboratory facilities that incorporate BSL-3 biocontainment precautions. Survey packets were distributed to 2,170 distinct entities with a survey return rate of around 40 percent. Federal government laboratories were not included in the survey. The survey results identified 1,356 CDC or

USDA-registered laboratories in 46 states that had BSL-3 capable laboratories (GAO 2007). That survey has been augmented and updated with additional data in 2008 showing 1,362 BSL-3 laboratories registered with CDC's Division of Select Agents and Toxins. As of March 2009, all 50 states have at least one BSL-3 laboratory).

1.4.2 Biocontainment

The term biocontainment is used to describe safe methods for managing pathogens in the laboratory environment where they are being handled or maintained. The three elements of biocontainment consist of the microbiological practices, biocontainment and safety equipment, and facility design and safeguards that protect laboratory workers, other facility personnel, the public, and the environment from exposure to pathogens that are handled and stored in a biocontainment laboratory.

Primary biocontainment involves protecting personnel and the immediate laboratory environment from exposure to pathogens and is provided by both good microbiological techniques and using appropriate biocontainment equipment. Biocontainment equipment consists of BSCs, enclosed containers, and other engineering controls designed to prevent or minimize exposures to pathogens. The BSC is the principal device used to provide biocontainment of infectious splashes or aerosols generated by many microbiological procedures. An example of another primary barrier is the aerosol containment centrifuge bucket/rotor and cover, an enclosure container designed to prevent aerosols from being released during centrifugation (see Figure 1-7). To minimize the hazard from potentially infectious aerosols, biocontainment controls such as BSCs or aerosol containment centrifuge buckets/rotors must be used when handling pathogens that can be transmitted through the aerosol route of exposure. Safety equipment also can include items for personal protection, such as gloves, coats, gowns, shoe covers, boots, respirators, face shields, safety glasses, or goggles. Such PPE is often used in combination with BSCs and other devices that contain the pathogen, animals, or materials being handled. In the case of BSL-4 biocontainment, as described above, PPE would consist of a full-body, one-piece, positive-pressure suit with externally supplied, HEPA-filtered air. In some situations in which it is impractical to use a BSC, PPE can form the primary barrier between personnel and the pathogens.

Figure 1-7. Researcher in BSL-4 PPE placing a rotor in a centrifuge.

Secondary biocontainment, protecting the environment external to the laboratory from exposure to pathogens, is provided by a combination of facility design and operational practices. The design and construction of the facility contributes to the laboratory workers' protection, provides a barrier to protect persons outside the laboratory, and protects the public and environment from pathogens that could be accidentally released from the laboratory. The recommended secondary barrier(s) will depend on the risk associated with specific pathogens. For example, the exposure risks for most laboratory work in BSL-2 facilities would be potential direct contact with the pathogens or inadvertent contact exposures through contaminated work environments. Secondary barriers in such laboratories can include separation of the laboratory work area from public access, availability of a decontamination facility (e.g., steam sterilizer), and hand washing facilities. When the risk of infection by exposure to an aerosol is present, higher levels of primary biocontainment and multiple secondary barriers might become necessary to prevent infectious pathogens from escaping into the environment. Such design features consist of specialized ventilation systems to ensure directional air flow, air treatment systems to remove pathogens from exhaust air, controlled access zones, airlocks as laboratory entrances (Figure 1-8), or separate buildings or modules to isolate the laboratory.

Figure 1-8. BSL-4 airlocks for laboratories.

1.5 Risk Assessment

The risk associated with the probability of becoming infected if exposure to an infectious agent has occurred is defined by the U.S. Environmental Protection Agency (EPA) as the combination of frequency and consequences. An RA is, therefore, a scientific and technical analysis that assembles and synthesizes information to determine the frequency and the extent of possible risk to human health and safety or the environment. For this RA, risk is a result of a potential sequence of unplanned events or malevolent actions that could result in exposure to a laboratory worker, facility worker, a member of the public, or an environment. An event could be caused by equipment malfunction, external events, human error, natural phenomena, or malevolent acts. This section presents the RA purpose and provides an overview of the RA methodology.

1.5.1 Purpose of the Risk Assessment

The purpose of this RA is to address and respond to the human health issues raised in the public and judicial review process and to respond to findings from the BRP and the NRC of the NAS . In a human health RA, the analyses determine what, if any, adverse human health effects would occur from an accidental or malevolent release of a pathogen or infected insects/animals from biocontainment. It also determines whether there are differences in the effects if the facility were in an area with a lower population density than the Boston NEIDL site.

That purpose is accomplished by identifying the characteristics of a known pathogen, the events that can result in an individual's exposure to a pathogen, the likelihood that such exposure will cause an infection, the potential for an infected person to transmit the pathogen to contacts, and the probable health consequences in terms of infections and fatalities attributable to the pathogen. A laboratory-acquired infection (LAI) is a result of laboratory-related activities with a pathogen. Generally an LAI results from contact with an infectious pathogen via inhalation (i.e., aerosol), ingestion, direct contact (i.e., skin or mucous membranes), or puncture wound from a sharp object (e.g., needle, scalpel).

An infection can also occur as a result of contact with an infectious pathogen outside the laboratory setting. For example, an infection could result from exposure to pathogens while they are being transported to/from the NEIDL. In addition, an infection could be acquired from contact with an infected and infectious individual. A chain of such secondary transmissions stemming from NEIDL-related events could occur, resulting in the spread of a pathogen through the community.

1.5.2 Scope of the Risk Assessment

The scope of this RA includes qualitative and quantitative analyses of an array of pathogens and events leading to exposure of individuals to pathogens and probabilistic estimates of initial infections, subsequent secondary transmissions, and fatalities. An analysis of potential differences among the three NEIDL sites in terms of infections and fatalities is also included. This RA follows guidelines established by federal agencies for conducting and reporting risk assessments (EPA 2000) and has been performed by using available scientific data and established methods of analyses. The RA acknowledges the uncertainty associated with the data and the appropriate role of judgment (expert opinion) in estimating key parameters required for risk assessment.

The four essential principles of risk assessment are applied as follows to this RA and are described in the preceding chapters and associated appendices:

1. Transparency: This is achieved by providing details of the assessment approach applied at each step of the analyses; stating the assumptions used for the analyses and the basis for those assumptions; addressing data gaps and the methods used to overcome the data gaps such as expert judgment; the uncertainties in the available data, qualitative discussions and quantitative assessments of the impact of the uncertainties in the data and sensitivity analyses to determine impact of variability in key parameters
2. Clarity: This is achieved by attempting to convey details with brevity; providing lay language summaries and discussions in chapters; providing details in appendices and using tables and graphs where possible to present technical data
3. Consistency: This is achieved by following established guidance and guidelines, following precedence wherever possible and using established and published methods for all analyses
4. Reasonableness: the RA is based on best available scientific information, uses generally accepted scientific knowledge and has been subjected to peer review by the BRP and NRC. Furthermore this RA strives to include reasonableness and realism in the analyses based on ‘real world experience’; however, the absence of appropriate operational data poses a significant challenge in that regard and in several cases the event sequence assumptions are expected to overestimate the likelihood or consequences of potential events. This use of conservative assumptions (i.e., overestimations) to account for uncertainty is consistent with National Environmental Policy Act (NEPA) accident analysis guidance (DOE 2002).

The following paragraphs describe the scope of each aspect of the RA.

Pathogens—The BRP considered and selected a total of 13 pathogens for detailed analyses. Those 13 pathogens were chosen on the basis of a review of the federal and state court decisions, the BRP, NRC committee, community concerns, and public documents. These pathogens differ in key characteristics such as their ability to be spread from person to person (transmissibility), the method by which they are spread from one person to the next (either directly or via vectors, such as insects), their ability to cause human disease (pathogenicity) and their ability to cause deaths among those infected (case fatality rate). All the pathogens are qualitatively modeled, and a subset of 5 of the 13 pathogens were chosen for detailed secondary transmission modeling because of representativeness and the availability of published mathematical models and adequate epidemiological data. These pathogens are classified as requiring biological safety level 3 (BSL-3) or BSL-4 biocontainment precautions and are analyzed separately for this RA (Table 11-1).

Table 11-1 Pathogens Selected for Analysis.

<u>Pathogen</u>	<u>Abbreviation</u>
BSL-3	
1. <i>Bacillus anthracis</i> (either BSL-2 or BSL-3)	<i>B. anthracis</i>
2. <i>Francisella tularensis</i>	<i>F. tularensis</i>
3. <i>Yersinia pestis</i>	<i>Y. pestis</i>
4. 1918 H1N1 influenza virus	1918 H1N1V
5. SARS-associated coronavirus	SARS-CoV
6. Rift Valley fever virus	RVFV
7. Andes virus (either BSL-3 or BSL-4 ^a)	ANDV
BSL-4	
8. Ebola virus	EBOV
9. Marburg virus	MARV
10. Lassa virus	LASV
11. Junín virus	JUNV
12. Tick-borne encephalitis virus, Far Eastern sub-type, formerly known as tick-borne encephalitis complex (Russian spring-summer encephalitis virus)	TBEV-FE
13. Nipah virus	NIPV

^a BSL-4 is required when infecting rodent species permissive for (susceptible to) chronic infection.

Event types—This assessment considers internally and externally initiated events. Scenarios were developed that account for NEIDL-specific operations based on NEIDL equipment and standard operating procedures (SOP) such as; equipment malfunctions and worker errors. Externally initiated events such as a loss of off-site power, transportation event, natural phenomena events such as an earthquake, and malevolent acts such as insider and terrorist actions were additionally considered.

Exposed groups—This RA considers potential effects on laboratory workers in the immediate area or laboratory space at the time of the event, facility workers who are elsewhere in the facility, and members of the public, which includes anyone outside the facility and in the surrounding communities. It must be noted that risk to lab workers is independent of site locations as the NEIDL structure, as designed and constructed at the BioSquare Research Park (urban site), is assumed to be the identical structure that would have been constructed at the Tyngsborough, Massachusetts (suburban site)[formerly Boston University Corporate Education Center], or the Boston University Sargent Center for Outdoor Educations at Peterborough, New Hampshire (rural site).

Route and extent of initial exposure—Direct exposure via direct contact is considered, which includes exposure to eyes, mucous membranes, and preexisting breaks in the skin (e.g., accidental needle sticks); ingestion; inhalation; and exposure via arthropods (i.e., insects and arachnids) and mammals (e.g., non-human primates, rodents). The extent of exposure is estimated for both workers and the public.

Secondary transmission—Secondary transmission is considered, which includes the transmission of a pathogen from an initially infected individual to another individual and any subsequent generations of transmission. The RA considers direct, person-to-person transmission and indirect, vector-borne transmission, as well as the possibility of establishing an animal or environmental reservoir of pathogens from which further human exposures could occur.

Infection and fatalities—This RA estimates the number of infections and fatalities that result from the initial exposures and secondary transmissions.

Locations—The NEIDL structure, as designed and constructed at the BioSquare Research Park (urban site), is assumed to be the identical structure that would have been constructed at the Tyngsborough, Massachusetts (suburban site)[formerly Boston University Corporate Education Center], or the Boston University Sargent Center for Outdoor Educations at Peterborough, New Hampshire (rural site), site if either of those locations had been selected. Therefore, the facility description and proposed operations are applicable for all three sites. In addition, the team considered medically vulnerable as well as minority and low-income populations at each location to determine if they would be disproportionately and adversely affected by an accidental event. That approach was necessary to provide a meaningful basis to compare the risks from one site to another.

1.5.3 Risk Assessment Approach

An RA includes the processes, methods, and techniques used to estimate both the frequency (i.e., rate of occurrence within a given period) and consequences of specified adverse events. The RA was initiated by assembling an interdisciplinary team composed of personnel with expertise in medical and veterinary microbiology, medical and veterinary virology, engineering, epidemiology, medicine, biodefense, mathematical modeling, risk analysis, risk modeling, security, and other fields.

The interdisciplinary team then used the following questions to guide the risk analysis:

1. What could go wrong? That is, what might be the sequence of events that could cause an infectious pathogen to escape the laboratory, set up a chain of transmission, and cause infectious disease in the surrounding community?
2. What are the probabilities of such a sequence of events?
3. What would be the consequences of such a sequence of events?

The scope of the guidance was expanded to include consideration of off-site transportation. This RA approach consists of two major analyses that, when combined, provide answers to those questions. The event sequence analysis addresses the first question and part of the second question above. The health effects analysis addresses part of the second question and the third question. Figure 1-9 provides a process overview of the entire RA process. The event sequence analysis consists of the first three steps of the process shown in Figure 1-9. The health effects analysis consists of steps 4 through 6 of the process shown in the figure. There are potential feedback loops among the various steps in the analyses that are not shown in this diagram. The final step is to characterize the risk, which includes a summary of the results of the analyses plus the synthesis of key findings regarding the risk to exposed groups, potential differences between sites, and the potential for disproportionate effects on vulnerable subpopulations. The following subsections describe the event sequence analysis and the health effects analysis, respectively.

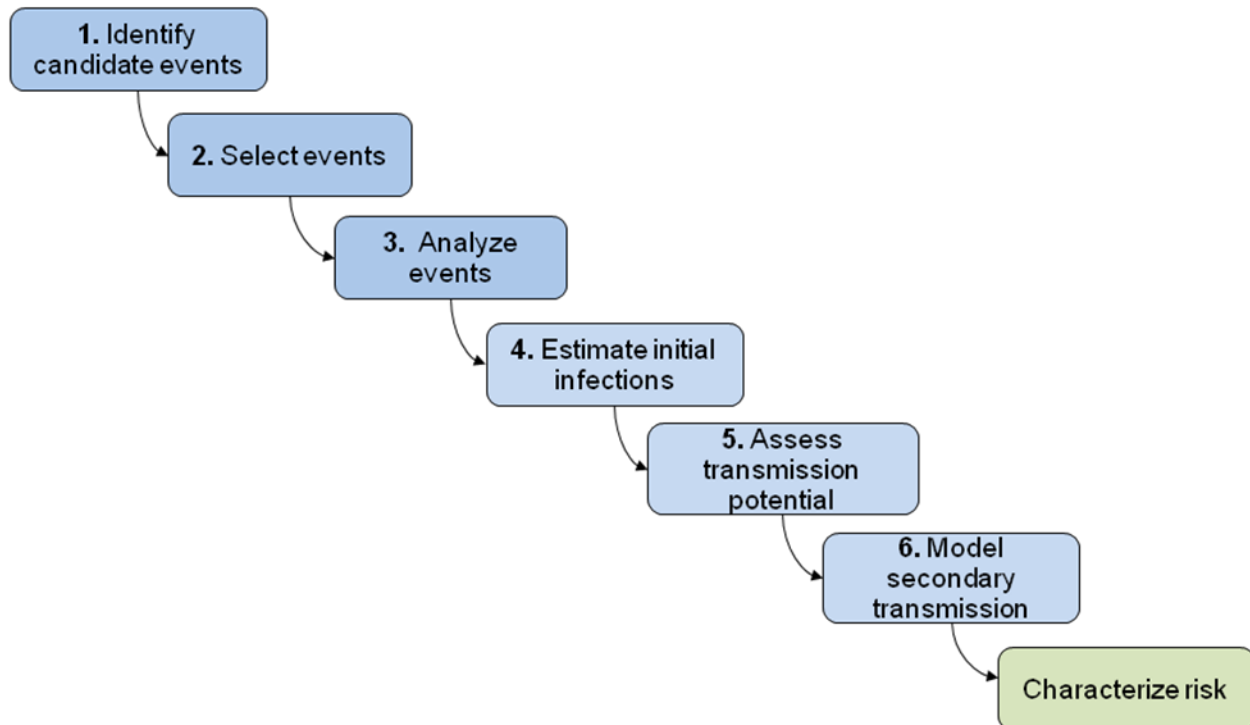

Figure 1-9. Hazard identification process overview.

1.5.3.1 Event Sequence Analysis

The event sequence analysis included a comprehensive identification of candidate events, selecting events for analysis, and detailed analyses of the events selected. Details of the event sequence analysis are presented in Chapter 4. The results of the event sequence analysis are inputs to the human health analysis.

Step 1 – Identify candidate events—This step of the RA process involves the comprehensive identification of candidate events. Candidate events were identified in consideration of known biosafety experience data, BRP guidance, NRC technical input, public comments, NEIDL design and operating plans, site characteristics, the adversary types present in the three locations, previous NEIDL studies, and analyses of similar facilities. The product of this step of the process is the list of candidate events.

Step 2 – Select event—Each of the candidate events identified in the previous step was categorized on the basis of the location, the groups exposed, and the initial route of exposure, as identified in Section 1.5.2. From that set of categorized candidate events, a subset of events was selected for detailed analysis. Events were selected to include high-consequence, low-frequency events as well as a variety of more plausible events. The team considered each of the 13 pathogens for each event to select relevant event-pathogen pairs for analysis. Events were selected to address each route of exposure at each location, for each exposed group. The team reviewed the list of candidate events to ensure that events are included that address potential pathogen and site differences.

Step 3 – Analyze events—The analysis of selected events began by defining the event sequence, which includes the initiating event as well as the failure of preventive and mitigation features, as appropriate. The frequency estimate of the event sequence was then developed on the basis of incident data from similar facilities as interpreted by professional judgment. The number of people potentially exposed by the loss of biocontainment and the route of exposure was identified. An analysis of the release and potential airborne transport provided a pathogen-specific extent of exposure. Those products are inputs for the health effects analysis.

1.5.3.2 Health Effects Analysis

The health effects analysis used exposure information from the event sequence analysis to estimate the number of initial infections and the health consequences, including fatalities, among those initially exposed individuals. It also considered the potential for secondary transmission for each of the 13 pathogens, including a quantitative analysis of potential for spreading within a community for a subset of

1 pathogens. An estimate of the numbers of infections and fatalities were also considered for secondary
2 transmissions.

3
4 **Step 4 – Estimate initial infections**—This step of the RA addresses factors that influence the probability
5 that an individual will develop an infection after exposure to a pathogen. The pathogen-specific
6 characteristics such as human infectious dose or human experimental infectious dose (HID_{50}) are key
7 concepts and challenging to obtain from the scientific literature. The HID_{50} is the minimum number of
8 infectious particles required to establish infection in 50 percent of exposed, fully susceptible humans.
9 Infectious doses vary between pathogens, hosts, and routes of exposure. Estimates of HID_{50} are available
10 from the literature for only 4 of the 13 pathogens. This RA used data in the literature and an expert
11 consultation approach, which is discussed in greater detail in later chapters of the RA, to estimate HID_{50}
12 for all pathogens and to estimate initial infections after exposure to a pathogen. The team performed a
13 comprehensive literature search to supplement the BRP guidance for initial infection assumptions. NIH
14 convened an expert panel to develop (1) estimates of HID_{10} , HID_{50} , and HID_{90} for all 13 pathogens; (2)
15 concurrence with reproductive numbers derived from the literature for secondary transmission modeling
16 for selected pathogens; (3) estimates of increased vulnerability to infection for specific population
17 subgroups; and (4) estimates of atmospheric decay of pathogens after release into the environment. The
18 team then used those consensus dose-effect relationships to estimate initial infections after exposure to a
19 pathogen.

20
21 **Step 5 – Assess transmission potential**—This step includes a summary of those event sequences that
22 could set up the possibility for secondary transmission, including undetected or unreported laboratory
23 events resulting in an infected NEIDL worker leaving the facility, events resulting in direct exposure and
24 infection of members of the public who subsequently interact with contacts, and events leading to the
25 escape of infected animals or arthropods with potential to transmit to humans. This step also includes a
26 qualitative discussion of transmissibility for each of the 13 pathogens, including a summary of evidence
27 for direct person-to-person transmission, indirect transmission via vectors, and potential establishment of
28 reservoirs for each pathogen.

29
30 **Step 6 – Model secondary transmission**—Quantitative epidemiological modeling was performed on
31 five of the pathogens. The five pathogens cover a range of characteristics, including higher and lower
32 levels of transmissibility, higher and lower mortality rates, direct and indirect (vector-borne) modes of
33 transmission, and BSL-3, BSL-4, Category A and select agents. The quantitative data for the remaining
34 eight pathogens were assessed, and Chapter 5 of this RA describes why the data were insufficient to

support detailed modeling for those pathogens. The quantitative modeling approach is based on models that are well established in peer-reviewed publications and suitable for answering a variety of questions relevant to the NEIDL RA. Results from model simulations were expressed in terms of the total number of infections over the course of simulated outbreaks and projected operating lifetime of the facility. Numerous simulations were run for each scenario to assess the effect of chance events and of varying input values for parameters that are uncertain. The team analyzed and presented the simulation results in a variety of forms, including analysis of low-probability but high-consequence outcomes. Onto the results of the number of infections, the team overlaid the results of the number of fatalities. The team then broke the results down for important subgroups, including the portion of infections/fatalities that were likely to have occurred among members of vulnerable subpopulations. The team ran simulations for each of the three sites by varying the transmission value on the basis of demographic data. The team then performed uncertainty and sensitivity analyses (i.e., parameters were systematically changed in the model to determine the effects of such changes) for all models.

That process is described in greater detail in Chapters 4 through 9.

1.6 Risk Assessment Organization

The content of the remaining RA chapters is as follows:

Chapter 2. Facility Design, Operations, and Site Description

This chapter describes the facility design and the operations and activities that would be conducted within the NEIDL followed by an overview and characterization of the potentially affected environments at the three sites.

Chapter 3. Pathogen Characteristics

This chapter identifies the pathogens selected for analysis, provides an overview of the pathogen selection process, data collection process, and concludes with a brief description of the pathogen characteristics.

Chapter 4. Event Sequence Analysis

This chapter summarizes the identification of candidate events, selection of events for analysis, the analysis of event sequences and the resulting exposures, and provides a summary of biocontainment elements that prevent and mitigate events.

Chapter 5. Transportation Analysis

This chapter summarizes the results of the off-site pathogen transportation analysis. The impacts of both truck-only and mixed mode (air-truck) shipments in the vicinity of the facility are addressed.

Chapter 6. Threat Assessment Methodology Overview

The TA addresses concerns raised by the courts, NRC, BRP, and the public regarding the capability of the facility's security systems (e.g., personnel, policy, procedure) to prevent or withstand a malevolent action against critical systems and assets at the facility that could result in the exposure of personnel or release of a pathogen into the community.

Chapter 7. Potential For Released Pathogens To Become Established In The Environment

This chapter summarizes the estimation of initial infections, the assessment of transmission potential, and the mathematical modeling of secondary transmission.

Chapter 8. Health Effects - Initial Exposure

This chapter provides details of the analysis of initial infections and fatalities, including estimates of dose-effects information for each pathogen and details of the procedure used to estimate the number of initial infections from a given exposure.

Chapter 9. Secondary Transmission

This chapter provides details of the quantitative modeling procedure for secondary transmission and the statistical analyses performed on the results of those simulations.

Chapter 10. Environmental Justice

This chapter identifies the economically and culturally disadvantaged (i.e., low-income and minority) communities in the vicinity of each site and determines whether those communities would be affected any more than other communities by a potential loss of biocontainment.

Chapter 11. Risk Characterization

This chapter summarizes the number of exposures, infections, and fatalities potentially resulting from each event. This chapter also synthesizes the key findings that include a summary of the risk to each exposed group, differences among sites, and potential disproportionate effects on vulnerable subpopulations.

Chapter 12. Authors and Contributors

This chapter identifies the personnel along with their project responsibilities, employment affiliation, education, and years of experience.

The appendices present the following articles or information:

Appendix A. Facility Design and Operations provides details on the NEIDL facility design and operations that affect biocontainment.

Appendix B. Site Characteristics provides the characteristics of the urban, suburban, and rural locations analyzed in the RA.

Appendix C. Pathogen Characteristics provides a comprehensive and cited list of pathogen characteristics, followed by a compilation of the cited references.

Appendix D. A Review of Reported Incidents, Exposures and Infections in BSL-3 AND BSL-4 Laboratory Facilities summarizes the operating experience at other high-biocontainment facilities. It also identifies the types of events that have occurred and provides some insight into their frequency.

Appendix E. Identification of Candidate Initiating Events identifies the candidate events and the results of the selection process.

Appendix F. Event Sequence Analyses provides the details of the event sequence analysis, which addresses the biocontainment element role in the event, estimates the frequency of the events, and characterizes the exposure from the events.

Appendix G. Transportation Analysis: is internationally blank because the details have been placed into Chapter 5.

Appendix H. Final Project Report: Expert Elicitation on Organisms Studied in the NEIDL Risk Assessment provides the input from an expert panel on topics where the available literature is not sufficient for this RA.

Appendix I. Medically Vulnerable Populations provides details of the choice of specific medically vulnerable subpopulations considered for this RA, the estimates of differential susceptibility to pathogens under study for the subpopulations and the use of subpopulation data in the estimates of initial infection and secondary transmission modeling.

Appendix J. Dose-Response Relationships provides the details for linking estimates of the amount of exposure to pathogens resulting from event sequences to estimates of initial infection in those potentially exposed.

Appendix K. Initial Infection provides details of the analysis of initial infections and fatalities, including estimates of dose-effects information for each pathogen and details of the procedure used to estimate the number of initial infections from a given exposure.

Appendix L. Health Effects - Secondary Transmission provides details of the quantitative modeling procedure for secondary transmission and the statistical analyses performed on the results of simulations.

Appendix M. Environmental Justice identifies the economically and culturally disadvantaged (i.e., low-income and minority) communities in the vicinity of each site and determines whether those communities would be affected any more than other communities by a potential loss of biocontainment.

Appendix N. References Not Cited provides references that were considered in the process of performing the RA but are not cited specifically.

Appendix O. Public Comments provides responses to comments and questions received during the public comment period for the Draft Supplementary Risk Assessment for the Boston University NEIDL.

2.0 Facility Design, Operations, and Site Descriptions

This chapter provides an overview of the NEIDL design, critical systems, and proposed operations. Following that information are descriptions of the environmental settings of the three comparable sites. The chapter concludes with a synopsis of the public safety and emergency response capabilities in the jurisdictions of the urban, suburban and rural site locations.

As stated in Chapter 1, the NEIDL facility, as designed and constructed at BU BioSquare Research Park, is assumed to be the identical structure that would have been constructed at the Tyngsborough, Massachusetts, and the Peterborough, New Hampshire, site if either of those locations had been selected. Similarly, NEIDL proposed bioresearch operations are considered to be the same for all three sites. Those assumptions are necessary to provide meaningful comparisons of the relative risks at the three sites.

The Tetra Tech team having the facility design, operational, and site description discussions, relied primarily on information obtained from review of the NEIDL design specifications, supplementary data provided by BUMC, the NEIDL Environmental Impact Report (EIR) and Environmental Impact Statement, original research and analysis conducted by the RA team, NEIDL tours, and site visits to the urban, suburban and rural sites. Additional details on each topic presented in this chapter are included in Appendices A and B.

2.1 NEIDL Design and Operation

In support of performing basic and clinical research on emerging infectious diseases and developing diagnostic tests, treatments, and vaccines, the NEIDL design and construction is intended to ensure the laboratory workers' protection, provide a barrier to protect persons outside the laboratory, and protect persons or animals in the community from pathogens that could be accidentally or malevolently released from a high-containment laboratory in the facility. The NEIDL was designed and constructed in conformance with the NIH's *Design and Policy Guidelines* (NIH 2008), the NIH's *Design Requirements Manual* (NIH 2003), the BMBL 5th edition (CDC and NIH 2007), the Massachusetts State Building Code 780 Code of Massachusetts Regulation (CMR 6th edition [expired on March 1, 2009]), Executive Office of Public Safety and Security, and NIH Security Guidelines Level 5 (BPHC 2009). Once the NEIDL becomes fully operational, it is anticipated that approximately 271–302 new positions would be established that would include administrative staff, maintenance personnel, research technicians, research scientists, safety officers, and management staff (BUMC 2009a).

1 The BMBL identifies the required elements of biocontainment as the following (CDC and NIH 2007):

- 2 • Facility design and construction;
- 3 • Safety equipment; and
- 4 • Laboratory practice and technique, referred to here as administrative controls.

5
6 A more nebulous but equally important element of biocontainment is the “culture of safety” The culture
7 of safety is the manner in which safety is managed and is reflected in the attitudes and values of the
8 employees and management. In 2010, BU appointed a task force to review its safety program and the task
9 force made the following key recommendations (BUMC 2010):

- 10 • Active embracement of a “culture safety” as a core value at every level.
- 11 • Inclusion of “safety” as a condition of employment for all those engaged in research and as a key
- 12 factor in the annual “Performance Appraisals”.
- 13 • Written confirmation by all individuals engaged in research that they have been adequately
- 14 trained and that they will follow the safety requirements.
- 15 • New procedures for the temporary or permanent removal of the privileges of individuals who
- 16 violate health and safety requirements.
- 17 • Clear indication that while safety is a shared responsibility of each individual working in a
- 18 laboratory ultimately the Principal Investigator has full responsibility for safety in their
- 19 laboratories.
- 20 • Appointment of a Laboratory Safety Coordinator” with specific responsibility for implementing
- 21 day-to-day safety requirements in the laboratory.
- 22 • Enhancements in the operation of the Institutional Biosafety Committee (IBC) operations and its
- 23 membership.
- 24 • Appointment of a Chief Safety Officer at the NEIDL with full oversight responsibility on all
- 25 safety aspects of the NEIDL and with the authority to stop any operations that are judged to
- 26 present a health and safety hazard or in violation of regulatory or policy requirements.
- 27 • Appointment of a NEIDL Safety Committee with a specific charge for the review of all aspects of
- 28 safety the NEDIL.
- 29 • Recruitment of a communication specialist to assist in developing campus-wide and NEIDL
- 30 specific “culture of safety” communication plans.

31
32 BUMC has developed the “Implementation Plan for Enhancing the Research Culture of Safety at Boston
33 University and Boston Medical Center” (BUMC 2010), which implements these recommendations and

includes a NEIDL-specific addendum (i.e., Section II). These enhancements have the potential to produce significantly improve safety at the NEIDL, but this analysis does not account for these potential impacts.

The following sections provide an overview of the NEIDL facility, a description of the biocontainment elements it contains, and a description of other facility systems critical to its safe and reliable operation.

2.1.1 NEIDL Overview

This section provides an overview of the NEIDL layout and descriptive information regarding its planned research and maintenance operations.

2.1.1.1 Facility Layout

The NEIDL facility is a structural steel and reinforced concrete seven-story building that houses BSL-2, BSL-3, and BSL-4 laboratories, including ABSL-3 and ABSL-4 animal facilities, ACL-3 and ACL-4 insectaries. It also has offices, conference rooms, and support facilities including an effluent treatment room, secure loading dock, and dedicated mechanical floors to support and maintain the containment features of the building. The superstructure is 139 feet (ft) high by 226 ft long by 120 ft wide, and it is surrounded by an 8-foot-high security fence. NEIDL's approximately 192,000 gross square feet (ft²) of floor space is allocated as follows (NEIDL Fact Sheet May 2008):

- 48 percent administrative, mechanical, and building management system support space
- 3 percent BSL-2 clinic research facility
- 20 percent BSL-2 laboratories and related support space
- 13 percent BSL-3 laboratories and related support space
- 16 percent BSL-4 laboratory and related support space

The building is designed to meet Massachusetts State Group III Building requirements, seismic performance criteria D (Haidar 2005), which is applicable to buildings considered essential to survive a seismic event, survive a 90 mph wind at 30 ft above the ground, and 30 pounds per square foot (psf) of snow load (CUH2A, Smith Carter, and Hemisphere Engineering 2005 and Boston Public Health Commission [BPHC] 2009). Critical building systems (e.g., biocontainment and life safety systems) were designed with built-in redundancy such that the failure (or removal for maintenance) of any one component would not affect overall system integrity (BUMC 2009b). Emergency backup power is provided by emergency diesel generators (BUMC 2009b). Day tanks provide approximately 15 minutes (min) of additional run time (BUMC 2009b). Loads supported by on-site power include but are not limited to: the fire suppression system components, fire alarms, exit lighting, air supply and exhausts,

cooling towers and chillers, and the building automation system (BAS) (BUMC 2008). The BAS control system is a computerized, intelligent network of electronic devices, designed to monitor and control the mechanical and lighting systems in a building. The BAS core functionality keeps the building climate within a specified range, provides lighting according to an occupancy schedule, and monitors system performance and device failures and provides notification to specified laboratory or engineering/maintenance staff.

The building has a lightning protection system grounded to the base of the structure (BUMC 2008). Liquid nitrogen is plumbed throughout the building for freezers, and natural gas is plumbed into the building for the BSL-2 laboratories (BUMC 2008). Exhaust stacks are on the roof.

The NEIDL's seven floors have the following (BUMC 2008):

- 16 BSL-2 Laboratory Modules;
- 6 BSL-3 General/Assignable Laboratory Modules;
- 1 BSL-3 Insectary;
- 8 ABSL-3 Animal Rooms;
- 3 BSL-4 General Laboratory Modules;
- 7 ABSL-4 Animal Rooms;
- 13 BSL-2/3/4 Scientific Core Technologies;
- 1 BSL-2 Clinical research facility;
- 21 Administrative Offices;
- 1 BSL-4 Training Simulator Laboratory; and
- 1 Multipurpose Meeting Room.

The highest biocontainment BSL laboratories are in the interior spaces of the building. Such a layout provides added protection against, and lowers the likelihood of, a low-frequency but high-consequence accident (e.g., aircraft crash) breaching high-biocontainment areas. In addition, the location reduces the probability of the highest biocontainment areas being breached by a malevolent act.

Rodents and nonhuman primates (NHP) will be the principal mammal species housed in the NEIDL, and NEIDL design features preclude their escape from the laboratory. The design of ABSL-3 and ABSL-4 laboratories comply with recommendations and requirements of the BMBL 5th Edition, NIH *Design Policy and Guidelines – Animal Research Facilities* (NIH 2003 and NIH 2008), and the *Guide for the*

Care and Use of Laboratory Animals (National Research Council 1996). Animal holding rooms and their associated support space will also be provided in conjunction with the BSL-3 and BSL-4 laboratories. The Institutional Animal Care and Use Committee will review and approve all research protocols involving animals in accordance with the *Public Health Service Policy on Humane Care and Use of Laboratory Animals* (Health Research Extension Act of 1985, Public Law 99-158, November 20, 1985 and NIH 2002b). All animals will be treated according to the applicable rules set forth by the Institutional Animal Care and Use Committee, the USDA Animal Welfare Act regulations, Title 9 of the *Code of Federal Regulations* (CFR) Subchapter A, and the *Guide for the Care and Use of Laboratory Animals* (NRC 1996).

Arthropods, such as mosquitoes and ticks, will be housed in specialized insectarium rooms. The construction and operation of the ACLs meet the recommendations and requirements of the ACME of the ASTMH *Arthropod Containment Guidelines*, Version 3.1 (ACME ASTMH 2002; Mary Ann Liebert, Inc. 2003), as well as the BMBL which is an internationally accepted standard. Uninfected arthropods will be completely segregated from those arthropods that contain vector-borne pathogens. Multiple insectaria barriers are in place that are designed to prevent the escape of any insects, such as manipulation areas where cooler temperatures will be maintained to slow arthropod movement to reduce the potential for escape. The surfaces of all insectaria spaces will be white—to allow for quick identification of arthropods that escape primary containment. Arthropod species will be kept segregated. Infected arthropod work will be conducted in the innermost rooms under negative pressure conditions, and all air supply and exhaust terminal devices will be screened to prevent arthropod escape. Additional room barriers in place will depend on the risk assessment of the pathogen/insect being studied.

Additional overview descriptions of the NEIDL facility are in Section A.1 of Appendix A.

2.1.1.2 Research and Operations

The NEIDL supports comprehensive core studies that enable basic, translational, and clinical research and developing products related to emerging infectious diseases. Administrative offices and support space will be provided to house administrative staff, safety staff, resident principal investigators (PIs), visiting PIs, and facility support staff employed to safely operate and maintain the facility.

The NEIDL will support key research and support operations. Clinical research space will be provided to support clinical research protocols. The clinical research facility will include reception, nursing, administration, and examination rooms. Specific protocols are also being developed to address the

1 transport of infected individuals from the NEIDL to the existing isolation facilities at BMC, if necessary.
2 In accordance with current practices, the BUMC Institutional Review Board, composed of members of
3 the academic community that the BUMC provost oversees, will approve all human investigation studies
4 to be performed at the NEIDL.

5
6 The research and support core operations that require high-biocontainment laboratories (BSL-3 and -4)
7 are listed below (Klempner 2008). Additionally, BUMC is responsible for developing standard operating
8 procedures (SOPs) for those operational services.

- 9 • *Aerobiology Core.* Animal research is an essential element of defining the pathogenesis of
10 infectious diseases, and such knowledge is essential for developing diagnostic tests, treatments,
11 therapies, and vaccines for such diseases. Because aerosol exposure is the primary route of
12 infection for many of the most important naturally occurring emerging infectious pathogens,
13 inhalational studies are an essential component for studying pathogenesis and preventing and
14 treating infectious diseases. Inhalation studies would focus primarily on NHP and rodents and
15 would be conducted in BSL-3 and -4 laboratories using aerosol-generating equipment within
16 Class III biological BSCs.
- 17 • *Laboratory Animal Science Core.* This support operation is primarily responsible for overseeing
18 the veterinary medical care of study animals. Such activity involves participating in experimental
19 design and setup, assisting in experimental procedures, providing training for core staff, and
20 providing necropsy and pathology services for study animals. Approximately 50–75 rodents and
21 up to 30 NHPs can be used for research in the BSL-3 or BSL-4 spaces at any time and will be
22 housed in single-occupancy cages.
- 23 • *Biomolecule Production Core.* This operational service is responsible for developing SOPs for
24 propagation and titration of all BSL-4 pathogens that will be used in the NEIDL. Personnel
25 provide inactivated viral antigens, purified genomic materials expression vectors of viral proteins,
26 and in vitro antiviral screening assays (i.e., samples) from the BSL-2 to BSL-4 facilities. In
27 addition, biomolecule production personnel will conduct simulations of all SOP protocols that
28 will be used for biomolecule production to validate their accuracy and, if necessary, modify the
29 SOPs for greater effectiveness and safety.
- 30 • *Cell and Tissue Imaging Core.* This support group offers multiple imaging systems to analyze
31 specimens using state-of-the-art technologies. The availability of different high-resolution
32 microscopy solutions will allow NEIDL investigators to integrate fine-scale topography of fixed
33 tissues gathered from transmission or scanning electron microscopy with information gathered

1 from multi-probe, live cell analyses using visible light, fluorescence, deconvolution (Deltavision),
2 or laser confocal microscopy.

- 3 • *Collaborative Research Core.* The objective of this core is to internally facilitate extramural
4 collaborations with investigators whose research requires high-containment capabilities. In
5 addition, this group is responsible for initiating the development of SOPs for specific domestic
6 and international research collaborations and initiating discussions and proposals with potential
7 collaborators.
- 8 • *Immunology Core.* Immunology support services personnel will have the necessary infrastructure
9 and provide support to characterize the innate and adaptive immune cellular response to
10 infectious pathogens and their products. That includes maintaining stocks of needed reagents,
11 providing consultation services and technical assistance, performing cell separation (via magnetic
12 beads), and other immunological analyses as needed.
- 13 • *Multimodal Whole Animal Imaging Core.* A unique operational objective of the NEIDL is to
14 provide the means to perform in vivo, whole-animal, multimodal imaging in a BSL-4
15 biocontainment setting. BSL-4 multimodal instrument configuration includes a small animal
16 Magnetic Resonance Imaging scanner, an optical imaging device, an ultrasound, and X-
17 ray/computerized tomography configuration. This core aims to serve as a central service facility
18 for experimental imaging in emerging infectious diseases, using the most recent and anticipated
19 advances in multimodal imaging.
- 20 • *Specimen Processing Core.* This service supports NEIDL investigators in studying emerging
21 infectious diseases by handling the collection and storage of animal specimens and cultures in the
22 appropriate biocontainment setting (e.g., BSL-2, BSL-3). In addition, the core provides a system
23 of centralized laboratory diagnostic testing.
- 24 • *Vector Transmitted Infectious Diseases Core.* This core (1) houses ACL-3 and ACL-4, which are
25 required for research on many of the emerging vector-borne infectious diseases; (2) breeds and
26 maintains arthropod colonies including mosquitoes and ticks; (3) conducts natural infection and
27 transmission studies; (4) conducts vector competence experiments to determine what insects are
28 capable of transmitting the microorganism, (5) develops novel strategies to interrupt pathogen
29 transmission at the vector level to eliminate the vector or pathogen and eliminate the vector
30 competence for pathogen transmission; and (6) is involved with new pathogen discovery in
31 potential vectors.

2.1.2 Facility Design and Construction

The facility design and construction contributes to laboratory and facility worker protection and provides a barrier that protects the public from potential accidental loss of biocontainment. Additional discussion of the facility design and construction is in Section A.2 of Appendix A.

2.1.2.1 Building Control Systems

The NEIDL has a BAS that consists of a dedicated operator work station with alarm status and trend logging printers. The BAS consists of a personal computer with graphic displays and the capability to monitor and control the operation of the building systems. Individual operator workstations allow human/machine interface with the BAS through visual displays in a dynamic graphic format of the laboratories. The BAS controls or monitors environmental and other operational parameters (temperature, humidity, flow, and pressure values) for individual areas or rooms, fire suppression, and liquid waste treatment. It also monitors enunciators for entry control systems. In addition to the graphic displays of laboratories, the central supply air and exhaust air systems dedicated to the individual spaces are also managed through the BAS. All control systems are equipped with an uninterruptable power supply. A satellite control center external to the NEIDL facility (i.e., in a nearby facility on the BUMC campus) provides redundant indication and control of NEIDL systems (BUMC 2009c).

2.1.2.2 HVAC Systems

The integrated heating, ventilation, and air conditioning (HVAC) system maintains a consistent and controlled indoor environment throughout the facility. The system allows the ability to adjust temperature and humidity (within selected laboratories) to parameters required by individual research activities. The NEIDL facility's HVAC has redundancies incorporated. Each air-handling system and corresponding exhaust system in the high-biocontainment laboratories (i.e., the BSL-3 and BSL-4 spaces) have multiple air handlers and exhaust fans. Some systems are sized to operate at full capacity with any individual unit out of service (Kajunski 2009). BSL-3 and BSL-4 laboratories are equipped with HEPA filtration. The HEPA filters meet the design criteria of removing at least 99.97 percent of particles having a diameter of 0.3 micrometer. Their efficiency is greater than 99.97 percent at particle sizes larger or smaller than 0.3 micrometer (CDC and NIH 2007). Figure 2-1 shows relative sizes and scale of particles. All BSL-3 exhaust passes through a single HEPA filter at the point of exit from biocontainment. The BSL-4 exhaust passes through double HEPA filters in series at the point of exit from biocontainment. The BSL-4 portion of the facility is supplied air from a common BSL-4 supply header through a single HEPA filter at the biocontainment barrier for each laboratory space.

The mechanical support space for BSL-4 biocontainment areas includes individual HVAC plenums for each BSL-4 laboratory room. The HEPA filter banks are above the laboratory suites and are connected to the individual suite rooms below using stainless steel ducts that are embedded in the concrete floor to minimize the potential for duct related issues. Each filter system is equipped with a damper system at the outlet, which is designed to close if an emergency occurs, maintaining negative airflow, and isolating the airflow path to and from the laboratory (Kajunski 2009; BUMC 2009c). Air flow is monitored through the filter houses via the BAS, and reduction of flow is used as an indicator of filter loading or breach.

Figure 2-1. Graphic representation of respirable particles.

2.1.2.3 Other Facility Features

The fundamental NEIDL public safety barriers are the high-biocontainment laboratories themselves. Other NEIDL features help prevent the accidental release of a pathogen from the laboratories. The BSL-3 and BSL-4 laboratories within the NEIDL were designed and built to the applicable federal standards, incorporating safety barriers and safeguards to prevent or mitigate the accidental release of a pathogen. Redundant, critical systems are incorporated in the utility and building infrastructure to ensure full operations. A networked electrical service provides four separate incoming feeds such that if any one feed is disrupted, the remaining electrical feeds provide the necessary service (BUMC 2009a).

Each BSL-4 laboratory is supported by multiple functional areas including a locker room, showers, suit room, air lock, and the laboratory itself—all surrounded by a non-containment corridor. Biological pathogens on the interior of the containment area will be isolated from exterior spaces by interlocked doors with the interlocking mechanism allowing only one door to open at a time to ensure proper function of the barrier (BUMC 2009b).

All electrical conduit, plumbing, piping, supply and exhaust ducts and miscellaneous penetrations are sealed at the point of penetration into the high biocontainment laboratories (BSL-3 and BSL-4) (BUMC 2009d). The high-biocontainment laboratories, animal laboratories, and insectary are separated by access controls (i.e., electronic recognition devices) and electronic recognition devices for overall building

access control. The high-biocontainment BSL-4 laboratory environment employs the concept of a *box-within-a-box* principle, whereby the laboratory is built within a pressure-controlled buffer. Laboratory air flows from areas with the lowest potential for contamination (e.g., office areas) to areas with the highest potential for contamination (e.g., the BSL-3 and BSL-4 laboratories), which helps to restrict pathogens to the laboratory environment. Ventilated airlocks separate the common corridors from the high-biocontainment laboratories. The airlock doors are interlocked to prevent multiple doors between the outside corridors and the high-biocontainment areas opening simultaneously. Directional airflow is provided through the airlock with differential pressure monitoring. The air pressure control system for maintaining the required pressure differentials is capable of being monitored inside and outside the BSL-4 laboratory. That direction of airflow into the BSL-4 laboratories is verifiable by gauges and an audible alarm system that will notify personnel of HVAC problems or a total or partial system failure. BSL-3 laboratories do not have those gauges or audible alarm system. All BSL-3 and BSL-4 laboratories will operate under negative air pressure. All high-biocontainment laboratory exhaust air is HEPA filtered before discharge through the NEIDL roof air emission discharge stacks. All surfaces in the high-biocontainment laboratories were designed and constructed to be easily cleaned and decontaminated. Seams, floors, walls, and ceiling surfaces are sealed to facilitate fumigation and are resistant to liquids and chemical used for cleaning and decontamination. No expansion joints or cracks are at the wall/floor interfaces (BUMC 2009c, 2009d).

One floor of the NEIDL is dedicated to BSL-4 laboratories and associated BSL-4 support space (e.g., access to ventilation system, instrument air compressors) directly above on the next upper floor level. The floor of the BSL-4 biocontainment areas is structurally isolated from the rest of the building, thereby minimizing the transfer of energy (i.e., vibration and shaking) from the building to the BSL-4 laboratories. The BSL-4 laboratories are also physically and functionally independent from other laboratory functions. The BSL-4 laboratories use airlocks for entry and exit, have dedicated supply and exhaust ventilation, and laboratory personnel will use positive pressure suits. Before exiting a BSL-4 laboratory, personnel will decontaminate the suit's outer surface via a chemical shower. Exhaust air will pass through dual HEPA filters mounted in series in a dedicated, sealed exhaust system before discharge through the NEIDL roof air emission stacks (BUMC 2009c).

2.1.3 Equipment

The NEIDL contains extensive equipment common to a biological laboratory. Much of the equipment and engineering controls are designed to remove or minimize exposures to hazardous biological materials.

The following list illustrates the major types of equipment that could be in the NEIDL (NIH and CDC 2007; BUMC 2009c):

- Autoclaves
- Biosafety Cabinets
- Centrifuges
- Flammable Storage Cabinets
- Freezers
- Incubators and Bioreactors
- Furnishings

The list is not intended to be comprehensive because NEIDL operations and BSL equipment can evolve. Thus, other equipment could be installed to meet research and safety considerations. In the following discussions, photos are provided as representative of the type of equipment.

2.1.3.1 Autoclaves

An autoclave is a device that uses steam, pressure, and heat to sterilize equipment, culture media, and contaminated wastes (Figure 2-2).

Bacteria, fungi, and viruses are killed via autoclave sterilization. Two methods are used to determine the proper operation of an autoclave.

Indicators can be biological or chemical (thermal). Biological

indicators are used to ensure autoclaves reach the correct temperature

and pressure for the specified length of time. Biological indicators

contain innocuous bacterial spores that will grow when the proper

operating temperature has not been achieved. In general, biological

indicator vials are placed inside biocontainment bags containing the

material to be processed in the autoclave. If the autoclave does not

reach the programmed temperature, the spores will subsequently grow, and change the color of a pH-

sensitive chemical in the growth medium. Colorimetric tape can also be used to verify the proper

operation of the autoclaves. The indicator changes color when exposed to the correct temperature. Those

steps provide multiple, independent, positive records to indicate the correct functioning of the autoclaves

(BUMC 2009c).

Figure 2-2. Autoclave.

2.1.3.2 Biological Safety Cabinets

BSCs are the principal devices used to provide biocontainment of biohazardous aerosols that can be

generated from laboratory operations (CDC and NIH 2007). There are three main classes (and multiple

subclasses) of BSCs.

Class II BSC. Class II BSCs (Figure 2-3) are available in several types. All types use HEPA filtration to filter exhaust air and incoming air, such that they provide personal, environmental, and sample protection (i.e., protection against contamination of the samples being processed).

Figure 2-3. A non-ducted Class II BSC. The parts are identified as follows: A. front opening, B. sash, C. exhaust HEPA filter, D. supply HEPA filter, E. common plenum, F. blower.

Class III BSC. A Class III BSC, is illustrated in Figure 2-4. The purpose of a Class III BSC is to provide an additional level of safety for workers. A Class III BSC has two chambers: the pass-through chamber and the working chamber. The pass-through chamber allows safe transfer of materials into and out of the working chamber. The pass-through chamber could consist, for example, of a steam sterilizer featuring interlocked double doors. The NEIDL Class III BSC is a detachable, mobile, HEPA-filtered rapid transfer cart which attaches on the ABSL-4 side of the BSL-4 cabinet line or the ABSL-3 side of the BSL-3 cabinet line. In BSL-3, samples can be removed via a sample (canister) port (under construction). Materials are passed between the pass-through chamber and the working chamber. The working chamber provides a maximum biocontainment enclosure for manipulating biohazardous materials. As required by the BMBL, the supply air for the Class III BSC is HEPA filtered; the exhaust air is double-HEPA filtered (with at least one filter integral to the BSC); and the BSC is directly connected (hard ducted) to a dedicated, independent, exhaust system. Air-tight dampers are on the supply and exhaust ducts of the BSC to allow gas or vapor decontamination of the interior. Long, heavy-duty gloves are attached in an air-tight manner to ports in the Class III BSC and allow direct manipulation of the materials isolated inside. Although the gloves restrict movement, they prevent the laboratory worker's direct contact with the biohazardous materials, maximizing personal safety (CDC and NIH 2007). Within the working chamber is a drain to allow liquids used in decontamination to be captured and processed in an autoclave before their removal from the laboratory.

2.1.3.3 Centrifuges

A centrifuge is an instrument used for separating particles of different masses in liquid suspension (Figure 2-4) by centrifugal force. It is used to concentrate particles, to separate insoluble molecules or whole cells from the suspension. When a centrifuge's motor is activated, the

Figure 2-4. Centrifuge.

spindle revolves at high speed, and centrifugal force drives the heavier materials toward the bottom of the centrifuge tube. Centrifuges come in various specifications to accommodate different applications. Some centrifuges (e.g., the tabletop model as shown in Figure 2-4) have multiple safety features, for example, gasket-sealed caps on each rotor bucket that holds each sealed centrifuge tube. Some centrifuges incorporate aerosol-containment technology. All modern centrifuges have automatic shutdown electronic sensors and indicators for unbalanced or disturbed operation. Sections F.2 and F.6 of Appendix F provide additional details on equipment and protocol used for centrifugation.

2.1.3.4 Flammable-Storage Cabinets

Flammable-storage cabinets provide for the safekeeping of flammable liquids close to the work area in an organized manner. All flammable-storage cabinets in the NEIDL comply with Occupational Safety and Health Administration regulations, are designed in accordance with applicable National Fire Protection Act (NFPA) standards, and have appropriate markings. The NEIDL will limit the amount of chemicals to be used in BSL-4 laboratories to quantities needed for the duration of the experiments.

2.1.3.5 Freezers

Ultra-low temperature freezers (Figure 2-5) provide long-term protection and storage for valuable samples of biohazardous materials. Many biological samples must be stored at below-freezing temperatures to prevent degradation and preserve them for future reference, analysis, or use. Protecting the integrity of biological samples is extremely important and can be achieved by combining rapid temperature recovery, temperature stability and operational efficiency. Ultra-low temperature freezers can maintain their internal compartments at temperatures as low as -86 degrees Celsius ($^{\circ}\text{C}$) (-123 degrees Fahrenheit [$^{\circ}\text{F}$]) to ensure the long-term preservation and storage of biological samples. Such sub-zero temperatures help maintain extended viability of preserved biological samples by dramatically reducing metabolic activity. Minimizing temperature fluctuations (achieved by temperature programming and alarms) is critical to preserving the viability of biological samples.

Figure 2-5. Ultra-low temperature freezers.

2.1.3.6 Incubators and Bioreactors

Biological incubators (Figure 2-6) come in a variety of sizes and types to serve a broad range of applications. They are designed to maintain optimal conditions to achieve growth or desired chemical reaction by controlling environmental factors such as temperature, humidity, and atmospheric composition. Incubators can be large, like a standard refrigerator, or small, as shown in Figure 2-6.

Figure 2-6 Incubator

Bioreactors, also known as fermenters, are highly specialized incubators designed for specialized liquid culture of microbes. Bioreactors allow continuous, precise control and monitoring of temperature, acidity, oxygen concentration, air input, air output, agitation, and allow for continuous input of fresh nutrients.

2.1.3.7 Furnishings

Laboratory furnishings are capable of supporting anticipated loading and use. Bench tops are impervious to water and resistant to moderate heat, chemicals, and disinfection solutions. Laboratory furnishings were selected to meet BMBL requirements.

2.1.3.8 Other Laboratory Equipment

Other laboratory equipment includes small, electric incinerators (dry heat), pipettes, refrigerators, ice makers, microscopes, mixers, shakers, and vacuum pumps. All instruments or devices will be used with the appropriate combinations of PPE and other physical biocontainment as required for biocontainment laboratory operations per BMBL guidance. The use of sharp instruments, also called sharps, will be avoided whenever practical.

Safety equipment also encompasses many of the items used for personal protection, such as gloves, coats, gowns, shoe covers, boots, respirators, face shields, and safety glasses or goggles. PPE is often used in combination with BSCs and other devices that contain the pathogens, animals, or materials being handled. In some situations in which it is impractical to work in BSCs, PPE might form the primary barrier between personnel and the infectious materials. Examples include certain animal studies, animal necropsy, pathogen production activities, and activities relating to maintenance, service, or support of the laboratory facility.

2.1.4 Administrative Controls

In addition to the NEIDL structure, biosafety is achieved by implementing various administrative controls. Administrative controls are a cornerstone to ensuring protection of the involved worker, the uninvolved worker, the public, and the environment. Administrative controls include programs, policies, and procedures designed to guide, direct, and assist employees with the safe handling of potentially hazardous biological materials. Additional details on administrative controls are provided in Section A.4 of Appendix A.

2.1.4.1 Laboratory Safety Program

The BUMC Office of Environmental Health and Safety (OEHS) oversees a laboratory safety program that emphasizes preventing illness and injury, promoting safe work practices, and protecting the environment while working with chemical, biological, and radioactive agents. Through the program, safety staff provide RA, consultation, and support to workers, supervisors, and management. Laboratory safety services include specialized safety training in biological, chemical, and radiation safety; routine laboratory inspections; new laboratory setups; emergency response; and laboratory decommissioning services in collaboration with the BUMC Facilities Department (BUMC 2009c).

2.1.4.2 Institutional Biosafety Committee

The Institutional Biosafety Committee (IBC) is a university-wide committee responsible for reviewing and approving recombinant DNA (rDNA) research and biohazard research projects throughout the BU system. The IBC is responsible for overseeing the Biosafety Program at BU and BMC. The committee sets biocontainment levels in accordance with the NIH and the CDC guidelines. It also periodically reviews previously approved research projects for changes that will necessitate changes to experimental protocols and SOPs or increasing the required BSL. The IBC evaluates research projects that use rDNA; agents that are infectious to humans, animals, and plants; other potentially infectious materials; select agents and biological toxins; human materials including blood, cells, unfixed human tissues, and other body fluids; xenotransplant; and gene transfer clinical studies. The IBC coordinates its application procedures with two other offices, Research Occupational Health Program (ROHP), to ensure that research personnel have adequate occupational health monitoring, training on safe work practices, exposure control emergencies, and use of PPE. The IBC carries out those functions pursuant to requirements set forth by federal, state, and local agencies as well as BU. The IBC is composed of faculty investigators (with expertise in rDNA and biohazards research) from both campuses, non-scientist and community members, and a biosafety officer. IBC responsibilities include the review and approval of all new research involving rDNA and biohazards; continued review of approved research projects; review of

laboratory inspection reports; investigation of complaints and concerns, and review of training and a medical surveillance programs. During and following approval from the IBC and before operations, NEIDL staff indicate that they will develop SOPs outlining the appropriate safety equipment, research equipment, safety processes and procedures, and the BSL in which the research must be conducted (BUMC 2009e).

2.1.4.3 Standard Operating Procedures and Training

Biocontainment administrative controls include strict adherence to standard microbiological practices and techniques, personnel training, and safety oversight and management. SOPs are under development for the NEIDL staff that will establish, implement, and control laboratory activities for BSL-2, BSL-3, and BSL-4 laboratories. SOPs provide direction to ensure that laboratory activities will be performed within the biological safety requirements pursuant to the BMBL guidance, CDC and USDA regulations, and BUMC policies pertaining to SOPs, laboratory practices, and training programs. The key elements of a successful administrative controls program are the direct involvement of laboratory workers in controlling the risks and the accountability of BUMC line management for safety, security, and environmental protection. The NEIDL director, line management, lab workers, and the biosafety officer are responsible for ensuring that NEIDL research activities are conducted in accordance with BUMC policies and procedures, and federal, state, and local regulations. The NEIDL training regimen being developed is intended to ensure that all personnel engaging in research or clinical activities have received the appropriate information about the biohazardous and hazardous materials in their work environment, the nature of the risks associated with handling such materials, and the conditions under which the materials can be harmful. Training programs will be integrated, comprehensive, and multidisciplinary and identify job-specific and task-specific training necessary to ensure safe and effective BSL-2, BSL-3, and BSL-4 laboratory techniques (BUMC 2009c, 2009e).

BUMC has policies and procedures in place to monitor and prevent worker exposure. They consist of a detailed medical surveillance training program, serum banking, and other procedures effective at preventing and monitoring worker exposures. The NEIDL will have a comprehensive medical surveillance program that will be integrated into the BU medical monitoring system. If a pathogen-specific immunization is available, laboratory personnel will receive immunizations for the pathogen handled or present in the laboratory. BUMC provides annual laboratory training as a minimum standard and increases training frequencies depending on the type of work being done in each laboratory. BUMC will determine the levels of training necessary to ensure that all NEIDL employees are compliant with and fully knowledgeable of all regulations. The laboratory safety program requires all personnel who work

with chemical or biological hazardous materials to be aware of the hazards that are present, use appropriate PPE, and be trained in emergency response procedures. All persons who plan to work in the BSL-3 and BSL-4 laboratories will be required to undergo additional specialized training. A training program still under development for laboratory practices and safety protocols in high-containment laboratories will be conducted in the NEIDL seminar room, mock BSL-4 training simulator (a fully functional laboratory operated in a non-contaminated state), and use of viewing windows into the operating, high-containment suite (BUMC 2009c and 2009e).

2.1.5 Waste Management

Waste management practices at the NEIDL are laboratory-specific and dependent on the wastestreams generated by individual BSL-2, BSL-3, and BSL-4 laboratory activities. In general, disposal of waste is specific to the organisms or SOPs of the research group, but in general the following principles apply:

- Rigid containers labeled with the universal biohazard symbol and lined with red biohazard bags are provided in every clinical and research facility in the NEIDL for all biohazard waste.
- Sharp containers are also provided, which are specifically designated for disposing of needles, syringes, and scalpel blades.

Solid waste is the classification given to all nonhazardous waste generated from offices and maintenance areas, including recyclable materials, in the NEIDL. In addition to normal solid waste, it is anticipated that the NEIDL will generate three types of special waste: biological waste, radioactive waste, and hazardous-chemical waste. The NEIDL will have chemical/biological mixed waste (and could also have radiological/biological). The biological (pathogen) component will be inactivated by the appropriate (and compatible) chemical disinfectant, and the material will then be disposed of properly as chemical or radiological waste. The use, storage, and disposal of all solid and special waste will be performed in accordance with state and local regulations.

Additional details on waste management are in Section A.5 of Appendix A.

2.1.5.1 Biological Waste

No waste materials will be removed from the high-containment laboratories without first being processed in an autoclave or decontaminated by a method approved and managed by BU's OEHS (BUMC 2009f). Several materials require special decontamination methods to assure safe removal from the BSL-3 and BSL-4 laboratories. Such materials are biological samples needing further analysis, laboratory equipment, and laboratory clothing (BUMC 2009f). BSL-3 and BSL-4 laboratories use a disinfectant that is particular

1 to each pathogen used as outlined in the research-specific SOPs and an autoclave to further disinfect solid
2 biological and nonbiological waste. The BSL-2 laboratories will use the conventional system of bagging
3 biohazardous waste and shipping the material off-site for incineration using a licensed third-party
4 contractor (BUMC 2009f).

5
6 The liquid effluent disposal system will include a sterilization system BSL-4 facilities and a dedicated
7 liquid effluent decontamination system. All liquid waste from the BSL-4 laboratories will first be
8 decontaminated with a chemical disinfectant and then be piped to a biowaste processor and heated under
9 pressure until the temperature reaches 121 °C (249 °F) where it will be maintained for a minimum of 60
10 minutes to ensure that two decontamination (BUMC 2009f) processes are completed. Decontamination
11 will be verified using biological indicators and electronic monitoring and charting of the process (BUMC
12 2009c). Once cooled and verified to meet acceptable discharge limits, the liquid waste effluent will be
13 discharged to the Boston Water and Sewer Commission sanitary sewer system. Ventilation from
14 plumbing system gases pass through a HEPA filter before discharge to the atmosphere. The filters will be
15 decontaminated and disposed of as appropriate (NIH and DHHS 2005).

16
17 The decontamination system for the BSL-3 and BSL-4 laboratories will include 5 large autoclaves and 11
18 medium autoclaves. Animal carcass materials will be placed on rack sterilizers for easy introduction or
19 removal of large materials, while smaller autoclave models will be used for general laboratory waste.
20 Once waste material has been processed in an autoclave in and removed from the BSL-3 and BSL-4
21 biocontainment space, all animal carcass waste will be placed in the tissue digestion system and undergo
22 alkaline hydrolysis for final processing and disposal (mineral oil could be added to the tissue digester to
23 aid in removal of the autoclave bags following processing) (BUMC 2009f).

24 25 **2.1.5.2 Radioactive Waste**

26 Radioactive waste generated at the NEIDL will consist primarily of solid waste such as paper, plastic and
27 glass contaminated with trace amounts of radioactive isotopes (radioisotopes). The wastes will be limited
28 to those materials that meet the definition of low-level radioactive waste as defined by the Nuclear
29 Regulatory Commission. The radioisotopes that are anticipated to be used at the NEIDL include both
30 long-lived and short-lived radioisotopes. Long-lived radioisotopes must be disposed of off-site. However,
31 waste contaminated with short-lived radioisotopes will be held on-site in the BUMC decay-in-storage
32 facility for periods ranging anywhere from one week to not more than 2 years and 9 months, depending
33 on the radioisotope's half-life, to allow sufficient decay and subsequently disposed of as nonradioactive
34 sanitary waste (BUMC 2009c).

2.1.5.3 Hazardous Chemical Waste

Hazardous-chemical waste generated at the NEIDL could include the following:

- Flammable liquids
- Flammable, toxic liquids
- Corrosive liquids
- Oxidizing liquids
- Ethidium bromide
- Liquid effluents
- Chemical disinfectants

Such wastes will be disposed of at off-site, permitted, commercial disposal facilities (BUMC 2009c) in accordance with the requirements of 40 CFR 260..

2.1.6 Security Risk Assessment

In accordance with federal regulations implementing the Bioterrorism Act of 2002, BUMC has completed a NEIDL site-specific security RA. The security RA identified and characterized the threat posed to the NEIDL-postulated inventory of biological toxins and agents, evaluated inventory protection from theft, loss, or release of the biological toxins and agents, assessed the current or necessary safeguards and security to protect the inventory, and provided recommendations for security enhancements to mitigate vulnerabilities.

In addition, an independent TA was conducted as a component of this RA. Chapter 6 of this document provides a synopsis of the TA because the actual TA contains Restricted Distribution Security Information, making it a controlled document under the provisions in the Bioterrorism Act of 2002. Therefore, Chapter 6 presents an overview of the TA and its findings to provide a description of the linkages between the TA and the overall RA process.

The primary objective of the TA was to identify and evaluate credible scenarios that would involve the internal or external breach of the NEIDL security systems due to a malevolent action, such as a disgruntled laboratory worker spreading a biological agent in the community or terrorist action. As such, the TA provides an evaluation of *initiating events* associated with malevolent acts that could result in the release of a pathogen. In the context of security, the term *system* is used to define an integrated set of building design, security policies and procedures, programs, activities, and equipment for protecting the NEIDL mission, personnel, operations, inventory, and sensitive information. The TA analysis was conducted specific to each of the three sites under evaluation using the *as built* condition of the NEIDL to model the security systems. Initiating event information was then provided to the RA team to integrate into the RA human health and environmental effects analysis.

2.1.6.1 Physical Security

Physical security protection consists of barriers, electronic surveillance systems, and intrusion detection systems that form a comprehensive site-wide network of monitored alarms. Various types of barriers are used to delay or channel personnel or to deny access to sensitive materials, and vital areas. Barriers are also used to direct the flow of vehicles through designated entry control portals and to deter and prevent penetration by motorized vehicles where vehicular access could significantly enhance the likelihood of a malevolent act being carried out.

NEIDL researchers working with select agents will be registered with the CDC before possessing, transferring, or using a select agent. The security layers will be operationally assured using security officers, biometric and card access devices, closed circuit television cameras, automatic door locking systems, and access alarms assigned or installed at each layer's barrier (BUMC 2009c).

Systems will monitor work being performed in high-level biocontainment areas to ensure that two authorized persons are in each area to minimize risk. Access to high-containment laboratories will be restricted to people whose presence is required and authorized. Strict operational protocols will be imposed on laboratory personnel including specific training and background checks before working in the facility. The security system will also monitor and control the Gasketed APR (air-pressure resistant doors) in BSL-4 and BSL-3 entry and exit doors. The Access Control Office will maintain a log of persons entering and exiting the laboratory that will include their name and the time, date, and reason for entering the lab. BUMC's OEHS professionals and security officers (i.e., BU public safety officers) assigned to the laboratory will periodically audit the log (BUMC 2009c).

BUMC security staff will provide building security. Public safety officers assigned to the NEIDL will receive training about the nature of the research, the risk associated with the building's unique emergency response protocols, and enhanced police academy training in addition to the significant, ongoing training program already in place (BUMC 2009c).

2.1.7 Facility Commissioning, Registration, and Operation Process

Commissioning is the process of ensuring that all building systems are installed and perform interactively according to the design intent, that the systems meet the user's operational needs, that the installation is adequately documented, and that the operators are adequately trained. Commissioning begins in the planning phase and proceeds through design, construction, startup, acceptance, and training. Ongoing and

1 routine inspections of the facility and systems performance assessments continue through the life of the
2 NEIDL (NIH 2008).

3
4 Commissioning of biocontainment laboratories includes verifying the design and operational parameters
5 established in the design documents are implemented, as outlined in the BMBL guidelines, NIH *Facility*
6 *Design Guidelines*, and other applicable guidelines and regulations. As stated in the BMBL, the NEIDL
7 building design and operational procedures must be documented, and the facility must be evaluated
8 before operation to verify that the design and operational parameters have been met (CDC and NIH
9 2007).

10
11 In addition, the operation of the NEIDL must comply with various city (including the BPHC), state, and
12 federal regulations must be met before operations with pathogens begin and throughout facility
13 operations. The NEIDL is subject to the requirements of the Select Agent Program, which requires that
14 the Secretary for HHS issue a certificate of registration.

15
16 CDC is responsible for the registration and oversight of laboratories that possess, use, or transfer select
17 agents that could pose a threat to human health. The Animal and Plant Health Inspection Service is
18 responsible for the registration and oversight of laboratories that possess, use, or transfer select agents that
19 could pose a threat to animal or plant health or products. For facilities registered with CDC or USDA that
20 possess, use, or transfer select agents, the Select Agent regulations require the following (GAO 2007a):

- 21 • An FBI security RA for a number of individuals involved in the operation of the facility,
22 including each person who is authorized to have access to select agents;
- 23 • Written biosafety, security and incident response plans;
- 24 • Training of individuals with access to select agents and individuals who will work in or visit areas
25 where select agents are handled and stored;
- 26 • A security plan sufficient to safeguard the select agent and toxin against unauthorized access,
27 theft, loss, or release, designed according to a site-specific RA, and that provides protection in
28 accordance with the risk of the select agent or toxin;
- 29 • Inspection by CDC or USDA of the facility and its records before the certificate of registration is
30 issued; and
- 31 • Maintaining and retaining records relating to the activities covered by the Select Agent
32 regulations.

In addition to the certification from HHS, an inspection of the NEIDL by CDC, USDA, or both, is required. Inspections by CDC or USDA may be conducted without advance notice at any time during the registration period. Each year thereafter, inspections by the designated Responsible Official for the Facility are required. Facilities must be re-verified and documented at least annually to comply with BMBL and Select Agent guidelines (CDC and NIH 2007). Facility registration with CDC or USDA includes the following (GAO 2007a):

- A list of each select agent and toxin the facility intends to possess, use, or transfer;
- The objectives of the work for each select agent and toxin, including a description of the methodologies or laboratory procedures to be used;
- A description of the physical security, biosafety, and incident response plans;
- Policies on review, authorization, and monitoring of biological research, including public participation in review process;
- Policies on the humane care and use of laboratory animals; and
- Assurance of security awareness and biosafety training for individuals who have access to areas where select agents are handled and stored.

2.2 Site Descriptions

This RA considers the impacts of potential events for urban, suburban, and rural settings for the facility. The same facility design and operations are assumed for all three settings. The following subsections describe the general population, environmental justice, public safety, and emergency response characteristics of the three settings.

Additional details of the sites (i.e., Boston, Tyngsborough, and Peterborough) are presented in Appendix B.

2.2.1 General Population

To evaluate the relative risk (i.e., frequency and consequence) of an accidental or malevolent act that results in a release of a pathogen in the three settings, a basic understanding of the characteristics and demographics—including environmental justice communities, emergency response capability, and medical infrastructure—is necessary for each of the alternate sites. The site characterization data presented in this section such as site location information, utilities descriptions, transportation access, and health care infrastructure began with consideration of the information presented in the *Draft Supplementary Risk Assessment and Site Suitability Analyses* (NIH 2007). Those data were augmented by site visits, additional research, and data-gathering activities.

Interviews were conducted the week of January 26, 2009, with public safety and emergency services officials whose jurisdictions include the three sites under analysis. The interview team used a standardized set of data-collection and analysis tools to assure consistency in the manner in which questions were presented to officials and their responses were recorded.

For the purposes of assessing general populations near the three sites, a 10-kilometer (km) (6.2-mile) radius was defined around each site centered on the actual or hypothetical location of the laboratory. Section F.4 of Appendix F present the resident and non-resident population estimates associated with each of the three sites.

Detailed environmental justice population data are presented in Chapter 10 and Appendix M.

2.2.2 Public Safety and Emergency Response

The following is a general overview and comparison of the public safety and emergency response capabilities at the three sites.

2.2.2.1 Law Enforcement

Law enforcement agencies provide a variety of services that are broadly intended to prevent criminal acts and to identify those responsible for committing crimes. Services include uniformed patrol, criminal investigation and attribution, intelligence gathering and data analysis, crime prevention, and specialized services such as special weapons and tactics (SWAT) teams and explosive ordnance disposal (EOD) teams or bomb squads. Rural and suburban police agencies typically have fewer resources than agencies serving urban areas. That held true when the law enforcement capabilities of Boston were compared those of Tyngsborough and Peterborough. More than 2,000 officers staff the Boston Police Department, while both of the smaller agencies had fewer than 25 officers. Unlike Boston, neither Tyngsborough nor Peterborough police agencies have the capabilities to conduct intelligence gathering nor do they directly participate in an intelligence fusion center. Established by many states and large cities, intelligence fusion centers share information and intelligence within their jurisdictions and with the federal government. Both Tyngsborough and Peterborough police agencies depend on external mutual aid for SWAT and EOD resources (BUMC 2009g).

In addition to the three cities, the BU Police Department (BUPD) has approximately 50 police officers dedicated to the campus. BUPD's 50 police officers have primary jurisdiction over the campus including

the NEIDL facility. The BUPD is supplemented by armed public safety officers and non-sworn security officers. The BUPD officers are also trained to operate within health care and biomedical research facilities (BUMC 2009g).

2.2.2.2 Fire Protection

Fire protection services generally include emergency response to extinguish fires, conduct rescues, encouraging fire prevention through public education programs, fire code enforcement through plan review and site inspections, and fire cause investigation. Specialized fire department services include hazardous material (HazMat) response, marine firefighting, high angle rescue, and trench rescue. Fire protection in the rural and suburban areas of the United States is largely provided by volunteer firefighters (BUMC 2009g).

The Boston Fire Department (BFD) is one of the oldest fire departments in the nation and is staffed by more than 1,600 full-time personnel operating from 35 fire stations. BFD provides specialized response services including a dedicated HazMat team. Personnel have received training to address incidents that involve biomedical research facilities. Boston has also adopted building and fire codes that address the unique characteristics and needs associated with biomedical research facilities. Tyngsborough and Peterborough, with 38 and 50 firefighters, respectively, both depend on volunteer and on-call firefighters. Both departments also depend upon mutual aid from nearby jurisdictions for fire suppression and specialized services including HazMat response (BUMC 2009g) this limits response capabilities respectively.

Successful fire suppression activities depend on access to a reliable water supply system. Of the three sites in the comparative analysis, only the Boston water system has the capacity to support the fire protection needs required to protect the seven-story, 192,000 ft² facility (BUMC 2009g).

2.2.2.3 Emergency Medical Services

Emergency medical services (EMS) involve the delivery of Basic Life Support (BLS) and Advanced Life Support (ALS) treatment and the transport of patients by ambulance to a hospital emergency department. EMS is typically a function of the fire department with firefighters cross trained as emergency medical technicians (EMTs) and paramedics (EMT-P). Fire department EMS can be a *first responder* service operating only from a HazMat vehicle. A HazMat vehicle is a vehicle specifically designed for responding to HazMat incidents. It is basically a truck filled with all the tools and supplies required for such situations. Many fire departments also provide ambulance response and patient transport services.

EMS can also be delivered by an independent government agency or a commercial provider (BUMC 2009g).

In addition to fire fighting, Tyngsborough and Peterborough fire department personnel provide EMS within their response areas. Tyngsborough provides BLS first responder services that are supported by a third-party ambulance provider. The Peterborough Fire Department provides both BLS and ALS first responder and ambulance transport services. EMS in Boston are provided by a division of the Public Health Commission. Boston EMS uses more than 350 EMTs and paramedics to staff an average of 20 ambulances at all times (BUMC 2009g).

2.2.2.4 Emergency Management

Emergency management functions fall into the categories of prevention, preparedness, response, and recovery. They include tasks such as developing contingency plans, coordinating resources and information during an emergency, processing disaster declarations to initiate external assistance, and guiding recovery operations. Each jurisdiction appoints an emergency management coordinator who is responsible for administering the preparedness program. Larger jurisdictions normally staff an Office of Emergency Management, while smaller cities typically assign the emergency management function to the fire department. Larger jurisdictions might also construct a dedicated Emergency Operation Center (EOC) that serves as a centralized location from which large-scale emergency incidents are managed (BUMC 2009g).

The mayor's Office of Emergency Preparedness is responsible for administering the homeland security and emergency management activities for Boston. A full-time emergency management coordinator leads a staff that is based out of Boston's EOC. The fire chiefs of both Tyngsborough and Peterborough also serve as the emergency management coordinator within their jurisdictions. Neither town has dedicated space for use as an EOC nor full-time dedicated Office of Emergency Management staff to support emergency preparedness functions (BUMC 2009g).

2.2.2.5 Public Health Preparedness

Public health agencies are responsible for providing services intended to safeguard the health and welfare of the general population. Public health agencies deliver a number of services including providing public health education, administering vaccination programs, identifying and monitoring disease trends, and assuring the safety of the food and water supplies. The threat of bioterrorism has significantly expanded the role of public health agencies in most communities. Since 2002 the CDC has provided funding to state

1 and local health departments to enhance public health preparedness measures. New public health
2 initiatives include the delivery of mass prophylactic medication, enhanced disease monitoring through
3 active surveillance and atmospheric sampling, and direct involvement in traditional first responder
4 activities (BUMC 2009g).

5
6 **Medical Response System.** Boston was an early adopter of the Metropolitan Medical Response System
7 concept developed after the terrorist attacks in 1995. The Boston Public Health Commission has
8 developed a robust public health preparedness program that is administered by the Office of Public Health
9 Preparedness. That office is responsible for a number of tasks including developing plans to deliver mass
10 prophylactic care in response to disease outbreak such as pandemic influenza. Tyngsborough and
11 Peterborough each have one individual assigned the duties of health officer. They are primarily tasked
12 with providing basic services such as restaurant inspections and approving the installation of septic
13 systems. Through the use of Assistant Secretary for Preparedness and Response (ASPR) and CDC grant
14 funding, plans are developed by state public health departments and local jurisdictions responsible for
15 preparedness efforts needed to protect the residents of the towns (BUMC 2009g).

16
17 **Emergency Services.** The capabilities of the public safety and emergency service agencies vary
18 significantly among each of the three sites. Since 2001 the capabilities of emergency service agencies in
19 the nation's urban areas have been enhanced through grant-funded U.S. Department of Homeland
20 Security (DHS) initiatives. Boston public safety agencies possess a greater number of resources and
21 capabilities because of the size of the agencies, collocation with other agencies, and participation in
22 national homeland security initiatives. Boston area agencies formed the nine-city Metro-Boston
23 Homeland Security Region (MBHSR) under the DHS Urban Area Security Initiative. The MBHSR has
24 implemented regional initiatives to enhance coordination among emergency response organizations
25 through training, acquiring compatible equipment, and creating a regional radio interoperability program.
26 Regional terrorism and criminal analysis activities are coordinated through the Boston Regional
27 Intelligence Center. Heavily populated metropolitan areas, such as Boston, have developed the public
28 safety infrastructure and capabilities necessary to provide services across the spectrum of prevention,
29 preparedness, response, and recovery (BUMC 2009g).

A. Facility Design and Operations

The fundamental objective of any biosafety program is the biocontainment (ie. Safe handling and containment) of hazardous biological material Biocontainment are microbiological practices, safety equipment, and facility safeguards that protect laboratory workers, the environment, and the public from exposure to infectious microorganisms that are handled and stored in the laboratory. . One fundamental principle to eliminate or mitigate hazards is to develop effective controls such as but not limited to:

- Developed training to enhance the understanding and awareness of the hazards;
- Provide clear SOPs for operational safety;
- Provide suitable and appropriate alarms and warnings;
- Restore the system to the safe condition in an off-normal event;
- Establish safety barriers to defeat the hazards; and
- Contain the hazards if the barriers fail.

As described in the *Biosafety in Microbiological and Biomedical Laboratories* (BMBL) 5th Edition (CDC and NIH 2007):

Biosafety in Microbiological and Biomedical Laboratories (BMBL) has become the code of practice for biosafety. These principles are [bio]containment and Risk Assessment (RA). The fundamentals of [bio]containment include the microbiological practices, safety equipment, and facility safeguards that protect laboratory workers, the environment, and the public from exposure to infectious microorganisms that are handled and stored in the laboratory.

Workers are the first line of defense for protecting themselves, coworkers, and the public from exposure to hazardous pathogens. Protection depends on an awareness of the hazard and a well-established protocol to operate safely. Humans are fallible, and mistakes have the potential to compromise any of the safeguards of the laboratory. For those reasons, it is critical that technical proficiency in using good microbiological practices, safety equipment, and emergency response are continuously trained, tested, emphasized, and enforced. In addition, a program of continuous improvement strengthens the biosafety program by constantly evaluating risk and Standard Operating Procedures (SOPs) and work practices for areas requiring improvement.

This appendix contains an overview of the National Emerging Infectious Diseases Laboratories (NEIDL) facility including laboratory layout, generic floor plans, and equipment and material flow within the facility. It also contains a description of the facility design and construction (secondary barriers), safety equipment (primary barriers), and laboratory practice and technique (administrative controls).

A.1 NEIDL Overview

A.1.1 Laboratory Layout

The NEIDL consists of biosafety level (BSL)-4 laboratories with the associated BSL-4 support space (e.g., access to ventilation system, instrument air compressors); BSL-3 laboratories and animal handling rooms; BSL-2 laboratories and one BSL-3 laboratory on each of those floors; office space, clinical research center space, and building systems support space. Laboratory spaces and air flow systems are segregated as necessary to avoid cross contamination and within the structure to provide optimum workflow. Figures A.5 through A.21 (which are placed at the end of this appendix to avoid breaking-up the textual flow) provide floor plans for the various laboratory rooms.

A.1.2 Generic Floor Plans

The RA team evaluated the floor plans, which indicate that the highest containment BSL laboratories are within the interior spaces of the building. Such a layout provides protection against and lowers the likelihood of an aircraft crash accident penetrating the containment areas. In addition, that location would be anticipated to lower the likelihood of the highest biocontainment area being successfully breached by a malevolent action (i.e., no direct exposure pathway exists from the higher BSL spaces to the exterior of the facility).

The ability to maneuver people, equipment, supplies, and animals throughout the facility efficiently, without compromising the integrity of the research programs or creating an unsafe environment for building occupants is extremely important in the design of the facility. Proper design of such process flow also prevents cross-contamination of vital research and diagnostic

programs and allows for compartmentalization of rooms and suites for decontamination purposes.

A.1.3 Material and Equipment Flow

Materials and equipment entering or leaving the BSL-4 suites do so through one of the following means, depending on the specifics and size of the item:

- Stainless steel chemical dunk tanks;
- Pass-through, double-door autoclaves; or
- Fumigation vestibules (provided for each BSL-4 area).

Smaller samples and other materials enter or exit via any one of the three means as stated above.

Large and more sensitive pieces of equipment enter and exit through the fumigation vestibules.

When an item exits via the fumigation vestibule, it must be decontaminated inside the vestibule before exiting from the BSL-4 containment.

Waste materials and contaminated instruments exit via a pass-through autoclave.

A.2 Facility Design and Construction (Secondary Barrier)

Facility safeguards are designed to protect the staff and facility and to mitigate the accidental release of a pathogen from the laboratories. This section discusses the secondary safety barriers and how the facility safeguards within the NEIDL were designed to ensure containment and defined to facilitate the evaluation and analysis of consequences associated with operations involving biological pathogens.

Structure features (i.e., secondary barrier) are discussed first, followed by a detailed discussion of the safety equipment (i.e., primary barrier) within the NEIDL.

A.2.1 Structure

The BSL-3 and BSL-4 laboratories within the NIEDL were designed and built to the applicable federal standards, incorporating safety barriers and safeguards to ensure a safe work environment

1 and mitigate the accidental release of a pathogen. The most fundamental safety barrier for the
2 public at the NEIDL is the high-biocontainment laboratory itself. The BSL-4 core laboratory
3 space incorporates technologically advanced scientific equipment for infectious disease research
4 in a high-biocontainment environment. The BSL-4 laboratory barrier is based on the *box within a*
5 *box* concept. The BSL-4 facilities were designed and constructed to be easily cleaned and
6 decontaminated. Seams, floors, walls and ceiling surfaces have been sufficiently sealed to
7 facilitate fumigation and be resistant to liquids and chemicals used for cleaning and
8 decontamination. The airtight enclosure allows a negative pressure cascade across functional
9 areas creating directional airflow to help contain pathogens to the laboratory environment. The
10 laboratory consists of multiple functional areas separated by pressure zones including a locker
11 room, showers, suit room, air lock, and laboratory, all of which are surrounded by a second
12 corridor, which serves as a buffer to the balance of the facility. Biological pathogens will be
13 isolated within the laboratory suite from exterior spaces by interlocked doors with the
14 interlocking mechanism allowing only one door to open at a time to ensure proper function of the
15 barrier system (BUMC 2009a).

17 **A.2.2 Codes and Standards**

18 The design team that designed and oversaw construction of the facility is made up of CUH2A,
19 Smith Carter, and Hemisphere Engineering (CUH2A et al. 2005). Those companies have been
20 involved in many of the BSL-4 projects designed and constructed in North America, including
21 the following (BUMC 2009b):

- 22 • National Institutes of Health (NIH), National Institute of Allergy and Infectious Diseases
23 (NIAID), Rocky Mountain Laboratories, Hamilton, Montana
- 24 • Centers for Disease Control and Prevention (CDC), Emerging Infectious Diseases
25 Laboratory
- 26 • NIH, NIAID, Integrated Research Facility, Fort Detrick, Maryland
- 27 • United States Army Medical Research Institute of Infectious Diseases (USAMRIID),
28 Fort Detrick, Maryland

29
30 The overall facility design and construction is in conformance with the following applicable
31 codes (BUMC 2009b):

- The NIH *Design Policy and Guidelines*, November 2003 ed.
- The U.S. Department of Health and Human Services, CDC/NIH, *Biosafety in Microbiological and Biomedical Laboratories* (BMBL), 5th ed.
- The Massachusetts State Building Code (780 CMR), 6th ed.
- Boston University Medical Center (BUMC) *Biosafety Manual*

A.2.3 HVAC Systems

The integrated heating, ventilation, and air conditioning (HVAC) system provides a controlled indoor environment. The system allows the ability to adjust temperature, pressurization, directional airflow and humidity (within selected laboratories) to parameters required by individual research activities. The NEIDL facility has incorporated a redundant design for the HVAC system. Each air handling system and corresponding exhaust system in the high-biocontainment labs (i.e., the BSL-3 and BSL-4 spaces) incorporate redundant air handlers and exhaust fans to ensure continuity of proper directional airflow (Kajunski, Joe, Assistant Director Engineering and NEIDL, Boston University, MED National Bio Lab. Telephone Meeting Notes, HVAC. Conversation with Tetra Tech, Inc., June 19, 2009).

A.2.4 Alarm Modes

This section describes the alarms for both BSL-3 and BSL-4. Note that no local alarms are planned for BSL-2.

A.2.4.1 BSL-3 Alarms

BSL-3 laboratories will have a local alarm, currently being planned, based on the operational state of directional airflow within the BSL-3 space (a wall-mounted device that captures attention with strobe lights and sound).

A.2.4.2 BSL-4 Alarms

Laboratory Internal Alarm Lights. A strobe light annunciating in the NEIDL indicates an emergency alarm condition in the laboratories. In addition, a local light tree will identify the type of alarm. Two lights relate to the following alarms:

- Red – Critical Evacuation; and
- Amber – Critical Seek Information.

Fire Alarm Mode. The fire signal for all Control Cells is an alert signal only, and it does not have any effect on the cell operation. If the room occupant decides to evacuate the Control Cell, the exit is through prescribed egress sequences. Room isolation is then achieved remotely through a building automation system (BAS) command of the bioseal dampers.

Power Interruption Alarm Mode. When a power interruption to the air distribution system in each cell occurs, the space goes into the system shutdown mode. Restart is by the BAS.

Emergency Mode. Alarm strobe lights and enunciator panels inform the occupants of any alarm that affects building safety.

Occupant Emergency Alarm Mode. When one of the panic buttons in each of the laboratories is activated, all lights for that suite are switched on, and a critical alarm goes to the BAS. The ventilation system remains operating in steady-state mode.

Breathing Air Alarm Mode. Failure of the breathing air system sends a critical alarm to the BAS. Failure of the backup breathing air system sends a critical alarm to the BAS.

Chemical Shower Alarm Mode. Low levels of chemical shower solution prompts a critical alarm to the BAS.

Door Override Alarm Mode. When either of the door override panic buttons is activated, the hard-wired magnetic door lock is released, and a critical alarm is sent to the BAS.

Biohazard Alarm Mode. The system has two levels of alarm function. The first occurs when a Control Cell pressure is ± 0.06 -inch water gage (wg) from a set point (operator adjustable). An alarm is initiated as described in Emergency Mode (above). The second level of alarm function occurs when the Control Cell static pressure is ± 0.1 -inch wg from a set point (operator adjustable), thereby approaching a positive pressure when referenced to adjacent Control Cells.

All bioseal dampers associated with the room or space close, and a critical alarm is sent to the BAS.

Decon Mode. BAS originated with a dedicated sequence during a room decontamination process.

A.2.5 Backup Systems

Redundant, critical systems are incorporated in the utility and building infrastructure to facilitate safe operations. As a backup to the electrical utility, the facility is equipped with an on-site diesel generator that is capable of providing 48 hours of uninterruptable power to prioritized loads. In addition, an uninterruptible power supply is available to selected prioritized loads. Additionally, three emergency power generators are connected in parallel to supply emergency power (BUMC 2009). Two independent heating mediums are available—district steam service and a natural-gas-fired heating plant. In addition, the water service has two independent utility connections. A networked electrical service provides four separate incoming feeds installed such that if any one feed is disrupted, the remaining two will provide the necessary service (BUMC 2009).

A.3 Safety Equipment (Primary Barriers)

A.3.1 BSL-2

The BSL-2 areas of the NEIDL will be suitable for work involving pathogens of moderate potential hazard to personnel and the environment. Laboratory personnel have specific training in handling pathogenic agents and are supervised by competent researchers. In addition, access to the laboratory is limited when work is being conducted, and personnel take extreme precautions with contaminated sharp items. Processes in which infectious aerosols or splashes can be created are conducted only in biological safety cabinets (BSCs) or other physical biocontainment equipment.

Guidance provided in *Safety Equipment* (Primary Barriers and personnel protective equipment [PPE]) specifies the following (BUMC 2009b, Appendix E):

- Properly maintained BSCs (preferably Class II), appropriate PPE, or other physical biocontainment devices must be used when dealing with high concentrations or large

volumes of infectious pathogens or when conducting procedures with the potential of creating infectious aerosols or splashes.

- Protective laboratory coats, gowns, smocks, or uniforms designated for laboratory use must be worn when working with hazardous materials (HazMat).
- Eye and face protection is used for anticipated splashes, or sprays of infectious or other HazMat when the microorganisms must be handled outside the BSC or biocontainment device.
- Gloves must be worn to protect hands from exposure to HazMat.

A.3.2 BSL-3

The areas of the NEIDL that have been designed and designated as BSL-3 are those areas where work will be conducted with dangerous and exotic pathogens that pose a potential risk for respiratory transmission and that can cause serious and potentially lethal infection.

At BSL-3, more emphasis is placed on primary and secondary barriers to protect personnel in contiguous areas, the community, and the environment from exposure to potentially infectious aerosols. For example, all activities will be confined to Class III BSCs or Class II BSCs, and the use of positive air-purifying respirators (PAPRs) will also be required. Secondary barriers for this level will include strictly controlled access to the laboratory and ventilation requirements that minimize the release of infectious aerosols from the laboratory.

Guidance provided in *Safety Equipment* (Primary Barriers and PPE) specifies the following (BUMC 2009b, Appendix F):

- All procedures involving the manipulation of infectious materials must be conducted within a BSC (preferably Class II or Class III) or other physical biocontainment device.
- Protective laboratory clothing with a solid front, such as tie-back or wrap-around gowns, scrub suits, coveralls, and PAPRs are worn in the laboratory.
- Gloves must be worn to protect hands from exposure to HazMat.

A.3.3 BSL-4

BSL-4 is required for work with dangerous and exotic pathogens that pose a high individual risk of aerosol-transmitted laboratory infections and life-threatening disease. Pathogens with a close

1 or identical antigenic relationship to BSL-4 pathogens are also handled at this level until
2 sufficient data are obtained either to confirm continued work at this level or to verify working
3 with them at a lower level can be conducted safely without undue risk. Members of the
4 laboratory staff have specific and thorough training in handling extremely hazardous infectious
5 pathogens, and they understand the primary and secondary biocontainment functions of the
6 standard and special practices, the biocontainment equipment, and the laboratory design
7 characteristics. They are supervised by competent researchers who are trained and experienced in
8 working with those pathogens. Access to the BSL-4 laboratories is strictly controlled by the
9 laboratory director. The BSL-4 facilities are in a controlled area, which is completely isolated
10 from all other areas of the building. A specific facility operations manual will govern the
11 operations of the spaces.

12
13 Within BSL-4 work areas, all activities are confined to Class III BSCs or Class II BSCs and all
14 activities are performed with one-piece, positive-pressure, personnel suits equipped with a life
15 support system (e.g., an escape bottle air apparatus). Air is supplied to the suits from an exterior
16 source and is not recirculated. The BSL-4 laboratory has special engineering and design features
17 to prevent microorganisms from being disseminated into the environment.

18 Guidance provided in *Safety Equipment* (Primary Barriers and PPE)—Suit Laboratory specifies
19 the following (BUMC 2009b):

- 20 • All procedures must be conducted by personnel wearing a one-piece, positive-pressure
21 suit ventilated with a life support system.
- 22 • All manipulations of infectious pathogens must be performed within a Class III BSC or
23 other primary barrier system.
- 24 • Equipment that can produce aerosols must be contained in devices that exhaust air
25 through a HEPA filtration system before being discharged into the environment.
- 26 • Protective laboratory clothing such as a scrub suit must be worn by workers before
27 entering the room used for donning positive pressure suits. All protective clothing must
28 be removed in the *dirty* side change room before entering the personal shower. Reusable
29 laboratory clothing must be processed in an autoclave before being laundered.
- 30 • Inner gloves must be worn to protect against break or tears in the outer suit gloves.

A.3.4 Biosafety Cabinets

Primary barriers include BSCs (or other biocontainment systems used for open handling of pathogens) and full-body, air-supplied, positive-pressure suits. The type of BSC used depends on the pathogens being handled. In general, the BMBL (CDC and NIH 2007) recommends Class I or II BSCs for BSL-2 and BSL-3 areas, and Class III BSCs (or Class I or II BSCs with positive-pressure suits) for BSL-4 areas. The NEIDL Final Environmental Impact Statement (FEIS) (NIH and DHHS 2005) reports anticipated use of Class III BSCs for the BSL-4 laboratory. Class III BSC within processing rooms for diagnostic samples; the FEIS (NIH and DHHS 2005) also reports anticipated use of Class II Type A2 BSC and/or Class II Type B1 BSCs in the BSL-4 laboratories and necropsy room in conjunction with required use of positive-pressure suits. Diagrams and brief descriptions of the above described BSCs follow in Figures A-1, A-2, and A-3 (CDC and NIH 2007).

Figure A-1. Class III BSC.

Cabinet air exits through an exhaust HEPA filter (C) into a facility airtight ducted negative pressure exhaust. Exhaust air from the cabinet is drawn through a final set of inline HEPA filters before discharge to the outdoors. A redundant (parallel) exhaust air system is available to accommodate servicing the units. An additional chemical dunk tank can also be installed, which would be beneath the work surface of the BSC with access from above.

Notes:

A. glove ports with O-ring for attaching arm-length gloves to cabinet

B. sash

C. exhaust HEPA filter

D. supply HEPA filter

E. double-ended autoclave or pass-through box

Figure A-2. Class II, type B2 BSC airflow patterns.

As shown in Figure A-2, HEPA-filtered exhaust air flows from the top to the work surface. A portion exits from the rear grill. A portion of the down-flow air is pulled into the front grill along with room air to prevent room contaminants from entering the work space. The air from the rear and front grills passes through the supply and exhaust filters preventing airborne contaminants from entering the room or the cabinet work area.

Figure A-3. Class II BSCs do not provide total barrier containment.

Note: An RA could require additional PPE to prevent aerosol exposure. Examples in BSL-3 labs include pathogens with low inhalation infectious doses (*Francisella tularensis* and *Coxiella burnetii*). One option is the PAPR.

A.4 Laboratory Practice and Technique

A.4.1 BUMC Biosafety Manual

The purpose of the BUMC *Biosafety Manual* (BUMC 2008) is to define and communicate the biological safety policies and procedures pertaining to research operations at BU and Boston Medical Center. The manual provides policies and procedures that are designed to safeguard personnel and the environment from biologically hazardous materials and to comply with federal, state, and local regulatory requirements. All BU and BUMC developed policies for principal investigators (PIs) and laboratory workers must adhere to the biological safety policies and procedures as they conduct their research and manage laboratories. For programs or operations not covered in the manual, the manual requires that PIs contact the Institutional Biosafety Committee (IBC) office or the biosafety officer to begin developing suitable programs before initiating their projects.

Descriptions of BSLs and assigned BSLs for specific organisms are in the CDC/NIH document, *Biosafety in Microbiological and Biomedical Laboratories* (BMBL), 5th ed. The BMBL outlines four BSLs, summarized in Table A-1 below.

Table A-1. Biocontainment elements for each BSL

BSL	Pathogens	Practices	Safety equipment	Facilities
1	Not known to cause disease in healthy adults; RG1	Standard microbiological practices	None required	Open bench-top, sink required
2	Associated with human disease, which is rarely serious and for which preventive or therapeutic interventions are often available; RG2	BSL-1 practice plus: - Limited access - Biohazard warning signs - Sharps precautions - Biosafety manual	Primary barriers: Class I or II BSCs or other containment used for manipulating pathogens that cause splashes or aerosols of infectious materials. PPE: lab coats; gloves; eye/face protection as needed.	BSL-1 plus: Autoclave available
3	Associated with human disease for which preventive or therapeutic interventions might be available; RG3	BSL-2 practice plus: - Controlled access - Decontamination of all waste - Decontamination of lab clothing before laundering - Baseline serum	Primary barriers: Class I or II BSCs or other physical containment devices used for all manipulations of pathogens. PPE: protective lab clothing; gloves; respiratory protection as needed.	BSL-2 plus: - Physical separation from access corridors - Self-closing, double-door access - Exhausted air not recirculated - Negative airflow into laboratory
4	Pathogens are likely to cause serious or lethal human diseases for which preventive or therapeutic interventions are not usually available; RG4	BSL-3 practices plus: - Clothing change before entering - Shower on exit - All material decontaminated on exit from facility	Primary barriers: All procedures conducted in Class III BSCs or Class I or Class II BSCs in combination with full-body, air-supplied, positive-pressure personnel protective suit.	SL-3 plus: - Separate building or isolated zone - Dedicated supply/exhaust, vacuum, and decontamination systems - Other requirements outlined in BMBL

Note: For a more complete description of the four BSLs and for recommended specific organisms, see the BMBL.

A.4.2 Procedures (SOPs)

BUMC has a system in place to evaluate risk and determine which types of research projects will be performed at the various BSLs. BUMC safeguards personnel and the environment from

1 biologically hazardous materials through the use of an internal biological RA process and IBC.
2 As required by NIH when conducting biological research with recombinant DNA (rDNA) and
3 receiving federal grant money to comply with the rDNA guidelines, BU has maintained an active
4 IBC for several decades. NIH guidelines are quite prescriptive for IBCs and require that they
5 ensure that all proposed research projects are in compliance with NIH and CDC guidelines (and
6 other guidelines). After the projects are initiated, the IBC must also ensure that the work is being
7 done safely so that the laboratory worker and the public are safe.

8
9 During and following approval from the IBC, NEIDL personnel develop SOPs outlining the
10 appropriate safety equipment that will be required during the research, as well as the appropriate
11 research equipment, the appropriate safety processes and procedures, and the appropriate BSL.
12 During the internal biological RA process, the reviewers (including biosafety and the IBC) can
13 modify the level of containment required for a pathogen. During the biological RA, many aspects
14 of the experiment protocols are evaluated to determine which (if any) of the procedures could
15 cause an aerosol, the mode of entry, transmission and exposure of the required experimental
16 pathogen, PPE requirements, and required equipment (e.g., type and use of BSC). When the IBC
17 is presented with a request for a change in use of a new pathogen, the IBC reviews the project
18 again. Additional requirements are followed depending on containment and the type of work
19 being performed.

20 21 **A.4.3 Training**

22 The purpose of the Laboratory Training Program for the NEIDL is to promote excellence in
23 conducting safe practices; to keep the laboratory and equipment in a safe operating order; to
24 maintain compliance with institutional policies and local, state, and federal regulations and
25 guidelines; and to reinforce awareness that laboratory safety protects the research, support
26 personnel, and the environment from potential hazards associated with level 4 research.

27
28 The NEIDL Biosafety Training Plan presents a strategy for developing a comprehensive training
29 program for the scientists, technicians, and guest scientists at BU who are authorized to conduct
30 research in the NEIDL; the operations and maintenance employees of BU who manage the
31 NEIDL's containment and engineering systems; and other groups of BU such as employees,

1 visitors, vendors, and service personnel who work in support of the NEIDL. In addition, the plan
2 includes training for members of the Boston community whose roles and interests support the
3 NEIDL mission.

4
5 The plan recommends six training tracks: (1) Orientation; (2) Operations and Maintenance; (3)
6 IBC and Institutional Animal Care and Use Committees (IACUC); (4) Science Program; (5)
7 NEIDL First Responders, and (6) Public Sector First Responders. For each track, the plan
8 includes recommended courses, learning objectives, and suggested content. The plan requires
9 that participants demonstrate that they have met the learning objectives of each course within
10 their training track. In addition, participants in the Science Program track are required to pass a
11 hands-on protocol proficiency examination (BUMC 2009b).

12
13 Table A-2 provides the NEIDL training matrix.

1

Table A-2. BUMC NEIDL training matrix

Course no.	Course title	Intended participants
1	General Orientation	Track 1: Administrative; visitors; vendors; service personnel; community members Track 2: Operations and Maintenance Track 3: IBC and IACUC Track 5: NEIDL Emergency Response Team Track 6: Public Safety Emergency Responders
2	Introduction to Microbiology and the Control of Infectious Diseases	Track 2: Operations and Maintenance
3	Fundamentals of Secondary Barrier Containment	Track 2: Operations and Maintenance Track 5: NEIDL Emergency Response Team Track 6: Public Safety Emergency Responders
4	Verification and Certification of Secondary Barriers	Track 2: Operations and Maintenance
5	Incident Response for Non-laboratory NEIDL Personnel	Track 2: Operations and Maintenance
6	NEIDL Emergency Response Team Incident Response Procedures	Track 2: Operations and Maintenance Track 4: Science Program Track 5: NEIDL Emergency Response Team Track 6: Public Safety Emergency Responders
7	Emergency Response Preparedness	Track 2: Operations and Maintenance Track 4: Science Program Track 5: NEIDL Emergency Response Team Track 6: Public Safety Emergency Responders
8	Comprehensive Review of BSL-4 Containment	Track 3: IBC and IACUC
9	Compliance Issues - Select Agent Rule, NIH Recombinant DNA Guidelines and BPHC Biological Laboratory Regulation	Track 3: IBC and IACUC
10	Independent Assessment of Risks	Track 3: IBC and IACUC
11	Biosafety and Biosecurity in the Conduct of Exemplary Research	Track 4: Science Program
12	Assessing Risks of NEIDL Research Protocols	Track 4: Science Program
13	Preparation of Research Protocols to Obtain Approval to Conduct Research Project in the NEIDL	Track 4: Science Program
14	Maintaining Compliance with the Select Agent Rule, NIH Guidelines, and the BPHC Biological Laboratory Regulation	Track 4: Science Program
15	Comprehensive Review of BSL-4 Safeguards and Research Practicum	Track 4: Science Program
16	First Aid, CPR and Automated External Defibrillator (AED)	Track 4: Science Program
17	Planning Emergency Response Drills	Track 5: NEIDL Emergency Response Team

2 Note: From BUMC 2009b, program under development..

A.4.4 Access Control

A combination of security systems and staffing reinforce the layers of access control at the NEIDL. Access to the BSL-3 and BSL-4 labs is restricted to workers who have received appropriate immunization and security clearances for the pathogens in use at the labs. Access to different areas or layers within the facility can require positive identification and signing in with a security officer (i.e., a public safety officer), using access control systems such as biometrics or proximity card technologies, requesting access via escort by an authorized colleague, or a combination of those approaches. Work being performed within high-level biocontainment areas will be monitored by systems to ensure that at least two authorized persons are in each area at all times to ensure safety and minimize risk of an individual initiating a malevolent or unauthorized act. Figure A-4 shows the secure perimeter, access-control points, and a few representative locations of security cameras for the NEIDL. Similar provisions would be used for the other candidate locations (NIH and DHHS 2005). Note that the specifics of the NEIDL security systems are considered restricted distribution security information, the disclosure of which could present an increased risk to the facility and its occupants and thereby potentially endanger the operations of the facility. Therefore, in accordance with guidance provided in the Bioterrorism Act of 2002, the details of the NEIDL security systems and the specifics of the Threat Assessment (TA) performed to evaluate the systems are not included in this document, nor will they be disclosed during public meetings or briefings for non-cleared individuals. However, detailed findings of that evaluation are included in the TA.

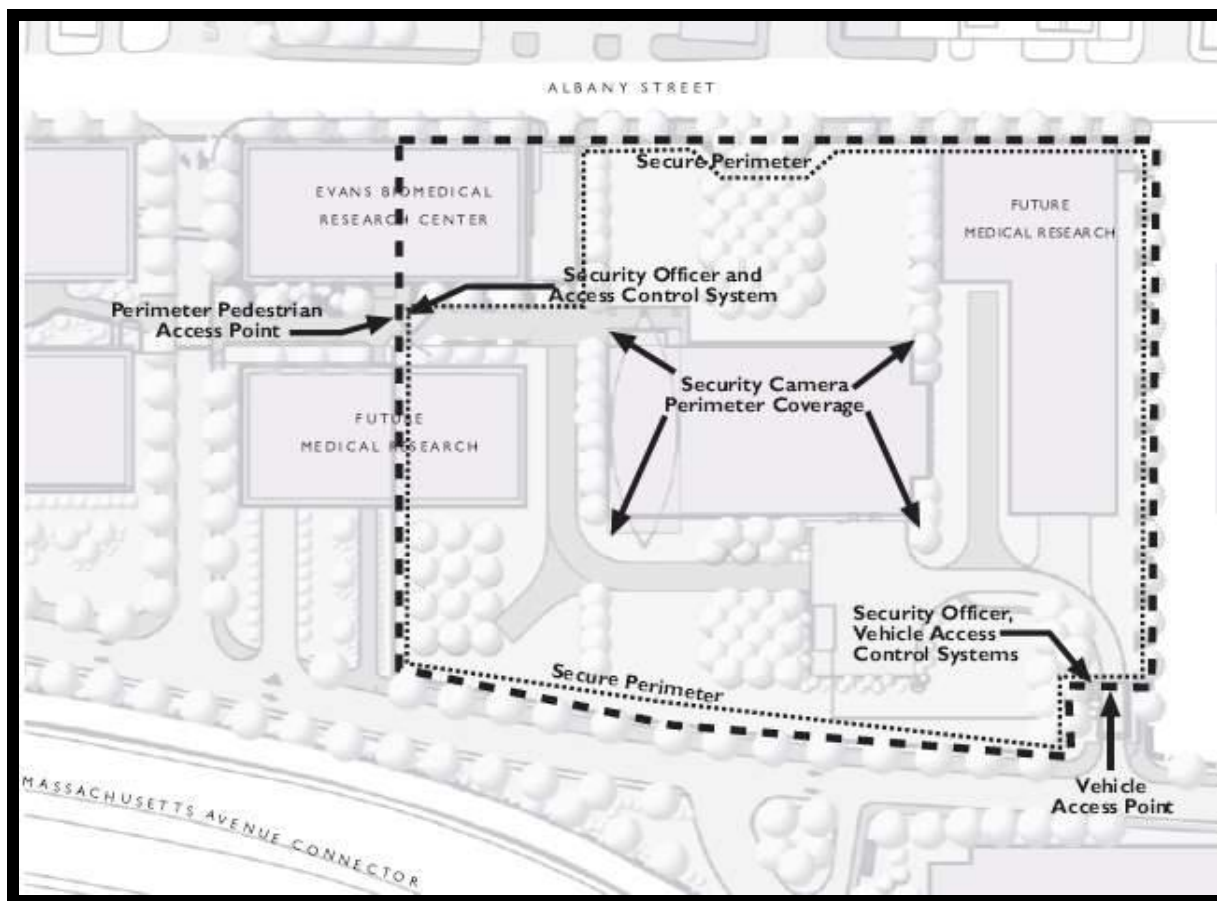

Figure A-4. Representative NEIDL security feature locations.

A.4.5 Disease Surveillance Plan

The Boston Public Health Commission's (BPHC's) *Guidelines for the Implementation and Enforcement of Boston Public Health Commission's Disease Surveillance and Reporting Regulation* requires laboratory registration and the implementation and maintenance of a medical surveillance program for research laboratories working with select agents and other high-risk pathogens that require containment in BSL3 and BSL-4 facilities. The BPHC compliance guidelines specify practices for ensuring that the BPHC receives timely access to information regarding incidence of disease syndromes, any outbreak or cluster of a disease, and potential exposures to reportable diseases deemed harmful to the public health. The BUMC Disease Surveillance Plan sets forth the roles and responsibilities of researchers and compliance staff at BU and Boston Medical Center (BMC), as mandated by the BPHC Disease Surveillance and Reporting Regulation.

1
2 The Disease Surveillance Plan is an integral component of the BU and BMC's select agent
3 research and occupational health and safety programs. The purpose of the plan is to prevent
4 laboratory-acquired infections associated with the receipt, storage, handling, and disposal of
5 select agents and high-risk pathogens in BSL-4 laboratory environments and to protect workers
6 outside the BSL-4 laboratory containment, the environment, and the public health from exposure
7 to those agents. The NEIDL plan includes policies and provisions for identifying at-risk
8 individuals, maintaining vigilance for the recognition of potential exposures, identifying
9 potentially exposed individuals and providing a quick and appropriate medical response to an
10 accidental exposure or to symptoms suggestive of a laboratory-acquired infection. The plan also
11 provides the direction, approaches, and responsibilities for maintaining compliance with the
12 BPHC's *Disease Surveillance and Reporting Regulation*; the federal government's *Final Rule on*
13 *the Possession, Use, and Transfer of Select Agents and Toxins* (Select Agent Rule); and the
14 NIH's *Guidelines for Research Involving Recombinant DNA Molecules* (NIH Guidelines).

15
16 The NEIDL has implemented a written biosafety plan that is commensurate with the risk of
17 possessing, using and transferring a select agent. In developing the plan, NEIDL considered (1)
18 the principles of biosafety and guidance described in the CDC, and NIH publication BMBL, 5th
19 ed., including all appendices; and (2) the NIH Guidelines. The BMBL guidance on occupational
20 health (BMBL Section VII) serves as the foundation for the comprehensive health and safety
21 management program that will enable the NEIDL to operate as a safe and healthy workplace.
22 The BMBL emphasizes that prevention is the most effective strategy for maintaining
23 occupational health and that prevention is achievable in a biomedical research setting where the
24 occupational health and safety programs are broadly shared responsibilities involving every
25 group and individual associated with the conduct and support of the research program.

26
27 At BU and BMC, those groups include the Office of the Associate Vice President Research
28 Compliance; the Office of Environmental Health and Safety (OEHS); the Research Occupational
29 Health Program; the BMC Emergency Care programs; Public Safety; IBC; and the IACUC. The
30 PIs, researchers and support staffs who work in the NEIDL all have primary roles in
31 implementing the Disease Surveillance and Biosafety Plans.

The NEIDL will also establish and maintain a health surveillance program for personnel engaged in animal research involving viable rDNA-containing microorganisms that require BSL-4 containment in the laboratory. The overall program includes a system for reporting laboratory accidents, exposures, employee absenteeism, and for the medical surveillance of potential laboratory-associated illnesses. The NEIDL requires researchers to immediately report spills and accidents that result in overt exposures to organisms containing rDNA molecules to the Biological Safety Officer, IBC, and to the NIH Office of Biotechnology Assessment.

The disease surveillance program also takes into consideration the potential hazards to which employees can be exposed and that have the potential to cause adverse health consequences. The surveillance program evaluates the work processes, tasks performed by individuals, the hazardous pathogens in use, and the potential exposure that can occur in handling the pathogens. The outcome of such risk and hazard assessments will determine the overall needs of the individuals with potential for exposure.

A.5 Waste Management

Waste management practices at the NEIDL are laboratory-specific and dependent on the wastestreams generated by individual BSL-2, BSL-3, and BSL-4 laboratory activities. In general, disposal of waste is particular to the organisms or SOPs of the research group, but, in general, the following principles apply:

- Rigid containers labeled with the universal biohazard symbol and lined with red biohazard bags are provided in every clinical and research laboratory at NEIDL for all biohazard waste.
- Sharp containers are also provided for the safe disposal of needles, syringes, and scalpel blades.

Solid waste includes all nonhazardous waste generated from offices and maintenance areas, including recyclable materials. In addition to normal solid waste, it is anticipated that the NEIDL will generate three types of special waste: biological and non-biological waste, radioactive waste, and hazardous-chemical waste. NEIDL operations will not generate mixed waste (a U.S. Environmental Protection Agency-defined term denoting wastes that are both radioactive and

hazardous). The use, storage, and disposal of all solid and special waste will be performed in accordance with state and local regulations.

A.5.1 Biologic Waste

Biological waste will be disposed of in strict compliance with the Massachusetts's Department of Public Health State Sanitary Code Title VIII (105 CMR 480.00), the Massachusetts Solid Waste regulations (310 CMR 19.000) and Section 2.01 of the BPHC Regulation titled *Waste Container Lot, Junk Yard, and Recycling Facilities*.

Solids Handling. No waste materials will be removed from the BSL-3 or BSL-4 laboratories without first being processed in an autoclave or decontaminated by a method approved and managed by the BU's OEHS. Several materials require special decontamination methods to assure safe removal from the BSL-3 and BSL-4 laboratories. BSL-3 and BSL-4 laboratories use a disinfectant that is particular to each pathogen used as outlined in the research-specific SOPs and an autoclave to further decontaminate solid biological and non-biological waste. The BSL-2 laboratories will use the conventional system of bagging biohazardous waste and shipping the material off-site for incineration using a licensed, third-party contractor.

Liquid Effluents. The proposed system will include a multi-sterilization system for BSL-3 and BSL-4 facilities, tissue digesters outside containment for animal carcasses after sterilization, and a dedicated liquid effluent decontamination system for BSL-4. All liquid waste from the BSL-4 laboratories will first be decontaminated with a chemical disinfectant and then be piped to a biowaste processor and heated under pressure until the temperature reaches 121° C (249.8 °F) for at least 60 minutes to ensure that two decontamination processes are completed.

Decontamination will be verified by using biological indicators and electronic monitoring and charting of the process verified to meet acceptable discharge limits levels. The liquid waste treated liquid waste effluent will be discharged to the Boston Water and Sewer Commission sanitary sewer system. Ventilation from plumbing systems will pass through a HEPA filter before discharge to the atmosphere. The filters will be decontaminated and disposed of as appropriate (NIH and DHHS 2005).

1 The NEIDL operates in accordance with all plumbing codes and Massachusetts Water Resources
2 Authority regulations requiring that sinks in laboratories drain to a pH adjustment system, where
3 pH adjustment and verification, flow monitoring, and water sampling take place. The NEIDL has
4 a plumbing system that will carry laboratory wastewater from every non-BSL-4 area to mixing
5 tanks in the basement where pH adjustment and compliance sampling occur (NIH and DHHS
6 2005).

7
8 The sterilization system for the BSL-3 and BSL-4 laboratories will include 5 large autoclaves
9 and 11 medium autoclaves. Animal carcass materials will be placed on rack sterilizers for easy
10 introduction or removal of large materials, while smaller autoclave models will be used for
11 general laboratory waste. Once waste material has been processed in the autoclave in
12 biodegradable bags and removed from the BSL-3 and BSL-4 contained space, all animal carcass
13 waste will be placed in the tissue digestion system and undergo alkaline hydrolysis for final
14 processing and disposal (mineral oil could be added to the tissue digester to aid in removal of the
15 autoclave bags following processing. Following completion of laboratory work in the BSL-3
16 facilities, workspace areas would be disinfected using a newly prepared 1:10 bleach solution or
17 other appropriate pathogen-specific disinfectant.

18 19 **A.5.2 Radioactive Waste**

20 Radioactive waste generated at the NEIDL will consist primarily of solid waste such as paper,
21 plastic and glass contaminated with trace amounts of radioactive isotopes (radioisotopes). Such
22 wastes will be limited to those materials that meet the definition of low-level radioactive waste
23 (LLRW) as defined by the Nuclear Regulatory Commission and codified in Title 10 of the *Code*
24 *of Federal Regulations* (CFR) Part 20. BUMC's Radioisotope Committee oversees the disposal
25 and management of LLRW. Researchers typically place LLRW in labeled, special containers at
26 the point of generation, and contact the BUMC's Radiation Protection Office (RPO) when the
27 special container is filled. An RPO representative then removes the waste, obtains an inventory
28 of the materials placed in the container (and their suspected level of activity and contamination,
29 both surface and volumetric), and manifests and transports the container to a licensed radioactive
30 waste storage facility for storage and handling. The RPO maintains all records associated with
31 LLRW, beginning from waste collection to final disposition. The radioisotopes that are

anticipated to be used at the NEIDL consist of both long-lived and short-lived radioisotopes. Long-lived radioisotopes require disposal off-site at a licensed LLRW-disposal facility. Waste contaminated with short-lived radioisotopes would be held on-site in BUMC's decay-in-storage facility for periods ranging anywhere from one week to not more than 2 years and 9 months, depending on the radioisotope's half-life, to allow sufficient decay and subsequently disposed of as nonradioactive sanitary waste.

A.5.3 Hazardous Waste

The generation of hazardous-chemical waste (as defined by the 40 CFR Part 261) at the entire NEIDL has been estimated on the basis of biological laboratories in comparable-sized facilities at BUMC. EPA has delegated Massachusetts to implement most aspects of hazardous waste regulation in Massachusetts and regulations regarding the generation of hazardous waste apply in lieu of federal regulations. Typical wastestreams anticipated at the NEIDL include the following:

- Flammable liquids
- Flammable, toxic liquids
- Corrosive liquids
- Oxidizing liquids
- Ethidium bromide solids
- Liquid effluents

A.6 Facility Support for BSL-2, -3, and -4 Areas

Decontamination (Equipment Wash Room). An equipment wash room will be provided for various pieces of equipment including socialization penning, animal caging systems and other reusable animal supplies. Typically, such equipment is capable of washing material in 82 °C (180 °F) water as recommended in the National Research Council guide and supported with redundant, instantaneous water heaters and will include the following:

- Bulk pass-through type equipment and cage washing systems;
- Gross wash for initial spray-down and acid soak of equipment, animal racks, caging, and penning;
- Staging for dirty and clean cages;

- Equipment zones and dedicated space for placing washing equipment (equipped with floor pits and overhead clearance for utility services); and
- Detergent storage, directly adjacent to the equipment zones to stage and pump chemical detergents to the washing equipment.

Dunk tanks. A barrier-designed dunk tank allows for the passage of materials that are heat sensitive or capable of being decontaminated using a liquid disinfectant or virucide across the biocontainment barrier. The types of disinfectants (e.g., phenolics, glutaraldehydes, quaternary ammonium compounds, hydrogen peroxide, alcohols, proteinated iodines, sodium hypochlorite) vary according to the types of infectious pathogens and their characteristics, such as corrosiveness, viability over time, and concentrations in use. Biosafety protocols (and SOPs) determine which disinfectant is used, when it is replenished, and what concentrations are required. Dunk tanks will be provided at all necropsy rooms in the NEIDL.

Autoclaves. Materials taken from primary biocontainment zones must be decontaminated. Those include waste (e.g., disposable PPE, paper goods, medical supplies); mobile and shared equipment; isolators, cages, racks, and penning; clinical waste; and samples (e.g., pathologic waste). For most materials, decontamination can be achieved via a steam autoclave. For certain sensitive items, however, alternate methods of decontamination (e.g., vaporized hydrogen peroxide [VHP], chlorine dioxide, paraformaldehyde burn) are available. Double-door autoclaves at the biocontainment barrier envelope allow material to be passed from the contaminated (i.e., *dirty*) side to the uncontaminated (i.e., *clean*) side with a full sterilization cycle. Interlocking doors also prevent both doors from being opened simultaneously. The double-door barrier autoclave has two types of barrier seals. It is recommended that the tight seal be pressure capable to at least 500 Pascal (Pa) (2-inch wg) of static pressure, have a flange that is bolted with a flexible neoprene (or silicone) seal, and have a receiving flange that is cast into the wall cavity. The location of the flange seal with respect to the autoclave body is important to consider in terms of maintenance requirements. Some autoclaves have close to 30 valves, numerous filters, and high-maintenance door seals. Such a combination requires that maintenance be both preventative and corrective. The autoclave body should be on the clean side of the biocontainment barrier, with the chamber condensate hard-piped directly to the waste

1 treatment system. Autoclaves are required inside the biocontainment zones of the necropsy
2 rooms (i.e., within primary containment areas) and along the secondary biocontainment corridor
3 leading to the zones outside the biocontainment area. For each zone within the facility, NEIDL is
4 considering two autoclaves for redundancy and is considering three sets of redundant bulk
5 autoclaves serving the BSL-3 animal facility including three medium-sized autoclaves to serve
6 smaller loads, when needed.

7
8 **Gas Decontamination.** Gas decontamination will be considered for large pieces of equipment
9 (e.g., penning, BSCs, carts) because gases pass between barriers of biocontainment. Both VHP
10 and paraformaldehyde gases are effective for such an application, which is dependent on room
11 size. A paraformaldehyde gas-generating machine capable of decontaminating large room spaces
12 might also be used. Such equipment also incorporates gas neutralization (using ammonium
13 carbonate) as part of the sterilization cycle. The humidity level and temperature are important for
14 effective sterilization (70 percent relative humidity and 20 °C [68 °F]). The decontamination
15 rooms are designed to be airtight via the use of bioseal dampers on the ventilation ducts, leak-
16 tight barrier doors with specialized seals, and leak-tight service penetrations. Fans, which are
17 used to circulate the gas within the room, can either be permanently mounted or portable. The
18 rooms can also be used for transferring materials and animals into the facility and will require
19 interlocking doors, penning, and door windows. Animal air locks are designed to accommodate
20 gaseous decontamination of equipment. The VHP process is an alternative for room
21 decontamination in the facility. Infrastructure will be required to be in place to support VHP
22 equipment, including supply and exhaust ports into the room, circulating fans, vaporizer
23 equipment, and dehumidification equipment. Because the infrastructure is provided in the NEIDL
24 facility, it is intended to use certain rooms or airlocks as a means to decontaminate large pieces
25 of equipment periodically.

26
27 **Decontamination Waste Treatment.** Solid waste and liquid effluent decontamination is
28 required of all materials infected with pathogens, including animal carcasses. For any waste
29 disposal technology, NEIDL must consider the following design criteria (according to the
30 biological RA and level of biocontainment):

- Ease of transport and loading into treatment equipment;

- Worker protection and reduction of biohazard aerosol generation;
- Decontamination effectiveness of given technologies;
- Consistent, repeatable, and verifiable performance;
- Volume reduction for final disposal;
- Compliance with local, state, and federal environmental requirements;
- Cost-effectiveness (capital and operating);
- Technical maturity and degree of automation to achieve effective labor savings; and
- Reliability and maintainability.

Several decontamination and sterilization technologies were initially reviewed and will be studied further including chemical, incineration, rendering, autoclave, and alkaline digestion.

B. Site Characteristics

Much of the site characterization information presented in this appendix, such as site location information, utilities descriptions, transportation access, and health care infrastructure was taken from the *Draft Supplementary Risk Assessment and Site Suitability Analyses* (DSRASSA) prepared by National Institutes of Health's (NIH's) Division of Occupational Health and Safety in July 2007 (NIH 2007). The data were augmented by site visits and additional research and data-gathering activities.

B.1 BUMC BioSquare Research Park—Urban Setting

B.1.1 Location

The National Emerging Infectious Diseases Laboratories (NEIDL) site is in the southeast portion of the South End in Boston, within Suffolk County. The South End is a densely developed residential area bordered by institutional and industrial areas south of Harrison Avenue. Commercial activity in the South End is concentrated along Columbus Avenue, Tremont Street, and Washington Street and includes numerous restaurants, while the medical and research uses are concentrated along Albany Street and Harrison Avenue. The institutional and industrial uses south of Harrison Avenue include the Boston University Medical Center (BUMC), the BioSquare, the Boston Flower Exchange facility on Albany Street, and the Suffolk County House of Correction.

B.1.2 Livestock and Animals

According to the Massachusetts State and County Data-2002 Census of Agriculture Suffolk County, in which Boston is located, has no livestock animals in the county inventory. Wildlife in the area would be typical of those adapted to city environments (i.e., mice, rats, feral cats and dogs, and various avian species).

B.1.3 Utilities

Natural gas is provided and purchased from KeySpan Energy. The NEIDL is designed to use either district steam or natural gas as the primary heating medium. Gas service is provided by a natural gas service connection from Albany Street. The NEIDL is capable of using district steam as its heating medium. NStar Electric provides electric service. An existing Boston Water and

1 Sewer Commission (BWSC) water main, in Albany Street, provides water service, and a BWSC
2 sanitary sewer line in Albany Street provides sanitary sewer service to the NEIDL. Stormwater
3 runoff from the site discharges into the existing BWSC system entering the Roxbury Canal
4 Conduit, which runs through the site and flows easterly toward an outfall in the Fort Point
5 Channel, a coastal waterbody approximately 0.9 mile from the site.

B.1.4 Transportation and Access

8 Boston is New England's leading port; a regional rail, bus, and truck terminal center; and an
9 important air transport center. Boston is a hub from which many highways extend to serve the
10 cities to the north, west, and south. Route 128 is a highway that circles Boston . The Central
11 Artery provides access to the downtown area, and the Southeast Expressway extends to the
12 South Shore area. The Massachusetts Turnpike (i.e., Interstate [I]-90) crosses Route 128 in
13 Weston and terminates in West Stockbridge, with an extension to the New York Thruway.
14 Amtrak provides passenger service to New York City and Washington, D.C. Massachusetts Bay
15 Transportation Authority (MBTA) subway service is available. Conrail and the Springfield
16 Terminal Railway offer freight service to Boston. Conrail has an intermodal facility in Allston
17 and a Flexi-Flo terminal in Boston. Boston is a member of the MBTA, which provides fixed
18 route bus service in the city and to surrounding towns. The MBTA also provides THE RIDE, a
19 paratransit service for the elderly and disabled. Logan International Airport, easily accessible
20 from downtown Boston, is the busiest Primary Commercial Service facility in New England.
21 Also, Hanscom Field in Bedford, Massachusetts, and Norwood Memorial Airport provide
22 commercial service. The Nashua Street Heliport is near North Station. MBTA commuter boat
23 service is available to Charlestown and Hingham.

B.1.5 Healthcare and Emergency Response

26 Within Boston's city limits are 22 hospitals and 35 colleges and universities. Many are in the
27 immediate area surrounding the NEIDL site. Boston Metropolitan Medical Response System
28 (MMRS) has a sophisticated, cooperative, multiagency emergency response system. The Boston
29 MMRS develops and exercises plans to mitigate the medical consequences of a weapon of mass
30 destruction (WMD) event by creating a highly trained, readily deployable, fully equipped
31 response system of medical, law enforcement, fire service, and other professionals to support

1 local resources. Those resources and plans will be used to respond to any major medical incident
2 affecting large numbers of people. Boston University works with the Boston Public Health
3 Commission (BPHC) on emergency planning related to the NEIDL. Those efforts include
4 training responders as well as drills and exercises. Additionally many activities are underway as
5 part of the Boston MMRS and include the following:

- 6 • An interagency management team has been established, including officials from the
7 BPHC, the BPHC Communicable Disease Control Bureau (CDCB), Boston Police and
8 Fire Departments, Boston EMS, Boston Emergency Management Agency, U.S.
9 Department of Veterans Affairs, Massachusetts Port Police and Fire Departments, the
10 MBTA Police, the Conference of Boston Teaching Hospitals, representatives of metro-
11 Boston's community and neighborhood health centers, and numerous academic
12 institutions.
- 13 • Cooperative partnerships are in place with many of Boston University's schools of
14 pharmacy, public health, and medicine.
- 15 • Advanced personnel protective equipment is in place for response personnel. The
16 personnel protective equipment allows responders to remain safe during a response to a
17 WMD event.
- 18 • Boston's local pharmaceutical cache is in place, ready for deployment in response to an
19 act of terrorism involving chemical or biological weapons.
- 20 • Syndromic surveillance program in operation through BPHC CDCB. The Web-based
21 surveillance system monitors daily volume at 10 acute care hospitals, one community
22 health care center, and call-code volume data from Boston EMS and the Massachusetts
23 Poison Control Center, ensuring that, subsequent to a release of a biological or chemical
24 agent, BPHC can rapidly detect changes in healthcare seeking patterns and mount an
25 effective and coordinated investigation and response.

26
27 Expanded citywide personnel training includes the following:

- 28 • All EMS personnel are trained to Hazardous Materials (HazMat) Operations level;
- 29 • All EMS personnel are trained to Department of Justice WMD Technician requirements;
- 30 • Approximately 40 EMS personnel are also trained as HazMat Technicians;

- A pilot HazMat training course is underway for Hospital Providers that specifically addresses issues of hospital-based care for patients involved in HazMat and WMD incidents; and
- A pilot MMRS Volunteer Responder Course is underway, preparing volunteers (i.e., BU students) from Boston's pharmacy, public health, and medical schools to participate in response to a WMD event or other large-scale emergency.

Boston Medical Center (BMC)

Boston Medical Center (BMC) is a private, not-for-profit, 581-bed licensed, academic medical center and is the primary teaching affiliate for the BU School of Medicine. The BMC is the largest safety net hospital in New England providing a full spectrum of pediatric and adult care services, from primary to family medicine to advanced specialty care. BMC is the largest 24-hour Level I trauma center in New England. A full complement of support services is available. BMC is fully accredited by the Joint Commission on Accreditation of Healthcare Organizations (Joint Commission). The Joint Commission is an independent, not-for-profit organization that is the nation's leading accreditor of hospitals. Obtaining Joint Commission accreditation is important for hospitals, as the Medicare Act of 1965 decreed that accredited hospitals were deemed to have satisfied federal health and safety requirements necessary to participate in Medicare. Hospitals also have considerable incentive to become accredited for marketing purposes, often using Joint Commission accreditation as a *third-party endorsement of quality*. As a result, approximately 80 percent of the 6,000 U.S. hospitals have sought Joint Commission accreditation.

The Infectious Disease Section of the Adult Department of Medicine provides Fellow and Attending physician coverage for expert consultation 24 hours a day. Those specialists are available to respond if a NEIDL worker becomes ill. Likewise, pediatric infectious disease attending physicians from the Pediatric Infectious Disease Section of the Department of Pediatrics are available 24 hours a day.

BMC has 60 negative-flow rooms throughout the institution. Five of those rooms are in the Emergency Department (ED). Air to the patient rooms is supplied by general purpose air

handlers equipped with high efficiency HEPA filters. BMC's radiology department is open and staffed by technicians to complete the studies, and radiologists are available to interpret the results 24 hours a day. Radiology suites are on both inpatient campuses and have mobile capabilities to accommodate portable X-rays for patients requiring continuous isolation.

BMC is a BSL-2 lab with service availability 24 hours a day. In addition, BMC is a designated Level A Support lab for the Massachusetts State Laboratory. BMC participates in multidisciplinary, interdepartmental planning for emergencies. BMC's planning activities include active participation in, and plan integration with, regional and state entities, such as the following:

- Conference of Boston Teaching Hospitals Disaster Committee;
- Region 4 C Surge Committee;
- Urban Area Security Initiative Region Homeland Security Committee;
- Metropolitan Medical Response System Committee;
- Local Emergency Planning Committee; and
- Massachusetts State Surge Committee.

The following Mutual Aide Agreements are in place with the following organizations:

- MMRS—Boston Hospitals: Share services, staffing, and supplies;
- Lemuel Shattuck Hospital—Capacity – Isolation specialty;
- Quincy Medical Center—Capacity;
- Boston Fire Department—Decontamination;
- Massachusetts Department of Public Health—Regional benchmarks for preparedness, laboratory support, National Disaster Medical System (NDMS) participating hospital;
- Centers for Disease Control and Prevention Quarantine Center Boston Logan Airport—Designated Receiving Hospital; and
- Vendor contracts for critical supplies.

BMC routinely participates in emergency response drills and exercises. The BMC also has experience in responding to mass casualty events and disasters. The BUMC emergency response

activities are supported by the Boston Police Department. The new headquarters is equipped with perhaps the most advanced imaging and ballistics identification technology in the country; a DNA laboratory (one of only 18 departments in the country with in-house DNA testing capacity; and an enhanced 9-1-1 call center, and a Computer-aided Dispatch system linked to Mobile Data Terminals.

B.2 Tyngsborough, Massachusetts (Suburban)

B.2.1 Location

The town of Tyngsborough is a small residential community in the northwest section of Middlesex County, in northeastern Massachusetts. Composed of 17.86 mi² (46.3 km²) of land and surface water, bordering towns include Dunstable and Groton on the west and northwest; Westford and Chelmsford on the south; Dracut and Lowell on the east; and Nashua and Hudson, New Hampshire on the north. The town is bisected by the Merrimack River. Tyngsborough is about 7 miles (11.27 km) west of Lowell, 31 miles (49.89 km) northwest of Boston, 26 miles (41.84 km) northeast of Fitchburg, and 235 miles (378.20 km) from New York City. Tyngsborough is dotted with numerous streams, lakes, great ponds, and wetlands.

The suburban site is on a 210-acre (0.85 km²) forested site overlooking a private pond. The site contains a mix of pine and mixed hardwood forests. Several old, abandoned quarries are found within the borders of the property. The site is bordered by residential areas on all sides except for the southeast property line, which is bordered by fields. The property is in the Merrimack River watershed, and all stormwater and groundwater is carried to the river. Stormwater from the site runs into a small brook on-site that flows into the Merrimack River.

B.2.2 Livestock and Animals

According to the Massachusetts State and County Data-2002 Census of Agriculture, Middlesex County, in which Tyngsborough is located, had

- 2,827 cattle and calves;
- 2,214 hogs and pigs;
- 1,964 horses and ponies;
- 816 sheep and lambs;

- negligible populations of goats; and
- 16,691 poultry species (i.e., chickens and turkeys).

Livestock populations in the vicinity of the site are low or negligible. The numbers of livestock have been decreasing since the 1997 census. Wildlife present are typical of those found in Massachusetts and composed of amphibians, birds, fish, mammals, and reptile species, such as deer mice, shrew, voles, rats, chipmunks, bats, squirrels, raccoons, bobcats, black bear, rabbits, fox, coyotes, white tailed deer, and moose. The varied habitats in the Merrimack River watershed support almost any bird species found in Massachusetts.

B.2.3 Utilities

If the NEIDL were constructed at the suburban site, Electric power would be supplied by the Massachusetts Electric Power Company. Electric power for chillers is on the grid that supplies the town. Heating most likely would be provided by natural-gas-fired boilers supplied by the town utility. The site is supplied by the municipal water system and sewage is disposed of through an on-site sanitary disposal system with a leaching field that was installed 10 years ago. Municipal water service is available at the site. Municipal sewer service is not available from Tyngsborough. It might be possible to tie into municipal sewer service from the adjacent town of Chelmsford approximately 600 ft (182.88 m) away. Water for fire suppression is obtained from a fire pond on the property. The NEIDL would probably tie into existing electrical and natural gas lines.

B.2.4 Transportation and Access

The development of transportation resources in the Merrimack River Valley, in which Tyngsborough is located, was shaped by the history of the region as a major site of American industrial development in the nineteenth century. The area has highway and rail facilities linking major cities and towns to each other and to the port, airport, and intermodal facilities of Boston. Principal highways are U.S. Route 3 running north-south between Nashua, New Hampshire, and the Boston region, and State Route 113. Tyng Road, the main access road to the property, is a collector street/quiet residential road with limited traffic. It is a country road with no lines and no

1 shoulder. The existing road infrastructure might not be ideal for the types and volume of
2 construction, operational, and service-related NEIDL traffic.

3
4 Commuter rail service to North Station, Boston, is available from neighboring Lowell. Travel
5 time is 45–49 min, and 680 MBTA parking spaces are available. Freight rail service is available
6 from the Springfield Terminal Railway. Tyngsborough is a member of the Lowell Regional
7 Transit Authority, which provides fixed bus service between Lowell and Tyngsborough.
8 Paratransit services for the elderly and disabled are available through the Tyngsborough Council
9 on Aging.

10
11 The Tew-Mac Airport, a General Aviation facility has two asphalt runways 600 ft x 60 ft and
12 2,830 ft x 26 ft (182.88 m x 18.29 m and 862.58 m x 7.92 m). Non-precision instrument
13 approaches are permitted. Other nearby airports are the Lawrence Municipal Airport in North
14 Andover and L.G. Hanscom Field in Bedford. The region is served by Logan International
15 Airport for most commercial and general aviation needs, and the primary airport that would
16 service the NEIDL if it were sited at Tyngsborough. There are no direct mass transportation
17 opportunities directly to the site.

18 19 **B.2.5 Healthcare and Emergency Response**

20 Tyngsborough has professional police and fire departments and a professional staff assisting the
21 Board of Health. The police department employs 25 full-time officers. The fire department
22 employs 38 on-call firefighters, rotated through four full-time slots. The nearest fire station is 1.7
23 mi (2.74 km) north of the site. The small, local department could be challenged to respond to the
24 safety and security requirements of a major research facility.

25
26 Tyngsborough does not have a hospital within the town limits but is served by Lowell General
27 Hospital (LGH) approximately 8 miles away across the Merrimack River. LGH is a 200-bed
28 community hospital with a 12-bed intensive care unit (ICU); an 18-bed intermediate care unit; 2
29 medical/surgical units with 40 beds each; and pediatrics and maternity services and an outpatient
30 cancer center. LGH has a daily patient census of 130–135 with between 11,000 and 12,000
31 discharges per year. LGH also operates an off-site outpatient surgery center. The ED has a

negative-pressure isolation room with no anteroom. Eight standard isolation rooms are in other areas of the hospital. One of those rooms has an anteroom. LGH has a Health Resources and Services Administration grant to renovate the isolation room in the ED to provide exhaust from that room directly to the exterior of the facility.

LGH has both an infection control practitioner and an emergency response coordinator. Two flexible patient transporters and two mass decontamination units are available on-site, as well as a portable chemical decontamination shower for use at the ambulance entrance. Emergency drills are performed once a year. Ambulance services are provided by a local company under contract to LGH with an established patient transport agreement and requisite protocols. An employee parking lot is cleared in the event that patient transport by helicopter is necessary. Members of the medical staff are board certified specialists; however LGH does not have an infectious disease specialist on staff though there is an infectious disease physician who provides consultations as necessary. A full-service clinical laboratory is on the premises, augmented by a reference laboratory as needed. LGH is fully accredited by the Joint Commission. If a serious incident, exposure, or infection occurred in an individual associated with the NEIDL, LGH would stabilize and then transport the patient to a more comprehensive healthcare facility by an appropriate method (e.g., ambulance, helicopter) according to the patient's stability and other factors such as weather conditions. In addition to LGH, the Tyngsborough area has a small number of ambulatory healthcare services (e.g., doctor's offices, clinics) and convalescent/nursing residential care facilities.

B.3 Boston University (BU) Sargent Center for Outdoor Education (Rural)

B.3.1 Location

The ruralsite is in Hillsborough County within the town limits of Peterborough, zoned as a Rural District in the scenic Monadnock Region of southwestern New Hampshire 85 miles (136.79 km) from Boston and 125 miles (201.17 km) from Hartford, Connecticut. The site, composed of 700 acres (2.83 km²) of open fields, forested land, streams, wetlands, and a river, is bordered on the north by Hancock, New Hampshire; to the northeast by Hunt's Pond and Nubanusit Lake; to the south by West Peterborough and the McDowell Artist Colony; to the southeast by Peterborough,

1 Sheiling Forest and the Wapack Nature and Wildlife Preserve. A 60-acre (0.24 km²) pond is on
2 the site (Halfmoon Pond), a 20-acre (0.08 km²) open meadow, and 22 miles (35.41 km) of
3 walking and hiking trails.

4 5 **B.3.2 Livestock and Animals**

6 According to the New Hampshire State and County Data-2002 Census of Agriculture
7 Hillsborough County, in which Peterborough is located, has a significant number of livestock
8 animals. According to the 2002 agricultural census, 2,325 cattle and calves, 3,774 goats, and 461
9 bison were in the county. Wildlife present are typical of those found in southern New
10 Hampshire and composed of amphibians, birds, fish, mammals, and reptile species such as deer
11 mice, shrew, voles, rats, chipmunks, bats, squirrels, raccoons, bobcats, black bear, rabbits, fox,
12 coyotes, white tailed deer, and moose. The varied habitats along the Contoocook and North
13 Branch rivers support almost any bird species found in southern New Hampshire. Many species
14 of waterfowl use the river as a migratory stop in the spring and fall.

15 16 **B.3.3 Utilities**

17 Electric power is provided by Northeastern Utilities; two diesel-fired back-up generators (150 kilowatts
18 [kW] each)—one for the north circle and for the south circle are provided for back-up power because
19 power failure is fairly routine in the area. Heat at the rural site is provided by a combination of liquid
20 propane gas and fuel oil, both stored underground. On-site water is provided via wells from an aquifer
21 running under the property, and septic fields and a sewage lagoon complete the utilities. Peterborough has
22 a municipal sewage collection and treatment system; however, the rural site is not currently served by the
23 sewerage system.

24
25 Fueling NEIDL operations at the other location would be a challenge. The site does not tie into natural
26 gas lines. Therefore, either large, aboveground storage tanks would be required to fuel all operations or
27 natural gas tie in lines would need to be installed to support the facilities needs.

28 29 **B.3.4 Transportation and Access**

30 Road access to the area is somewhat limited to U.S. Route 202 and State Routes 101, 123, and
31 136. The nearest interstate routes are Everett Turnpike and I-89, 27 and 33 miles (43.45 and

53.11 km) away, respectively. Access from the west is via a dirt road. The university encourages traffic to arrive from the east; however, the road is an unlined country road with no shoulder. Access to the site is by a rural, unpaved road that would not support the needs of a large biomedical research facility. The existing road infrastructure would not support the types and volume of construction, operational, and service-related NEIDL traffic. No railroad or public transportation is available near the site. The region is served by Logan International Airport for most commercial and general aviation needs, and the primary airport that would service the NEIDL if it were sited at the rural site.

B.3.5 Healthcare and Emergency Response

Peterborough has three full-time administrative employees; a town administrator, assistant administrator, and town clerk. The town has a volunteer fire and rescue service department with one full-time employee and 50 volunteer and on-call firefighters. The Peterborough fire station is 4.8 mile southeast of the site (7.72 km). The Hancock fire station is 3.9 miles (6.28 km) from the site, which is approximately a 9-min drive north of the site. The town has 12 full-time police officers. The local Board of Health is made up of volunteers who might not necessarily be trained to address health and safety issues associated with a research facility. The nearest medical facility is Monadnock Community Hospital (MCH) in Peterborough, a 7.4 mi (11.91 km) from the proposed site. MCH at 452 Old Street Road, is a 25-bed acute care facility (licensed for 62 beds) including 4 ICU beds, 7 obstetrical beds, and 14 medical surgical beds. MCH is the primary care facility for 13 surrounding towns and serves a total population of approximately 36,000. The large majority of patients are Medicare patients; many people in the surrounding area are either self-employed or employed by small businesses and do not have other health insurance.

The MCH ED offers health services 24 hours a day, 7 days a week to patients of all ages with all presenting complaints. The ED is responsible for the immediate treatment of any medical or surgical emergency; for initiating life saving procedures in all types of emergency situations; and for providing emergency and initial evaluations and treatment for other conditions including minor illnesses and injuries, and sub-acute medical problems. After initial assessment and stabilization, patients are transported to other medical institutions if necessary. The MCH ED

1 services about 12,000 patients per year, most of which are primary care visits. It has two trauma
2 rooms with two beds each, and one of the other rooms is maintained under slight negative
3 pressure to have inward airflow. Decontamination showers are available at the MCH ED, and the
4 MCH has a decontamination trailer and a heliport with room for a second. The hospital has an
5 Emergency Response Plan that was developed in conjunction with town administrators and
6 operates under the Hospital Incident Command System.

7
8 In the event of the need to transport a patient to a tertiary care facility, either the Monadnock
9 Emergency Medical Services or the Dartmouth-Hitchcock Advanced Response Team (DHART)
10 would be used. The DHART is based in Lebanon, at Dartmouth-Hitchcock Medical Center, New
11 Hampshire's only verified Level 1 Trauma Center. DHART crews provide both ground and air
12 medical transportation services to the medical communities of Northern New England. In
13 addition, DHART flight crews respond to public safety agency requests for medical evacuation
14 of trauma patients from scenes of injury and will transport to the closest trauma center in the
15 region's five states. University of Massachusetts-Worcester helicopters can also be used. BUMC
16 is one and a half hours away by ground transport or 35–40 min by helicopter. Transport
17 decisions are based on the case urgency and prevailing weather patterns. Under severe weather
18 conditions, transportation of an ill NEIDL worker would be problematic. The MCH medical staff
19 includes more than 125 primary and specialty care physicians, 15 dentists, and 23 health
20 professional affiliates. Medical staff offices are in the Medical Arts Building on MCH's campus
21 and in the communities of Peterborough, Jaffrey, Antrim, and New Ipswich. One hundred
22 percent of the medical staff are board certified in their specialty area. However no infectious
23 disease specialists are at MCH. An infectious diseases specialist consults as necessary by
24 telephone. A pathologist is available two days a week in the clinical laboratory. MCH is not
25 accredited by the Joint Commission. The hospital is accredited as *Critical Access* through the
26 Centers for Medicare and Medicaid Services (CMS, formerly the Health Care Financing
27 Administration).

28
29 Peterborough is one of the most flood-prone areas in the state and has been included in three
30 disaster declarations since 1987. It is subject to a variety of natural hazards including riverine
31 flooding, wildfires, ice storms, and river ice jams. The town has more than 40 dams, 2 of which

1 have been classified as high-hazard dams. Specifically, the rural site property is encompassed by
2 a Special Flood Hazard Area designated as Zone A, a 100-year floodplain. The site is adjacent to
3 U.S. Army Corps of Engineers flood control easements and the spillway for the MacDowell
4 Lake. In an emergency, the spillway can be opened to prevent Peterborough from flooding.
5 Peterborough has joined the disaster resistant efforts of the Federal Emergency Management
6 Agency's Project Impact, a national effort to change the way disasters are handled. That effort
7 shifts the focus of emergency management from responding to disasters to taking actions before
8 disasters that reduce potential damage. Peterborough has adopted a strict floodplain management
9 program and introduced intensive community growth management efforts, including planning
10 for open space and conservation areas as a Project Impact disaster-resistant community.

3. Pathogens

3.1 Introduction

NIAID is the primary Institute at the NIH for emerging infectious disease research. The mission of NIAID is to carry out research needed to understand the pathogenesis of these microbial pathogens and the host responses to them, and to translate this knowledge into useful interventions and diagnostic tools for an effective response to natural outbreaks, accidental releases, or bioterrorist events. For the latter, NIAID is committed to an agenda of basic and translational research for bioterrorism defense, working with partners in academia, industry, and other private and public-sector agencies. NIAID has developed a Strategic Plan for Biodefense Research to guide the implementation of the necessary research and development program (US Department of Health and Human Services 2011).

Key elements of the NIAID Strategic Plan for Biodefense Research are:

- Support biomedical research on microbes and the human immune response to them
- Apply such research to the discovery and development of vaccines, drugs, and diagnostic tests designed to protect the general population
- Ensure that the United States has enough research facilities to carry out these activities.

To meet these key elements, research is needed on a range of microbial pathogens.

3.2 Selected Pathogens

This RA addresses 13 pathogens that are currently considered likely research areas of interest at NEIDL:

Pathogens	Abbreviation
BSL-3	
1. <i>Bacillus anthracis</i> (either BSL-2 or BSL-3)	<i>B. anthracis</i>
2. <i>Francisella tularensis</i>	<i>F. tularensis</i>
3. <i>Yersinia pestis</i>	<i>Y. pestis</i>
4. 1918 H1N1 influenza virus	1918 H1N1V
5. SARS-associated coronavirus	SARS-CoV
6. Rift Valley fever virus	RVFV
7. Andes virus (either BSL-3 or BSL-4 ^a)	ANDV
BSL-4	
8. Ebola virus	EBOV
9. Marburg virus	MARV
10. Lassa virus	LASV

Pathogens	Abbreviation
11. Junín virus	JUNV
12. Tick-borne encephalitis virus, Far Eastern sub-type, formerly known as tick-borne encephalitis complex (Russian spring-summer encephalitis virus)	TBEV-FE
13. Nipah virus	NIPV

3.3 Pathogen Characteristics

Characteristics of each of the 13 pathogens and the diseases they cause can be used to place them (Table) among four hazard categories for humans that were identified by the Advisory Committee to the Director of the NIH (Mahmoud 2008). The categories are:

- Highly transmissible pathogen, highly pathogenic, with a high case fatality ratio (CFR).
- Highly transmissible pathogen, pathogenic, with a lower CFR.
- Poorly transmissible pathogen, highly pathogenic, with a high CFR.
- Vector-borne pathogen that is relevant to the particular sites under evaluation.

These four categories serve to describe the general nature of risks from infectious pathogens to laboratory workers and to the public at large, and to describe in broad terms the range of potential effects from the release of such pathogens. The first category describes characteristics of pathogens that can be easily spread from person to person during casual contact, potentially resulting in large numbers of infections among the general population. This category also specifies a relatively high number (based on comparisons between the 13 pathogens) of deaths due to infection. As indicated in Table 3-1, only SARS-associated coronavirus is placed into this category.

The second category likewise describes characteristics of pathogens that can be easily spread from person to person during casual contact. However, it differs based on a relatively lower specified fatality rate that would be expected to result in fewer deaths as a result of infection. As indicated in Table 3-1, only the 1918 H1N1 influenza virus is concluded as meeting these two criteria.

The third category describes characteristics of pathogens that have very little or no ability to spread from person to person during casual contact, and therefore have very little or no potential to spread among the general population. However, infection from a pathogen in this category can pose a high or relatively high risk of death for an infected laboratory worker if the infection is not treated. As indicated in Table 3-1, 10 of the 13 pathogens meet these two criteria.

The fourth category recognizes that some of the 13 pathogens exhibit the additional characteristic of a vector (such as a mosquito, tick, or other arthropod) being involved in the spread of infections among populations of humans and animals. This refers to spread of these pathogens that can occur apart from the direct person to person pathway. As a result, such pathogens, if established in vector species in the environment, could be particularly difficult if not impossible to eradicate. As indicated in Table 3-1, 4 of the 13 pathogens fit this characterization. The environmental concerns posed by vector-borne pathogens are considered in detail in Chapter 7.

Table 3-1. Pathogen categorization by pathogen and disease characteristics

Highly transmissible, highly pathogenic, and high CFR	Highly transmissible, pathogenic, and lower CFR	Poorly transmissible, highly pathogenic, and high CFR	Vector-borne relevant to the sites to be assessed
SARS-associated coronavirus ^a	1918 H1N1 Influenza virus ^a	<i>Bacillus anthracis</i> ^c	<i>Francisella tularensis</i> ^c
		<i>Francisella tularensis</i> ^c	<i>Yersinia pestis</i> ^c
		<i>Yersinia pestis</i> ^c	Rift Valley fever virus ^{a,e}
		Andes virus ^d	TBEV-FE ^b
		Ebola virus ^b	
		Marburg virus ^b	
		Lassa virus ^b	
		Junín virus ^b	
		TBEV-FE ^b	
		Nipah virus ^b	
<p>a. BSL-3 biocontainment precautions with enhancements are recommended (CDC and NIH 2007)</p> <p>b. BSL-4 biocontainment precautions recommended (CDC and NIH 2007)</p> <p>c. BSL-3 biocontainment precautions are recommended (CDC and NIH 2007)</p> <p>d. BSL-4 biocontainment is required when infecting rodent species permissive for chronic infection (CDC and NIH 2007)</p> <p>e. RVFV will be assessed also as Poorly transmissible (person-to-person), pathogenic, and lower CFR</p>			

Several parameters, including potential consequences of release of pathogen, were considered in placement of the pathogens into the above hazard categories:

- Susceptible host species (host range)
- Infectivity (infectious dose, primary routes of human infection, primary infection rate)
- Incubation period
- Infectious period

- Transmissibility (including secondary transmission)
- Reproduction ratio (R_0)
- Pathogenesis
- Morbidity
- Mortality (case fatality ratio)
- Pathogen concentrations
- Pathogen stability
- Reservoirs
- Vectors
- Availability/effectiveness of antiviral/antibacterial agents and vaccines

3.4 Literature Review

To compile representative data for the thirteen pathogens, literature searches were conducted which resulted in review of more than 2,500 publications from a variety of sources, with primary emphasis being placed on data published in peer-reviewed scientific journals. Additional sources included reference and textbooks, government documents, conference proceedings, and personal communications with leading authorities. Most of these sources are available through the internet and in printed copy. Data are representative of the open literature as of January 2009, but are not necessarily exhaustive. A brief update from the open literature was performed in April, 2010 and May 2011. It is acknowledged that additional relevant data may exist under classified status; these data were not available for review for this RA.

Internet-based sources used for this RA included:

- PubMed
- CDC fact sheets
- BMBL 5th Edition, 2007
- The International Catalog of Arboviruses
- Terrestrial Animal Health Code
- ProMed-mail
- Defense Technical Information Center
- Community Strategy for Pandemic Influenza Mitigation, 2007
- Public Health and Biosafety Practices for Research with 1918 H1N1 Influenza Virus

PubMed is a free service of the U.S. National Library of Medicine and the NIH that comprises an internet platform for electronic access to more than 19 million citations for biomedical articles from MEDLINE

1 and life science journals. It may be freely accessed at <http://www.ncbi.nlm.nih.gov/pubmed/>. Citations
2 may include links to full-text articles from PubMed central or publisher web sites. Many of these articles
3 are freely available while others can be accessed through a subscriber such as a university library. CDC
4 Fact Sheets for a variety of topics are freely available online from the DHSS, CDC. CDC documents
5 may be freely accessed at <http://www.cdc.gov/>.

6
7 *Biosafety in Microbiological and Biomedical Laboratories*, 5th Edition (BMBL) 2007: BMBL, is the
8 cornerstone of biosafety practice and policy in the United States. Historically, the information in this
9 publication has been advisory in nature even though legislation and regulation, in some circumstances,
10 have overtaken it and made compliance with the guidance provided mandatory. The 5th edition of the
11 BMBL remains an advisory document recommending best practices for the safe conduct of work in
12 biomedical and clinical laboratories, from a biosafety perspective and is not intended as a regulatory
13 document; though it is recognized that it will be used that way by some. BMBL is available at
14 http://www.cdc.gov/OD/ohs/biosfty/bmbl5/BMBL_5th_Edition.pdf.

15
16 *The International Catalog of Arboviruses Including Certain Other Viruses of Vertebrates* originally
17 began publishing data from a continuously revised, confidentially-communicated working document
18 entitled *The Catalog of Arthropodborne and Selected Vertebrate Viruses of the World*. The first published
19 edition in 1967 contained information regarding 204 viruses; two supplements describing 37 and 14
20 additional viruses were published in the *American Journal of Tropical Medicine and Hygiene* in 1970 and
21 1971, and the second edition describes 359 viruses. The Catalog currently describes more than 573
22 registered viruses. These catalogs are results of efforts of the Subcommittee on Information Exchange of
23 the American Committee on Arthropod-borne Viruses. The history of the origin and development, and the
24 operation of the Working Catalogue are described in this second edition, as are the two other
25 Subcommittees whose activities relate directly to the Catalogs (Interrelationships Among Catalogued
26 Arboviruses formed in 1966, and Evaluation of Arthropod-borne Status started in 1971). The Catalog is
27 now freely available online through the CDC at www.ncid.cdc.gov/arbocat.

28
29 *The Terrestrial Animal Health Code 2009* is freely available from the World Organization for Animal
30 Health (OIE) on the internet at www.oie.int/eng/normes/mcode/en_sommaire.htm. The purpose of the
31 Code is to assure the sanitary safety of international trade in terrestrial animals (mammals, birds, and
32 bees) and their products by detailing health measures to be used by veterinary authorities. Information
33 contained in the Code is relevant to some of the diseases under consideration in the RA (i.e. tularemia,
34 anthrax, Rift Valley fever, and Nipah virus).

ProMed-mail (Program for Monitoring Emerging Diseases) is a free internet-based reporting system dedicated to rapid global dissemination of information on outbreaks of infectious diseases and operates as an official program of the International Society for Infectious Diseases. It is freely available at <http://promedmail.oracle.com/pls/otn/f?p=2400:1000>.

Defense Technical Information Center (DTIC): DTIC serves the Department of Defense (DoD) community as a central resource for DoD- and government-funded scientific, technical, engineering, and business-related information. All visitors can search DTIC's publicly accessible collections and read or download scientific and technical information, using DTIC Online service. DTIC also makes available sensitive and classified information to eligible users who register for DTIC services.

<http://www.dtic.mil/dtic/index.html>

Community Strategy for Pandemic Influenza Mitigation (US Department of Health and Human Services 2011) provides interim planning guidance for State, territorial, tribal, and local communities that focuses on several measures other than vaccination and drug treatment that might be useful during an influenza pandemic to reduce its harm. The document is available at

<http://www.flu.gov/professional/community/commitigation.html>.

“Public Health and Biosafety Practices with 1918 H1N1 Influenza Virus”, Safety symposium, NIH RAC Dec 2, 2008. An agenda, audio recording, and slide presentations are freely available at

http://oba.od.nih.gov/rdna_rac/rac_past_meetings_2000.html#RAC2008 and <http://oba.od.nih.gov/oba/RAC/meetings/dec2008/FINAL%20AGENDA.pdf>

Non-internet sources reviewed included textbooks and reference books such as:

- Principles and Practice of Infectious Diseases 7th edition, 2010, GL Mandell, JE Bennett, R Dolin editors, ISBN 978 0 4430 6839 3
- Topley & Wilson's Microbiology and Microbial Infections 19th edition, 2005, ISBN 0 340 614706
- Infectious Disease Epidemiology: Theory and Practice 2nd edition, 2007, ISBN 978 0 7637 2879 3
- Biological Safety: Principles and Practices 4th edition, 2006, ISBN 978 1 55581 339 0
- The Arboviruses: Epidemiology and Ecology, CRC Press, 1989, ISBN 0849343852 (v.1)
- An Introduction to Experimental Aerobiology, 1969, SBN: 471 21558 9
- Bioaerosols Handbook, 1995, ISBN: 0 87371 615 9
- Bioaerosols, 1995, ISBN: 0 87371 724 4

3.5 Abridged Literature Search Results of Pathogen Characteristics

The following are brief synopses of literature search results for each pathogen, sorted by biosafety level (BSL) designation for fully virulent, wild-type strains. The goals of providing the synopses are to introduce the 13 pathogens to the reader and provide a basis for their selection for analysis in this RA. Pathogen characteristics that are highlighted include a general description of the diseases caused and extent of knowledge regarding infectious doses and potential for spread from person to person. The history and potential for laboratory associated infections is also discussed. All 13 pathogens have the potential to cause life-threatening and fatal illnesses and are the subjects of on-going research in high bio-containment laboratories around the world. Full search results of the available literature on these pathogens are contained in Appendix C Pathogen Characteristics.

Data concerning infectious doses for humans for these 13 pathogens are minimal or absent in the literature. Accordingly, opinion elicited from a panel of experts as described in Appendix H was used to supplement data from the literature for infectious doses. All other data in this chapter were obtained from the sources listed above and are individually referenced below.

3.5.1 BSL-3 Biocontainment Precautions: Pathogens

3.5.1.1 *Bacillus anthracis*

Introduction

Bacillus anthracis is a bacterium that causes the animal and human disease known as anthrax. For this RA, *B. anthracis* was selected for analysis based on its characteristics of being highly pathogenic with a high case fatality ratio despite its poor transmissibility (Mahmoud 2008). Anthrax is contracted largely by exposure to *B. anthracis* spores from the environment. Based on a review of the existing epidemiologic literature, there is no evidence for direct spread of *B. anthracis* vegetative forms from a person infected with anthrax to another person. The human infectious dose of *B. anthracis* is not known. The potential for laboratory acquired infections (LAI) from *B. anthracis* exists and LAI have been reported. There were no secondary cases of anthrax in the close contacts of the laboratory worker or in the community as a result of the LAI.

The name of the pathogen is derived from the Greek word for coal, *anthrakis*, as the disease typically causes black, coal-like skin lesions. Reports of suspected anthrax outbreaks in animals and humans have

1 been reported for centuries throughout the world, with the earliest reports dating back to 1250 BC.
2 Recently, *B. anthracis* has been of interest to the public and scientific community after an intentional
3 release of spores caused disease and deaths in humans in the United States in 2001 (Greene et al. 2002;
4 Inglesby et al. 2002)

5
6 Outbreaks of anthrax in animals occur routinely throughout the world. Grazing herbivores, especially
7 cattle, sheep, goats, and horses are particularly susceptible to anthrax, while pigs are more resistant. Birds
8 are resistant with some exceptions such as ostrich (Beyer and Turnbull 2009) The disease is endemic
9 among animals in the Middle East, equatorial Africa, Mexico and Central America, Argentina, Cambodia,
10 Chile, China, India, Myanmar, Papua New Guinea, Peru, Thailand, and Vietnam. Recent outbreaks have
11 been described among cattle and horses in Canada (Center for Infectious Disease Research & Policy
12 2006; Kumor et al.) and non-human primates in Cameroon and Ivory Coast (Leendertz et al. 2004;
13 Leendertz et al. 2006; Leendertz et al. 2006). In the US, anthrax is seen in animals in several counties in
14 southwestern Texas near the border of Mexico (Johnson), and in pockets of infection in Nebraska,
15 Oklahoma and South Dakota (McBride et al. 1998) During the period 1996-2001, 21 outbreaks in animals
16 in the US accounted for 1,862 animal deaths (Johnson 2008).

17
18 The natural reservoir for anthrax spores is the soil with reports of spores in soil samples from around the
19 world (Turnbull et al. 1998; Hugh-Jones and Blackburn 2009) (Dragon et al. 2001) (Titball et al. 1991)
20 Naturally occurring anthrax infections in humans occur after contact with the spores, an anthrax-infected
21 animal, or anthrax-contaminated animal products.

22
23 This pathogen is studied in laboratories around the world, including high biocontainment laboratories in
24 the US. BSL-3 practices, biocontainment equipment, and specially designed biocontainment facilities are
25 recommended for work involving production quantities or high concentrations of cultures, for screening
26 environmental samples (especially powders) from anthrax-contaminated locations, and for activities with
27 a high potential for aerosol production. *B. anthracis* is a Select Agent requiring registration with CDC
28 and/or US Department of Agriculture for possession, use, storage, and/or transfer (Chosewood et al.
29 2009).

31 **Human Disease and Outbreaks**

32 Human anthrax is classified based on the natural route of infection. Cutaneous anthrax is acquired by
33 contact with *B. anthracis* through a skin lesion; gastrointestinal anthrax is contracted via the oral route,
34 usually by ingesting contaminated food, primarily meat from an herbivore animal that died from the

1 disease; and inhalational anthrax which is acquired by breathing in airborne spores via the respiratory
2 tract (Inglesby et al. 2002) (Chosewood et al. 2009). Naturally occurring anthrax is also classified by the
3 occupation of the exposed individual. This differentiates non-industrial exposure in butchers, farmers,
4 and veterinarians from industrial exposure in those employed in the processing of wool (wool sorter's
5 disease), bones, and hides. The number of cases of natural disease in humans is directly correlated to the
6 level of animal disease and to the level of exposure to affected animals, which occurs mostly in
7 developing countries.

8
9 Cutaneous disease accounts for approximately 95 percent of naturally occurring human cases. The skin
10 lesions develop 1-12 days after infection and are characterized by ulceration and the characteristic black
11 eschar that is reminiscent of coal. Patients who are not treated early may progress to a systemic disease
12 with sepsis and death. Ingestion of *B. anthracis* spores may result in oropharyngeal anthrax that is
13 localized to the oral cavity, tongue, tonsils, or pharyngeal wall. Ingestion may also lead to gastrointestinal
14 anthrax. This is the next most common form and accounts for the majority of the remainder of naturally
15 occurring cases. Symptoms such as nausea, vomiting, and diarrhea appear 3-7 days after ingestion of
16 contaminated food. Symptoms may be mild at first and, if untreated, can lead to bleeding in the
17 gastrointestinal tract resulting in vomiting blood or blood in the stools. Inhalational anthrax in humans is
18 rare, is infrequently seen in industrial settings and has been noted as a result of accidental or intentional
19 release of spores (Meselson et al. 1994) (Greene et al. 2002). The incubation period in inhalational
20 anthrax is typically 1-6 days; with a wide range of 2-43 days noted in an accident at Sverdlovsk, USSR.
21 Germination of spores is followed by rapid hemorrhage, edema, and necrosis of surrounding tissue from
22 release of bacterial toxins. The case fatality rate is highest for inhalational anthrax, especially in untreated
23 cases or where the treatment was initiated late. Meningitis is a frequent complication of inhalational
24 disease and contributes to poor outcomes (Sejvar et al. 2005).

25
26 The true numbers of cases of naturally occurring anthrax in countries where the disease is endemic are not
27 known. This is due to lack of surveillance systems to track the disease, lack of facilities to diagnose the
28 disease, and under-reporting. It is estimated that there have been several hundred thousand cases of
29 cutaneous anthrax over the past several centuries (World Health Organization. 2008). Numbers of cases
30 of gastrointestinal anthrax are estimated to be in the several thousands and naturally occurring
31 inhalational anthrax is rare.

32
33 An oft-cited accidental release of *B. anthracis* spores was noted in 1979 from a military facility in the
34 former Soviet Union (Meselson et al. 1994; Wilkening 2006). It is noted that *B. anthracis* is the only

1 pathogen examined in this RA for which there is a documented historical example of a large-scale aerosol
2 release from a biological research facility that caused infections in members of the public downwind of
3 the release point (the Sverdlovsk incident, discussed in Appendix J). The exact quantity of *B.anthraxis*
4 that was released from the facility is not known. There were a total of 77 likely human cases with 66
5 deaths from this release. In a factory that was 2.8 km downwind of the facility, the attack rate was
6 calculated to be approximately 1-2% with 18 out of about 1500 employees infected, including 10 out of
7 450 employees working in a single unpartitioned building (Meselson et al. 1994).

8
9 Naturally occurring anthrax in all three forms is rare in the US and has been infrequently seen since the
10 first half of the 20th century. Most of the cutaneous anthrax cases in the US are linked to the processing of
11 imported goat hair, hides, and other animal products.

12
13 More recently, there have been reports of anthrax infections from accidental exposure to animal hides
14 used in drums. Cases of inhalational anthrax were confirmed in a drum-maker from New York City
15 (Nguyen et al. 2010), London, England (Anaraki et al. 2008) and from Scotland (2006). There were two
16 cases of cutaneous anthrax in a drum maker and his child in Connecticut in the US (Centers for Disease
17 Control and Prevention (U.S.) 2008; Guh et al. 2010). A rare presentation of gastrointestinal anthrax was
18 noted in a woman in New Hampshire in the US who participated in a drumming circle (Centers for
19 Disease Control and Prevention (U.S.) 2010). In August 2011, a case of inhalational anthrax was
20 confirmed in a patient who was hospitalized in Minnesota (The Center for Infectious Disease Research
21 and Policy (CIDRAP) 2011). Preliminary evidence suggests that this person may have contracted the
22 disease from a natural source (soil and animal remains) while traveling through the states of North
23 Dakota, Montana, Wyoming, and South Dakota.

24
25 In the past decade, there have been outbreaks of anthrax associated with intravenous drug users in
26 Scotland, prompting the suggestion of including ‘injectational’ anthrax as a type of disease (Ringertz et al.
27 2000; Booth et al. 2010; Jallali et al. 2011). The heroin they used was reportedly contaminated with *B.*
28 *anthracis*, presumably spores. The disease was characterized by skin lesions, sepsis and meningitis with a
29 total of 31 cases and 11 deaths in the 2010 outbreak.

30
31 The ‘anthrax attacks’ in the US in October 2001 are a notable example of the potential for *B. anthracis*
32 spores to be used for malevolent purposes. The intentional release of spores through the US postal system
33 resulted in a total of 22 cases of anthrax (11 inhalational, 11 cutaneous); 5 of the inhalational cases were
34 fatal (Jernigan et al. 2002). Twenty of these cases (91%) were associated closely with the US Postal

1 Service in that those affected were either mail handlers or were exposed at worksites where mail
2 contaminated with *B. anthracis* spores was processed or received. The attack rate at one postal sorting
3 facility was estimated to be 1.2% (Greene et al. 2002; Inglesby et al. 2002).
4

5 The diagnosis of anthrax is based on the clinical picture along with a strong epidemiological history of
6 appropriate occupation and exposure that could include travel and contact with animal products from
7 developing countries. A positive diagnosis of anthrax is made by using the Gram stain to demonstrate
8 square-ended, encapsulated, Gram-positive chains of bacilli in blood smears and tissues (World Health
9 Organization. 2008). The laboratory confirmation of anthrax is made from microbiologic cultures.
10 Cutaneous anthrax is often diagnosed with skin biopsies.
11

12 Anthrax can be prevented or treated effectively with several different anti-bacterial medications if the
13 medications are given early in the course of disease. Delays in diagnosis and institution of appropriate
14 therapy, especially in inhalational anthrax, contribute to the high case fatality rate in human anthrax. The
15 CDC recommends the use of intravenous or oral doxycycline or fluoroquinolones depending on the type
16 and severity of disease (2001). Often, combinations of appropriate antibiotics by the intravenous route
17 are used for severe cases, especially with suspected meningitis. Duration of therapy is often guided by
18 clinical improvement and may be prolonged in cutaneous anthrax. For those who have been exposed,
19 prophylaxis is recommended with oral doxycycline or fluoroquinolones for 60 days to prevent the
20 disease. There is also a recommendation to add a 3-dose regimen of the available vaccine to the oral
21 medications (2001).
22

23 There is an FDA-licensed vaccine for anthrax available in the US. The vaccine is produced by Emergent
24 BioSolutions, Inc., Rockville, MD (BioThrax®, Anthrax Vaccine Absorbed). A precursor to the currently
25 available vaccine was shown to be 92.5% effective in a clinical trial (Brachman et al. 1962). The pre-
26 exposure use of this vaccine is based on quantifiable risk of exposure and is recommended for workers in
27 settings in which repeated exposure to aerosolized *B. anthracis* spores might occur (Prevention 2002;
28 CDC and NIH 2007). These guidelines do not recommend the vaccine for members of the general public
29 who do not engage in work that places them at risk for repeated exposures. There is a recommendation to
30 consider pre-exposure vaccination in emergency first responders under the supervision of an occupational
31 health program for purposes of maintaining a workforce ready and prepared to respond to agents of
32 bioterrorism such as *B. anthracis* (Wright et al. 2010)
33

For non-vaccinated individuals who may have been exposed to aerosolized *B. anthracis* spores, the CDC recommends the following post-exposure prophylaxis: 60 days of selected oral antibiotics in conjunction with a 3-dose regimen of BioThrax® (AVA) vaccine, a combination that has proven effective in nonhuman primates exposed to *B. anthracis* (CDC, 2000). Antibiotics taken by exposed individuals may prevent infection if applied before inhaled spores germinate and reproduce, while the vaccine may promote the immune system to neutralize disease-causing toxins produced by active *B. anthracis* vegetative cells.

B. anthracis occurs in two forms. One is the vegetative form that occurs within the low-oxygen environment of the human or animal host. Once outside the host (for example by means of shedding from the blood at death of an infected host), sporulation commences on exposure to air and *B. anthracis* persists in the environment in the spore form. Anthrax is contracted by animals and humans largely by the uptake of spores from the environment (World Health Organization. 2008). Thus, based on a review of the available epidemiologic literature, human anthrax disease is generally considered to be non-communicable in the classical sense of the vegetative form of the pathogen spreading directly from a person infected with anthrax to another person. There are no data to indicate that patient -to-patient transmission of anthrax occurs (Inglesby et al. 2002). Direct person-to-person transmission of anthrax has not been described for inhalational or gastrointestinal anthrax.

There are rare reports of person-to-person transmission of cutaneous anthrax. There are reports of humans acting as vectors in physically carrying spores on hands or inanimate items such as clothing to close contacts resulting in infection in the close contact (World Health Organization. 2008). In one epidemiologic study in Gambia, the transmission of spores was mediated by inanimate objects such as shared grooming instruments (Heyworth et al. 1975). The most recent example of this is the cutaneous anthrax that developed in a 7-month old infant who most likely came into contact with *B. anthracis* spores while being held by co-workers of his mother at her workplace in New York City that was contaminated with spores during the 2001 intentional release (Freedman et al. 2002).

Disease in Medically Vulnerable Subpopulations

Children are infected by anthrax, though the disease among children is reported rarely in the literature. This likely indicates under-reporting or under-diagnoses rather than a true lower incidence (Bravata et al. 2006). There are no published reports of increased susceptibility to anthrax among children, the elderly, or those among disadvantaged socio-economic status in the US. Similarly, there are no specific reports of increased susceptibility to anthrax among those with immune-compromised conditions such as diabetes or

1 HIV/AIDS. It is postulated that the infectious dose required to cause anthrax infections among those with
2 immune-compromised conditions and lung disease may be lower, based on the experience from the
3 Sverdlovsk accidental release (World Health Organization. 2008). The worldwide literature on anthrax in
4 pregnancy is limited with a total of 6 cases reported (Kadanali et al. 2003; Jamieson et al. 2006). In two
5 cases reported in 2003, both women were successfully treated, though they both experienced pre-term
6 labor and delivery (Kadanali et al. 2003). There are no published reports on possible associations of
7 asthma and anthrax.

9 **Human Infectious Dose**

10 The human infectious dose for *B. anthracis* is not known. With regard to industrial exposures and
11 infections, the body of human evidence with regard to inhalational anthrax suggests that humans have a
12 moderate level of resistance to exposure, given the relative rarity of human cases among animal workers
13 who likely inhaled spores repeatedly (World Health Organization. 2008). No human experimental data
14 are available for inhalational anthrax and it was not possible to determine the infectious doses for the
15 patients affected in the anthrax attacks of 2001 (Greene et al. 2002; Jernigan et al. 2002) or in the
16 Sverdlovsk facility release in 1979 (Meselson et al. 1994). Estimates of the dose needed to cause infection
17 in 50% of exposed individuals (HID₅₀) range from 8,000 to 55,000 spores (Franz 2009) (Wilkening
18 2006). One study estimated the HID₅₀ dose to be as low as 100 spores (Peters and Hartley 2002).
19 Data from experiments with non-human primates for inhalational anthrax provide an estimate in the range
20 of 4,130 to 27,000 spores required to cause lethal infection in 50% of cynomolgus monkeys exposed to *B.*
21 *anthracis* (LD₅₀) (Glassman 1958) (Brachman et al. 1966). A study in rhesus monkeys noted this LD₅₀
22 estimate to be in the range of 96,800 spores.

24 Though inhalational route is considered the most dangerous, many human infections occur by the
25 cutaneous or intestinal route due to consumption of infected meat from terminal near-death or recent-
26 death slaughter of livestock in developing countries. The human infectious dose for *B. anthracis* by these
27 routes is also not known.

29 **Laboratory Acquired Infections**

30 Anthrax infections were frequently reported among laboratory accidents prior to 1965 (Pike et al. 1965).
31 In the past few decades, there have been very few laboratory-acquired anthrax infections, though
32 accidents and exposures have occurred. Of the 15 recently reported laboratory-related incidents involving
33 *B. anthracis* detailed in the Biosafety Appendix, only one incident has resulted in anthrax infection
34 (Biosafety Review, Appendix D).

1
2 In the aftermath of the October 2001 intentional release, a laboratory worker in Texas was confirmed to
3 have cutaneous anthrax (Centers for Disease Control and Prevention (U.S.) 2002; Centers for Disease
4 Control and Prevention (U.S.) 2002). The investigation revealed that the possible source of *B. anthracis*
5 spores may have been the surfaces of vials containing *B. anthracis* isolates that the worker had handled
6 while placing them in the freezer. These isolates were from environmental samples taken during the
7 intentional release investigation.

8 There are several lessons learned from a review of these laboratory incidents. Laboratory-associated
9 infections can occur from laboratory accidents leading to clinical infection in the worker. Only cutaneous
10 anthrax has been confirmed from laboratory exposure in the past 10 years. There were no secondary cases
11 of anthrax in the close contacts of the laboratory worker or in the community as a result of the laboratory-
12 acquired infection. These incidents reinforce the importance of biosafety practices and laboratory worker
13 education and training.

14 15 **Summary**

16 *B. anthracis* causes anthrax, an ancient disease that continues to be seen in animals throughout the world,
17 with very few naturally occurring human infections. The pathogen is, in general, poorly transmissible and
18 humans can acquire the disease when they come into contact with spores, anthrax-infected animals, or
19 anthrax-contaminated animal products such as hides. There is a potential for *B. anthracis* to be highly
20 pathogenic and cause a high fatality rate among humans if not recognized or treated early. Based on the
21 October 2001 intentional release incident, there is high potential for this pathogen to be used in
22 intentional malevolent release scenarios, especially via the inhalational route of exposure. Isolated
23 laboratory-acquired infections have been reported.

24
25 There is a possibility of infection if an individual is exposed to *B. anthracis* spores. Of the three types of
26 anthrax, based on a review of the literature, there does not appear to be any evidence of person-to-person
27 transmission of inhalational or gastrointestinal anthrax. Person-to-person transmission may occur from
28 cutaneous anthrax; this may result from contact with discharges from the lesions that are potentially
29 infectious (Centers for Disease Control and Prevention (U.S.) 2009) or carriage of spores via inanimate
30 objects (Heyworth et al 1975). Cutaneous anthrax resulting from contact with spores from either
31 inanimate objects in the laboratory (Centers for Disease Control and Prevention (U.S.) 2002; Centers for
32 Disease Control and Prevention (U.S.) 2002) or from humans acting as vectors in carrying the spores
33 during close contact has occurred in the US (Freedman et al. 2002).

1 Anthrax can be treated with currently available anti-bacterial medications. There is a vaccine available
2 that is offered to those individuals engaged in laboratory work or other high-risk occupations involving *B.*
3 *anthracis*. This pathogen is expected to be studied in BSL-3 high biocontainment laboratories worldwide,
4 including NEIDL.

5
6 For the purposes of this RA, *B. anthracis* will be analyzed in detail with regard to (1) possible event
7 sequences that could lead to loss of biocontainment at NEIDL resulting in exposure of laboratory workers
8 and the general public to *B. anthracis*; (2) estimates of the amount of pathogen the laboratory workers and
9 general public would be exposed to as a result of those event sequences; (3) probabilistic estimates of
10 initial infection in those exposed to those amounts of *B. anthracis*; and (4) discussion of potential
11 scenarios by which laboratory workers may act as physical vectors for transmission of *B. anthracis* spores
12 to another person. As there is no possibility of secondary transmission of inhalational anthrax and very
13 low possibility of secondary spread in cutaneous anthrax, secondary transmission modeling of spread of
14 infection in the community will not be performed for *B. anthracis*.

16 **3.5.1.2 Francisella tularensis (F. tularensis)**

17 **Introduction**

18 *Francisella tularensis* is the causative pathogen of tularemia, which is an infectious disease of animals
19 that also affects humans. For this RA, *F. tularensis* was selected for analysis based on its characteristic of
20 being highly pathogenic with a high case fatality ratio despite its poor transmissibility (Mahmoud 2008).
21 This pathogen can be transmitted to humans via arthropod vectors and also by close contact with infected
22 animals. Based on a review of the epidemiologic literature, there is no evidence for direct spread of *F.*
23 *tularensis* from a person infected with this pathogen to another person. The human infectious dose for *F.*
24 *tularensis* is not known, though there appears to be evidence that the infectious dose is extremely low for
25 *F. tularensis* subsp. *tularensis*. The potential for laboratory acquired infections (LAI) from *F. tularensis*
26 exists and LAI have been reported. There were no secondary cases of tularemia in the close contacts of
27 the laboratory workers or in the community as a result of the laboratory-acquired infections.

28
29 The common name of ‘rabbit fever’ indicates one of the natural reservoirs of this pathogen. Tularemia
30 was first described as a plague-like disease of rodents in California in 1911 and soon after was recognized
31 as a potentially fatal illness in humans (Dennis et al. 2001; Ellis et al. 2002). The disease occurs
32 worldwide and in the US in animals. There are a significant number of naturally occurring cases reported
33 in the US annually (Centers for Disease Control and Prevention 2002).

1 *F. tularensis* is small Gram-negative coccobacillus of the *Francisella* genus within the *Francisellaceae*
2 family (Dennis et al. 2001; Ellis et al. 2002). The pathogen is a hardy non-spore-forming microorganism
3 that survives for weeks at low temperatures in water, moist soil, hay, straw, and decaying animal
4 carcasses. There are two major subspecies or biovars that are differentiated by virulence testing,
5 biochemical reactions, and epidemiological features. **Francisella tularensis** biovar *tularensis* (type A)
6 is highly virulent and is the most common biovar seen in North America. Type B (biovar *palaeartica*)
7 is relatively benign.

8
9 The natural reservoirs of *F. tularensis* include small animals such as squirrels, rabbits, hares, voles, mice,
10 and water rats (Dennis et al. 2001; Ellis et al. 2002). The pathogen is widely distributed in nature and
11 can be found in diverse animal hosts and habitats and can be recovered from contaminated water, soil,
12 and vegetation. Animals acquire the pathogen through bites by ticks, flies, and mosquitoes, and by
13 contact with contaminated environments.

14 BSL-3 is required for work the fully virulent strain of *Francisella tularensis* in high biocontainment
15 laboratories (Chosewood et al. 2009).

17 **Human Disease and Outbreaks**

18 The exact numbers of worldwide human cases is not known as tularemia is not an internationally
19 notifiable disease. In the US, the incidence of human cases has decreased from the thousands in prior
20 years to several hundred in the 1990s (Centers for Disease Control and Prevention 2002).

21
22 *Francisella tularensis* can infect humans through the skin, mucous membranes, gastrointestinal tract,
23 and lungs (Dennis et al. 2001; Ellis et al. 2002). The route of entry and virulence of the pathogen
24 influence the clinical manifestations. The most common presentation of tularemia is the
25 ulceroglandular form that consists of a skin lesion and infection of the regional lymph node. Tularemia
26 often presents abruptly with fevers, chills, body aches, and sore throat. The illness can progress rapidly
27 to more serious forms such as septicemic and pneumonic forms; these are the clinical forms of most
28 concern with regard to management and mortality. Untreated, the severe forms of tularemia had a
29 fatality rate of 30-60 percent in the pre-antibiotic era. With the advent of antibiotics and modern
30 hospital and intensive care, the overall mortality from tularemia is less than 2 percent (Evans et al.
31 1985).

32
33 There are several routes of transmission of *F. tularensis* to humans (Dennis, Inglesby et al. 2001; Ellis,
34 Oyston et al. 2002). An infection from the bite of an arthropod vector which has previously fed on an

1 infected animal is considered a major route; this leads to the ulceroglandular or septicemic type of
2 tularemia. Direct contact with infected animals during hunting and skinning is also considered a common
3 route of infection in the US; this route may also lead to pneumonic form, apart from ulceroglandular or
4 septicemic type. Pneumonic tularemia results from inhalation of aerosolized pathogen or as a
5 complication of other forms of tularemia such as septicemia. Ingestion of infected animals or
6 contaminated water may lead to oropharyngeal or gastrointestinal tularemia.
7 There are naturally occurring cases of human tularemia in the US; the numbers have dramatically
8 decreased over the past 5 decades. Currently reported cases are generally limited to those involving
9 hunting and trapping of animals.

10
11 In the past decade, there have been two outbreaks of tularemia reported in the US. In 2000, there were 15
12 cases of tularemia (11 were pneumonic, 1 death) reported from Martha's Vineyard in Massachusetts. The
13 risk factor was mowing lawns or cutting brushes (weed whacking). It was postulated that the exposed
14 individuals had inhaled aerosolized *F. tularensis* from an infected small animals (Feldman et al. 2001;
15 Feldman et al. 2003; Matyas et al. 2007). More recently, there were 14 cases of tularemia reported from
16 Utah (Petersen et al. 2008; Calanan et al. 2010). The risk factor was noted to be visiting a lodge and
17 participating in outdoor activities near Utah Lake; the pathogen was transmitted by the bite of the deerfly.

18
19 There are no reports of direct transmission of *F. tularensis* from a person infected with this pathogen to
20 another person, even from the pneumonic form. It is important to note that there were no secondary cases
21 of tularemia reported in contacts of patients described in the outbreaks from Martha's Vineyard and Utah
22 Lake. There is one published report that suggests that bacteria are aerosolized from patients and in animal
23 models of pneumonic tularemia and this could potentially cause secondary human infections (Jones et al.
24 2005); these conclusions have not been validated by other authors or experts

25
26 The diagnosis of tularemia is based on a high index of suspicion, clinical presentation, epidemiological
27 history of exposure or travel to endemic areas, and laboratory confirmation. Rapid testing is not
28 commercially available. Identification of the bacterium by direct examination of secretions, exudates, or
29 biopsy specimens using direct fluorescent antibody or immunohistochemical stains is possible. Bacterial
30 culture is considered the gold standard. Other specialized testing is available only in reference and
31 research laboratories (Dennis et al. 2001).

32
33 Management of patients with tularemia consists of specific anti-bacterial medications and supportive
34 therapy (Dennis et al. 2001; Ellis et al. 2002). The aminoglycoside antibiotics, streptomycin and

gentamicin, are the drugs of choice. In the US, the availability of streptomycin is limited. Another class of antibiotics, the fluoroquinolones have been shown to be active *in vitro*, and ciprofloxacin has been used in outbreaks in Europe. Tetracycline and chloramphenicol are bacteriostatic against *F. tularensis* and have been used to treat tularemia. In mass casualty settings, oral ciprofloxacin and doxycycline are recommended for adults and children.

A vaccine was available for both military and civilian use that was offered to laboratory workers; however, currently, there are no FDA-approved vaccines available for *F. tularensis*.

Disease in Medically Vulnerable Subpopulations

In general, all age groups and both genders are susceptible to *F. tularensis*. There are no reports of increased susceptibility to the pathogen in medically vulnerable Subpopulations. The limited published literature of tularemia is from the 1930s and there are no reports of increased incidence, susceptibility, or worse outcomes in pregnant women.

Human Infectious Dose

The exact human infectious dose of *F. tularensis* is not known. There is strong evidence that the infectious dose is extremely low for *F. tularensis* subsp. *tularensis* and that potentially one to 10 organisms could cause infection in a human. The amount required to cause disease in 50% of humans exposed to the Schu4 strain of *F. tularensis* is estimated to be between 10-50 cells. As few as 10 microorganisms of *F. tularensis* by skin inoculation or 15 microorganisms by aerosol were determined to be sufficient to cause infections in human challenge of immunity studies (Saslaw et al. 1961; Franz et al. 1997). These estimates are also supported by data from laboratory-acquired infection rates that are estimated to be 1 infection/1,000 at-risk worker years in vaccinated laboratory workers (Overholt et al. 1961; Pike 1976; Burke 1977; Shapiro and Schwartz 2002).

Laboratory Acquired Infections

Laboratory-acquired infections (LAI) with *F. tularensis* have been reported from the early days of the study of this pathogen in laboratories; it was consistently in the top three of the lists of LAI from the 1930s to the 1970s both in the US and worldwide (Pike et al. 1965; Pike 1976; Pike 1979). A recent review of select agent incidents reported by the CDC to the National Research Council indicates that of 7 LAI reported to the CDC's Division of Select Agents and Toxins during the period 2003-2009, two were from *F. tularensis* (NRC (National Research Council) 2011; NRC (National Research Council) 2011). The incidence of *F. tularensis*-related LAI have decreased with modern biosafety practices and

1 recognition of the importance of adhering to these precautions; this was especially noted in US maximum
2 biocontainment laboratories such as the USAMRIID (National Research Council (U.S.). Committee to
3 Review the Health and Safety Risks of High-Biocontainment Laboratories at Fort Detrick. 2010).

4 In the past decade, there have been several laboratory incidents involving *F. tularensis*, with very few
5 infections. As noted in the Biosafety Review (Appendix D), during the period 2000-2010, there have
6 been at least 11 incidents reported to the NIH involving this pathogen.

7
8 In 2004, there was an incident involving laboratory researchers at Boston University. Researchers were
9 working under BSL-2 biocontainment protocols with what was believed to be a non-infectious vaccine
10 strain of the *F. tularensis* bacterium. Later, it was determined the bacterial culture also contained the
11 infectious wild-type strain that requires BSL-3 biocontainment precautions. There were a total of 3
12 infections and no deaths. Subsequent investigations resulted in revising standard operating protocols to
13 prevent such incidents from occurring again (Lawler 2005).

14
15 More recently, in November 2009, a laboratory worker at USAMRIID was diagnosed with tularemic
16 pneumonia (National Research Council (U.S.). Committee to Review the Health and Safety Risks of
17 High-Biocontainment Laboratories at Fort Detrick. 2010). She had previously had a non-laboratory
18 related clinical case of tularemia and was found to have positive hemagglutinin titers suggesting
19 immunity to the bacterium. She was working with *F. tularensis* and subsequent investigation concluded
20 that she most likely had an aerosol exposure to the pathogen in the laboratory.

21
22 Laboratory-associated incidents and infections with *F. tularensis* remain a concern. The recent incidents
23 reinforce the importance of biosafety practices and laboratory worker education and training. The
24 incidents also underscore the importance of prompt reporting of laboratory incidents to supervising
25 authorities so that appropriate prophylactic and mitigative strategies can be promptly instituted.

26 27 **Summary**

28 *Francisella tularensis* is the pathogen that causes tularemia, a serious human illness. Human infection
29 results from transmission of *F. tularensis* from the animal reservoir via arthropod vectors; by direct
30 contact with infected animals, or by ingesting contaminated food or water. The human mortality was
31 higher in the pre-antibiotic era; available antibiotics and modern hospital care have decreased the
32 mortality rate to below 2%. There is concern that the pathogen could be used for malevolent purposes.
33 There is no known direct person-to-person transmission of *F. tularensis*.

For the purposes of this RA, *F. tularensis* will be analyzed in detail with regard to: (1) possible event sequences that could lead to loss of biocontainment at NEIDL resulting in exposure of laboratory workers and the general public to *F. tularensis*; (2) estimates of the amount of pathogen the laboratory workers and general public would be exposed to as a result of those event sequences and (3) probabilistic estimates of initial infection in those exposed to those amounts of *F. tularensis*. As there is no risk of direct person-to-person transmission of *F. tularensis*, secondary transmission modeling of the spread of this bacterium in the community following an initial infection will not be performed.

3.5.1.3 Yersinia pestis (Y. pestis)

Introduction

Yersinia pestis is a bacterium that causes the animal and human disease known as plague. For this RA, *Y. pestis* was selected for analysis based on its characteristics of being highly pathogenic with a high case fatality ratio despite its poor transmissibility (Mahmoud 2008). This pathogen can be transmitted to humans via arthropod vectors and also by close contact with infected animals. *Y. pestis* can be transmitted directly from a person infected with this pathogen to another person in the setting of pneumonic plague affecting the lungs. The human infectious dose for *Y. pestis* is considered to be low, though there are no direct human dose-response data available in the literature. The potential for laboratory acquired infections (LAI) from *Y. pestis* exists and LAI have been reported. Laboratory-acquired infections involving *Y. pestis* are rare in the era of modern biosafety practices. The recent case of death from an LAI from an attenuated strain resulted in septicemic plague with no features of pneumonic plague, thus posing minimal risk to the public.

Plague is one of the oldest diseases known to humanity, with the first pandemic dating back to AD 541. There continues to be interest in this pathogen with several thousand human cases of *Y. pestis* infection reported in several countries around the world in recent years and its potential as a biologic weapon (Inglesby et al. 2000; Butler 2009). More recently, this pathogen has been in the news with the report of the death of a wildlife biologist who contracted the disease from the carcass of a mountain lion (Wong et al. 2009) and the death of a researcher exposed to an attenuated strain of *Y. pestis* in the laboratory (Centers for Disease Control and Prevention (U.S.) 2011).

Primarily a disease of wild rodents, plague is spread from one rodent to another by fleas, cannibalism, or possibly from contaminated soil. Wild plague exists in its natural foci of rodents independent of human activity. Domestic plague is associated with rodents living in close proximity to humans and can cause

disease in both rodents and humans (Dennis et al. 1999). *Yersinia pestis* occurs in 17 of the contiguous western U.S. states (Dennis and Mead, 2010).

Y. pestis is maintained in nature through endless cycles between fleas and reservoir hosts, such as rodents. Wildlife biologists have increasingly realized that certain wild mammal species also are highly susceptible to plague (Gage and Kosoy 2005). More recently, it has been recognized that cats and mountain lions could be infected with plague and transmit to humans (Gage et al. 2000) (Wong et al. 2009). The pathogen has also been shown to survive and persist in soil, especially in the presence of blood, thus raising the possibility of another reservoir for human infections (Eisen et al. 2008). *Y. pestis* is a Gram-negative coccobacillus that belongs to the group of bacilli with low resistance to environmental factors. Sunlight, high temperatures, and desiccation have a destructive effect on the pathogen.

This pathogen is studied in laboratories around the world, including in maximum biocontainment laboratories in the US. Virulent *Y. pestis* is a BSL-3 pathogen and also is a Select Agent requiring registration with CDC for the possession, use, storage, and transfer of the bacterium (Chosewood et al. 2009).

Human Disease and Outbreaks

Humans are extremely susceptible to plague and may be infected either directly or indirectly. Indirect transmission through the bite of a flea is the most common route of transmission between plague-infected rodents and humans. People can be infected directly from a plague-infected rodent or other animal while handling, skinning, or cutting up the meat. *Y. pestis* enters humans through skin lesions or through the mucous membranes of the mouth, nose, or eyes. More recently, it was postulated that human primary pneumonic plague was caused by inhaling aerosolized bacteria during the post-mortem examination of an infected mountain lion (Wong et al. 2009).

Human disease occurs primarily in three forms (Dennis et al. 1999). Bubonic plague is the most common and classical form. This condition is characterized by enlarged regional lymph nodes (the ‘buboes’) resulting from exposure to the pathogen through the skin or mucous membrane. Primary septicemic plague is an overwhelming blood stream infection with the pathogen following exposure through the skin. Primary pneumonic plague occurs when *Y. pestis* aerosols are inhaled through the respiratory tract. Less common plague syndromes include plague meningitis which follows the seeding of the pathogen into the central nervous system from the bloodstream (from septicemic plague) Plague pharyngitis follows inhalation or ingestion of the pathogen.

1
2 Of these forms, bubonic plague is not transmissible directly from person-to-person. Based on a review of
3 the available epidemiologic literature, pneumonic plague where the pathogen is in the lungs can be
4 transmitted directly person-to-person. This may be a result of primary pneumonic plague or secondary
5 pneumonic plague resulting from spread of *Y. pestis* to the lungs from the bloodstream (from septicemic
6 plague). The pathogen is not truly airborne and so transmission of pneumonic plague from person-to-
7 person requires close face-to-face contact within 3-6 feet of a person with pneumonic plague who is
8 actively coughing. From historical accounts and recent experiences, the risk of transmission is considered
9 lower than previously claimed (Kool 2005).

10
11 The first certain pandemic, known as Justinian's plague, was recorded in the sixth century AD in Africa,
12 Asia, and Europe and claimed large numbers of victims. The second pandemic in the 14th century is well
13 known as the 'black death' or 'great pestilence' that caused the death of a third of Europe's population
14 at that time. The third pandemic occurred in the 19th century, causing similar havoc in Asia. Plague
15 remains endemic in many natural foci around the world. The decrease in the incidence of plague today is
16 due primarily to the improvement of living standards and health services in many countries. Despite the
17 general decline in the incidence of plague worldwide, the numbers of countries affected by plague
18 remains substantial. Human cases continue to be reported from several countries, with most of them being
19 in developing countries (Butler 2009).

20
21 In the US, 415 cases were reported from 1970-2007 (Dennis and Mead 2010). Recent cases that received
22 attention were in two New Mexico residents who became ill and were diagnosed with plague in New
23 York City (2003) and a case of fatal pneumonic plague in a wildlife biologist who contracted the
24 pathogen while performing a necropsy examination on an infected mountain lion (Wong et al. 2009).

25
26 Historically, plague has been considered in biologic warfare with reports of the Japanese dropping
27 plague-infected fleas over China during World War II (Inglesby et al. 2000). Following this, several
28 countries including the US and the former Soviet Union initiated programs to look at plague as a biologic
29 weapon. There are no reports of accidental or intentional release of plague. There is one report of a
30 scientist with suspect motives ordering *Y. pestis* in the mail (Inglesby et al. 2000) and another report of
31 samples of this pathogen being 'mishandled' (Malakoff and Drennan 2004).

32
33 The diagnosis of plague is based on the clinical presentation along with a strong epidemiological history
34 of appropriate exposure that includes contact with small wild animals. A positive diagnosis may be made

1 from blood, sputum, or lymph-node samples by the characteristic bipolar staining of the bacteria using
2 Wright-Giemsa stain (safety pin appearance). The laboratory confirmation is made from microbiologic
3 cultures. Other diagnostic methods such as immunodiagnosis and PCR-based tests that were previously
4 only available through state public health laboratories, the CDC, or military laboratories (Inglesby et al.
5 2000) are now more widely available (Butler 2009).

6
7 Untreated, mortality, particularly from pneumonic plague, may reach high levels. In the pre-antibiotic
8 era, nearly 100% of the cases were reported to be fatal. When rapidly diagnosed and promptly treated,
9 plague may be successfully managed with antibiotics reducing mortality from 60% to less than 15%.

10
11 Plague can be treated using several classes of antibiotics. Streptomycin was the mainstay of treatment for
12 several decades and remains the drug of choice (though availability of this medication is limited in the
13 US). Monotherapy with gentamicin has been used in the US. Doxycycline or tetracycline has been used as
14 an alternative for treatment. Cephalosporins and other beta-lactams, along with fluoroquinolones, have
15 been shown to be effective in animal models. Chloramphenicol is also effective, though it is rarely used in
16 the US due to toxicities. The 1995 appearance in Madagascar of a strain of *Y pestis* showing resistance to
17 routinely used antibiotics is a matter of much concern (Butler 2009). In that situation, combinations of
18 medications have been used.

19
20 Doxycycline and trimethoprim/sulfamethoxazole have been recommended as prophylactic medication for
21 those exposed to pneumonic plague. Plague vaccines have been administered to high-risk workers in the
22 past; however the vaccine is no longer available in the US.

23 24 **Disease in Medically Vulnerable Subpopulations**

25 Individuals of all ages are susceptible to plague. In recent years, there were many cases of plague reported
26 in children, including in the 1995 outbreak in Madagascar (Butler 2009). There is an increased incidence
27 of plague among those in lower socio-economic strata in developing countries due to their closer
28 proximity to rodents and fleas. However, there are no published reports of increased susceptibility to
29 plague among children, the elderly, or those among disadvantaged socio-economic status in the US. The
30 literature on plague in pregnancy is extremely limited with only three published reports (Mann and
31 Moskowitz 1977; Coppes 1980; Wong 1986). There are no reports of increased susceptibility to plague in
32 pregnancy although there is a mention of septic abortion. There are no published reports on possible
33 associations of plague and asthma.

Human Infectious Dose

The human infectious dose for *Y. pestis* is considered to be low, though there are no direct human dose-response data available in the literature. The infectious dose for humans exposed to *Y. pestis* aerosols has been stated to be between 100-500 organisms although from the reference, it is not clear whether those numbers were derived from animal or human data (Franz et al. 1997). Epidemiological information from human outbreaks of pneumonic plague have lead to estimates of a low attack rate, with approximately 8% of close, unprotected contacts of symptomatic primary cases becoming secondarily infected (Begier et al. 2006) (Ratsitorahina et al. 2000). This likely is due to the low transmissibility of the pathogen rather than a higher infectious dose (Kool 2005).

Laboratory Acquired Infections

Plague infections have been reported from laboratory incidents prior to 1965 with at least four known cases; the last was reported in 1959 (Pike et al. 1965) (Burmeister et al. 1962). Of the 7 recently reported laboratory-related incidents involving *Y. pestis* detailed in the Biosafety Review (Appendix D), there have been no reports of plague infection. Several laboratory workers received prophylactic medications.

In 2010, there was a report of the death of a senior laboratory researcher at the University of Chicago who was found to be infected with an attenuated strain of *Y. pestis* that had to date not been reported to cause any laboratory-acquired infections or fatalities (Centers for Disease Control and Prevention (U.S.) 2011). The route of transmission was not clearly identified and the researcher developed primary septicemic plague. A detailed investigation revealed that the researcher had underlying co-morbidities that included diabetes and hitherto undiagnosed hemochromatosis, which could have contributed to his increased susceptibility to the attenuated strain. *Y. pestis* has an inherent need for iron and it is postulated that in the setting of iron overload, the researcher had increased susceptibility to the attenuated strain. The CDC concluded that under certain environmental and host conditions, even infection with attenuated strains of pathogens may result in severe disease and death.

Laboratory-acquired infections involving *Y. pestis* are rare in the era of modern biosafety practices. The single case of death from an attenuated strain resulted in septicemic plague with no features of pneumonic plague, thus posing minimal risk to the public. Laboratory worker education and training remain important components of biosafety, as well as prompt reporting and seeking of medical attention when symptomatic.

Summary

Y. pestis causes plague, an ancient disease that continues to be seen in animals throughout the world, and in humans, mostly in developing countries. The pathogen is in general, poorly transmissible and humans acquire the disease from the bite of infected fleas or when handling infected animals. It is widely distributed in the tropics and subtropics and in warmer areas of temperate countries. Several thousand cases of human disease have been reported from several countries during the period 1993-2004, with a case fatality rate of 7.1% (Butler 2009). Naturally occurring human infections in the US are rare and limited geographically to the western states. There is a potential for *Y. pestis* to be highly pathogenic and cause a high fatality rate, especially if the diagnosis and treatment are delayed. There have been no intentional releases in modern times, though the potential for its use as a biological weapon remains. Only one laboratory-acquired infection has been reported in the US since 1959; the circumstances were unique in that the researcher had an underlying undiagnosed condition that likely contributed to his increased susceptibility to an attenuated strain of *Y. pestis*.

There is a possibility of infection if an individual is exposed to *Y. pestis*. Of the three types of plague, bubonic plague is not known to be transmitted directly from person-to-person. There is a possibility of transmission of pneumonic plague directly from person-to-person. Plague can be treated with currently available anti-bacterial medications, though resistance has been reported. There is no plague vaccine available for use in the US at this time. This pathogen is expected to be studied in BSL-3 high biocontainment laboratories, including NEIDL.

For the purposes of this RA, *Y. pestis* will be analyzed in detail with regard to (1) possible event sequences that could lead to loss of biocontainment at NEIDL resulting in exposure of laboratory workers and the general public to *Y. pestis* including routes of exposure ; (2) estimates of the amount of pathogen the laboratory workers and general public would be exposed to as a result of those event sequences; (3) probabilistic estimates of initial infection in those exposed to those amounts of *Y. pestis*, including the type of infection (bubonic, septicemic, or pneumonic); and (4) transmission modeling of the potential for secondary transmission of *Y. pestis* among the general public in the event of a laboratory worker or member of the public experiencing an initial infection of pneumonic plague.

3.5.1.4 1918 H1N1 Influenza Virus (1918 H1N1V)

Introduction

The 1918 H1N1 Influenza Virus (1918 H1N1V) is the prototypical pandemic strain of influenza and was the etiology of the 1918-1919 “Spanish Flu” pandemic (reviewed in (Taubenberger and Morens 2006; Morens and Fauci 2007). For this RA, 1918 H1N1V was selected for analysis based on its characteristics of being highly transmissible and highly pathogenic (Mahmoud 2008). The case fatality rate for this pathogen is considered high, though relatively lower compared to pathogens such as SARS-associated corona virus. This pathogen is easily transmitted directly from person-to-person. The human infectious dose for 1918 H1N1V is not known. Though there have been no LAI reported with 1918 H1N1V, the potential for LAI with influenza viruses exists and these have been reported. The risk of secondary transmission in the community exists from LAI resulting from influenza viruses.

The 1918-1919 "Spanish Flu" is the deadliest influenza pandemic known with estimates of 675,000 deaths in the US and 50-100 million deaths worldwide. Contrary to popular opinion, this was not the first influenza pandemic to occur; there are reports of the first recorded pandemic from 1510 AD (500 years ago) (Morens et al. 2010). With many unique characteristics in terms of the biology of the virus, the disease it caused, and the death toll among healthy young adults, the 1918 H1N1V remains an important pathogen to study.

The impact of the 1918 H1N1V is not limited to just this pandemic. From analysis of circulating influenza viruses and pandemics since then, it is postulated that all influenza A cases worldwide have been caused by descendants of the 1918 virus, literally earning this pathogen the moniker of “the Mother of All Pandemics” for reasons beyond its virulence (Taubenberger and Morens 2006). The only exceptions are the avian influenza viruses H5N1 and H7N7.

1918 H1N1V is a spherical or pleomorphic, single-stranded, negative-sense RNA enveloped virus of the genus *Influenzavirus A* belonging to family *Orthomyxoviridae*. The virus was recovered from lung tissue from victims of the Spanish Flu and has been studied extensively; the sequencing of the entire coding region was completed and the fully reconstructed virus was generated for the first time in 2005 (Taubenberger et al. 1997; Reid et al. 2000; Tumpey et al. 2005). Much of the laboratory work on pathogenicity of the virus has been performed on ‘reconstructed’ or recombinant influenza viruses (Tumpey et al. 2004; Tumpey et al. 2005; Tumpey et al. 2005). These 1918 recombinant viruses exhibit pathogenicity, can infect laboratory animals, and behave in essence as the original virus. There is variability in the transmission potential of the recombinant viruses when they contain less than the entire

complement of 8 gene segments (reviewed in (Tumpey and Belser 2009). An interesting observation was that the 1918 H1N1V did not arise from genetic re-arrangement between a human and animal virus as has been the case for most other pandemic influenza viruses, but rather it was gene adaptation.

This RA considers both the original 1918 H1N1V and the recombinant viruses used in laboratory work to be equivalent with regard to their potential for causing human disease and ability to be transmitted from person-to-person. The pathogen description is focused on what is known of the 1918 H1N1V; additional information gleaned from the study of other circulating influenza viruses and more recent pandemics is also provided for context as to how influenza would be managed in the 21st century.

The origins of 1918 H1N1V are not known, though the ancestral sources of its genes are considered avian (Reid et al. 2004; Taubenberger 2006). There is no known natural reservoir for 1918 H1N1V (Taubenberger 2006). Influenza A in general can infect several different species, including humans, ducks, chickens, pigs, whales, horses, and seals.

BSL-3 is required for work 1918 H1N1V in high biocontainment laboratories (Chosewood et al. 2009).

Human Disease and Outbreaks

The 1918 H1N1V was the cause of the 1918-1919 Spanish Flu pandemic which is the most devastating of known influenza pandemics. It is estimated that roughly one third of the world's population at that time was affected by the disease; there were an estimated 675,000 deaths in the US and 50-100 million worldwide (Taubenberger and Morens 2006; Morens and Fauci 2007).

One key feature of this pandemic was the high case fatality rate among healthy young adults; in reviewing the data for excessive deaths due to influenza and pneumonia from 1918-1919, the less than 65 year age group accounted for 99% of those deaths (Taubenberger and Morens 2006). There appeared to be a relative sparing of older adults who were born before 1889 and had experienced or lived through the prior influenza pandemic. The high fatality rate caused by this pathogen has been a subject of great debate and was likely a combination of its biology and the high incidence of post-influenza pneumonia noted in victims (Morens et al. 2008). It is interesting to note that all influenza A descendants of the 1918 H1N1V have only a fraction of the parent pathogen's virulence or case fatality rate.

The attack rates for 1918 H1N1V were high in the younger age groups, with incidence rates of 300-400/100,000 individuals noted for the 5-25 age groups (Taubenberger and Morens 2006). Older adults had attack rates that were two-fold lower. The overall fatality rate of 1918 H1N1V in the US was

1 estimated to be nearly 2.5 percent, with higher rates in the age group 20-40 (Taubenberger and Morens
2 2008). In comparison, all other influenza A pandemics have a fatality rate of less than 0.1 percent. Based
3 on CDC statistics, seasonal influenza attack rates in the US typically range between 5-20% of the
4 population and there are, on average, 36,000 fatalities attributable to influenza every year (Fiore et al.
5 2010).

6
7 The reproductive number (R_0), the average number of secondary cases caused by an index human case
8 with 1918 H1N1V, has been estimated for different countries and settings. Overall, the range for R_0 was
9 in the range 1.5 to 3.5 for large US cities (Mills et al. 2004) (Bootsma and Ferguson 2007) (Chowell et al.
10 2007) Estimates have been in that range for most other locations such as Iceland (2.2) (Dowell and Bresee
11 2008) England and Wales (2.1) (Viboud et al. 2006) and Switzerland (spring wave 1.49, fall wave 3.75)
12 (Chowell et al. 2006)

13
14 Since the 1918 Spanish Flu, there have been several influenza pandemics (all caused by influenza A) that
15 have affected humans worldwide, including the US. Each of the viral strains responsible for pandemics
16 has, by definition, been described to be a new or previously unknown strain of influenza virus. The 1977
17 outbreak has several features that make it unique. The disease was noted in children and young adults
18 generally less than 23 years old and some consider this to be a Russian Flu outbreak and not a true
19 pandemic (US Department of Health and Human Services 2011). The virus was shown to be genetically
20 and antigenically similar to the H1N1 virus that had circulated in 1950 (Nakajima et al. 1978) and this has
21 raised the question of the origin of the 1977 virus. It seems unlikely that the virus remained unchanged in
22 human hosts or animal reservoirs between 1950 and 1977; some speculate that the virus may have been
23 accidentally re-introduced into nature in 1977 from a frozen state, possibly a laboratory freezer (Ennis
24 1978; Kendal et al. 1978; Webster et al. 1992; Zimmer and Burke 2009).

25
26 The most recent was the 2009 H1N1 influenza pandemic that originated in Mexico and caused a
27 worldwide pandemic (Peiris et al. 2009; Schuchat et al. 2011; Sverdlow et al. 2011). Though there was
28 concern for high morbidity and mortality from this novel influenza A virus with human, avian, and swine
29 ancestry, the pandemic, in the end, was milder than expected.

30
31 Seasonal influenza is the classical febrile illness with fever, cough or sore throat, accompanied by chills,
32 severe myalgias, fatigue, and headaches. The incubation period of seasonal influenza is short, typically 2
33 days, with a range of 1-4 days (Bridges et al. 2003). Complications include primary viral pneumonia,
34 secondary bacterial pneumonia, or combined bacterial and viral pneumonia (Barnard 2009). Pandemic

influenza caused by 1918 H1N1V or a new strain would likely follow a similar pattern with likely variations in the incubation period and severity of illness.

Influenza viruses in general and 1918 H1N1V, in particular, can be transmitted directly from person-to-person. The routes of transmission include large droplet, aerosol, direct contact with virus-laden secretions, and via fomites (Bridges et al. 2003; Tellier 2006). The exact contribution of these modes in transmission of influenza is not known; however droplet mode appears to be the most common with aerosol transmission posing a concern for infection control and biosafety.

The diagnosis of 1918 H1N1V would be based on clinical presentation and laboratory confirmatory testing using molecular methods such as PCR. With the experience of 2009 H1N1 pandemic (2009), it is very likely that currently available rapid influenza antigen tests would have suboptimal test characteristics for diagnosing 1918 H1N1V. Other modalities of testing for influenza in general include direct fluorescent antibody testing; the gold standard would be viral culture and sequencing.

Management of patients with 1918 H1N1V would consist of supportive therapy including intensive care and treatment with specific anti-viral medications such as neuraminidase inhibitors or adamantanes. Circulating influenza strains often have variable and varying anti-viral medication susceptibility profiles; as such, the use of anti-viral medications for an outbreak of 1918 H1N1V would have to be based on testing of the circulating strain and its specific anti-viral susceptibility profile. In an outbreak situation with 1918 H1N1V, it would be very likely that treatment and prophylaxis with neuraminidase inhibitors and/or adamantanes would be offered until more information was available; if the circulating strains were sensitive to these medications, there would be good efficacy in treating or preventing illness. There is, of course, the risk of the pathogen developing resistance to these medications as has been noted for seasonal and pandemic influenza, especially in those on treatment or with an immunocompromised condition (2009; 2009; Couturier et al. 2010; Gubareva and Fry 2010; Gubareva et al. 2010).

There is no specific vaccine for 1918 H1N1V. Recent observations, however, provide some support for optimism with regard to existing vaccines and immunity in the population. The population today, as compared to 1918, has pre-existing immunity to the influenza antigens such as H1N1, and other related viruses including H3N2; all humans older than 2–3 years have immunity to both H1N1 and H3N2 viruses (Murphy 2008). There is evidence of cross-protection among vaccines (seasonal influenza vaccine & 2009 H1N1 and 2009 H1N1 pandemic vaccine & 1918 H1N1V) (Johns et al. 2010; Manicassamy et al. 2010; Medina et al. 2010). The search for a ‘universal’ influenza vaccine that would cross-protect against

several different strains is an active area of research (Epstein and Price 2010; Henderson 2010; Rudolph and Ben Yedidia 2011). With this background, it is possible that vaccination to protect or at least mitigate disease due to 1918 H1N1V would be available at some point after an outbreak.

During the 1918 Spanish Flu pandemic, there was an interesting set of observations from a few studies that blood transfusions or blood products from convalescent patients were of benefit in decreasing risk of death in patients (Luke et al. 2006). There are parallels in modern day medicine of using pathogen-specific immune globulin for post-exposure prophylaxis for conditions such as hepatitis A, hepatitis B, and varicella zoster virus infection. The ‘passive immunization’ protocol for 1918 H1N1V would have to be modified and updated to 21st century scientific and ethical standards before there is any consideration of application to patients today.

Disease in Medically Vulnerable Subpopulations

In general, influenza affects all age groups. For seasonal influenza, morbidity and mortality is noted at extremes of ages, those with medical co-morbidities, and pregnant women. Pandemic influenza has the potential to preferentially affect Subpopulations; the 1918 H1N1V was especially severe and fatal for younger age groups. {Rasmussen, 2011 #2231; Mosby, 2011 #13693; Louie, 2011 #2228; Patel, 2010 #2276; Labant, 2009 #2285; Jamieson, 2009 #10568} Pregnant women are considered to be immune-suppressed and they are at high risk of adverse events from seasonal and pandemic influenza (Jamieson et al. 2009; Siston et al. 2010; Mosby et al. 2011; Rasmussen et al. 2011). Seasonal influenza related hospitalization rates from selected acute cardiopulmonary conditions were found to nearly 5-fold higher in pregnant women in their third trimester (Neuzil et al. 1998). Specifically with respect to pandemic influenza, the historical mortality rates of pregnant women have been noted to be in the range of 20 to 51% for the 1918 and 1957 influenza pandemics (reviewed in (Callaghan et al. 2010)). In reviewing observations from the 2009 H1N1 influenza pandemic, pregnancy was associated with an increased risk of hospital and intensive care unit admission and of death (Mosby et al. 2011). Pregnant women were disproportionately represented in hospitalizations and deaths; pregnancy-specific mortality rates were not provided.

Those with co-morbidities such as HIV/AIDS are considered at increased susceptibility to seasonal influenza, however, a recent review of the literature has found no evidence of increased susceptibility to pandemic influenza in the setting of HIV infection. However, it would appear that more studies are needed (Sheth et al. 2011). Diabetes is considered a risk factor for adverse outcomes in influenza infection; this has been noted for seasonal and pandemic influenza (Diepersloot et al. 1990; Valdez et al.

1999; 2000; Allard et al. 2010). Applying observations from seasonal and prior pandemics including the 1918 Spanish Flu, with regard to 1918 H1N1V, it would be likely that the pathogen would preferentially affect younger age groups, the elderly would likely be relatively spared, diabetics would experience worse outcomes, HIV/AIDS patients may experience worse outcomes, and pregnant women would be severely affected.

Preliminary reports from the 2009 H1N1 influenza pandemic have suggested a disproportionate impact of the pandemic on racial and ethnic minorities (Kwan-Gett et al. 2009; Centers for Disease Control and Prevention 2010; Truelove et al. 2011; Uscher-Pines et al. 2011; Wenger et al. 2011), indicating higher rates of hospitalization, morbidity and mortality among racial/ethnic minorities. No clear reason was noted for the increased hospitalization and mortality, though it was postulated that underlying chronic diseases may have played a role. A detailed study based on survey responses of minorities during the 2009 influenza pandemic has also expressed concern of the disproportionate impact of the pandemic, however, the authors were unable to demonstrate an increased risk of susceptibility when controlled for socioeconomic status and demographics (Quinn et al. 2011).

Human Infectious Dose

The human infectious dose of 1918 H1N1V is not known. There are experimental data from the early 1970s that looked at infections in human volunteers after exposing them to a related H1N1 strain of influenza virus (Carrat et al. 2008). In these volunteers, doses ranging from ten thousand to one million CCID₅₀ result in approximately 80% to 95% infection probability. In other experiments (Alford et al. 1966), the low-dose inhalational data reveal that roughly 50% of unprotected humans were infected after inhaling doses of 1–5 CCID₅₀. Thus the human infectious dose is presumed to be low for 1918 H1N1V.

Laboratory Acquired Infections

During the period 2000-2010, there were 7 incidents reported in government and academic laboratories as noted in the Biosafety Review (Appendix D). These included a centrifuge leak and other incidents leading to potential exposures of several different strains of influenza virus. There were no influenza virus infections reported and no deaths from these incidents.

From a review of the published literature, there are at least 3 laboratory-acquired infections reported for influenza viruses (Wentworth et al. 1997; Harding 2006). Of these, symptomatic influenza infections were reported in two laboratory workers who were involved in taking nasal swabs from laboratory pigs infected with a swine influenza virus. The influenza viruses isolated from the laboratory workers were

antigenically identical to the inoculum swine influenza virus used in the experiments. Partial gene sequencing of the viruses isolated from humans indicated that they were direct descendants of the inoculum swine virus; they were 99.7% identical with regard to the hemagglutinin genes.

Summary

The 1918 H1N1V is a pathogen that has caused one of the deadliest influenza pandemics known. Recovery of the pathogen and complete sequencing has allowed scientists to construct ‘recombinant’ influenza viruses that contain some or all of the genes from 1918 H1N1V. This pathogen is extensively studied in high biocontainment laboratories around the world, including the US. The pathogen caused severe illness and death in healthy young individuals in the 1918-1919 pandemic. There are antiviral medications that could potentially be effective against this pathogen. There is no vaccine specifically for 1918 H1N1V. There is a possibility of infection if an individual is exposed directly to this pathogen; secondary cases are likely to occur as the pathogen can be transmitted directly from person-to-person. Laboratory-acquired infections with influenza virus have been reported.

For the purposes of this RA, 1918 H1N1V will be analyzed in detail with regard to: (1) possible event sequences that could lead to loss of biocontainment at NEIDL resulting in exposure of laboratory workers and the general public to 1918 H1N1V; (2) estimates of the amount of pathogen the laboratory workers and general public would be exposed to as a result of those event sequences and (3) probabilistic estimates of initial infection in those exposed to those amounts of 1918 H1N1V and (4) secondary transmission modeling of the spread of 1918 H1N1V in the community following an initial infection.

3.5.1.5 SARS-associated Coronavirus (SARS-CoV)

Introduction

The Severe Acute Respiratory Syndrome-associated coronavirus (SARS-CoV) is an emerging pathogen that was first discovered and described in 2003. For this RA, SARS-CoV was selected for analysis based on its characteristics of being highly transmissible and highly pathogenic with a high case fatality rate (Mahmoud 2008). This pathogen is easily transmitted directly from person-to-person. The human infectious dose for SARS-CoV is not known. The potential for LAI with SARS-CoV exists and such infections have been reported. The risk of secondary transmission in the community exists from SARS-CoV laboratory acquired infections and this has been reported from China; the secondary infections were in a limited number of close contacts.

1 The disease caused by SARS-CoV, severe acute respiratory syndrome (SARS), was first noted as an
2 atypical pneumonia in patients and their health care providers in a rural province in China; the pathogen
3 spread within weeks to several countries around the world. Overall, there were nearly 8000 confirmed
4 cases and 800 deaths.

5
6 SARS-CoV is an RNA virus classified in the genus *Coronavirus*, family *Coronaviridae*, order
7 *Nidovirales* (Weiss and Navas-Martin 2005). The virus was first isolated from patient samples from the
8 worldwide outbreak in 2003 by viral culture and identified by electron microscopy and complete genomic
9 sequencing (Parashar and Anderson, *International Journal of Epidemiology* 2004;33:628–634).

10
11 The natural reservoirs appear to be horseshoe bats, *Rhinolophus* species (Shi and Hu 2008). It is
12 hypothesized that human infections occurred via numerous mammalian species used for food in Eastern
13 Asian cultures (Guan et al. 2003; Feng and Gao 2007).

14
15 SARS-CoV propagation in cell culture and the initial characterization of viral pathogens recovered in
16 cultures of SARS-CoV specimens must be performed in a BSL-3 facility using BSL-3 practices and
17 procedures. SARS-CoV is currently not on the list of HHS and USDA Select Agents and Toxins.

18 19 **Human Disease and Outbreaks**

20 SARS-CoV causes the clinical disease called severe acute respiratory syndrome (SARS). This is a highly
21 infectious viral disease of humans first described in 2003 and retrospectively recognized earlier in
22 November 2002. The disease is highly transmissible among humans and is characterized by fever,
23 malaise, and headache and progressing rapidly to frequently fatal atypical pneumonia. The highest attack
24 rate was noted in Beijing (25% among males aged 20-39) (Liang and Xue 2004). Secondary household
25 attack rates were 10% in Toronto, 8% in Hong Kong, 6.2% in Singapore and 4.6% in China (Goh et al.
26 2004) (Lau et al. 2004) (Wilson-Clark et al. 2006) The disease was mild in children and severe in adult
27 age groups with an overall *case fatality rate* (CaseFR, percentage of those individuals who were
28 diagnosed with SARS and died as a result of SARS) worldwide of 9.6% during the 2003 outbreak,
29 although the fatality rate reached 50 percent among patients >60 years old (Anderson et al. 2004; Liang
30 and Xue 2004; Zhong and Wong 2004; Gillim-Ross and Subbarao 2006). Initially, SARS-CoV was
31 transmitted rapidly and mortality rate was high. As the epidemic continued and prevention/control
32 methods were implemented, CaseFR fell to 0 in many countries (Chan-Yeung and Xu 2003) as a result of
33 prompt identification and institution of supportive care in a hospital setting.

1 The estimates of the incubation period from the China/Hong Kong data were in the range of 2-12 days
2 (Anderson et al. 2004). In Toronto, the estimate was a mean of 5 days (median 4 days; range 2-10 days)
3 (Varia et al. 2003); overall worldwide data consistently estimated the range to be 4 to 6 days (Donnelly et
4 al. 2004). The infectious period estimated from the Amoy Gardens, Hong Kong cluster of cases was in the
5 range of 5-15 days with peak viral loads from naso-pharyngeal washes noted at day 10 and correlated
6 with symptoms (Peiris et al. 2003).

7
8 The 2003 spread of SARS-CoV across several continents in a shortspan of days to weeks represented a
9 modern day outbreak of an emerging infection. One of the important lessons learned from this outbreak
10 was that air travel by individuals exposed to the pathogen who were in their incubation period can lead to
11 outbreaks in their destination location when they start exhibiting symptoms of the disease. Another
12 lesson was that efficient direct person-to-person transmission of SARS can occur, leading to large
13 outbreaks in the community. Worldwide, there were a total of 8096 confirmed cases reported to the WHO
14 as of December 31, 2003 Mainland China, followed by Hong Kong Special Administrative Region,
15 Taiwan ROC, Canada and Singapore accounted for the majority of cases. There were a total of 27
16 confirmed cases reported from the US.

17
18 There is a large body of literature on the transmission of SARS with the majority of the work describing
19 the large outbreaks in China, Hong Kong, Canada and Singapore. Overall, it was estimated that one
20 person infected with SARS transmitted the disease to 2 to 3 other contacts in a population that had not yet
21 instituted control (Lipsitch et al. 2003). There was a phenomenon described as “super spreaders” that
22 referred to the observation that some individuals spread the disease to many other contacts. In Singapore,
23 it is hypothesized that individual patients may have transmitted the virus to >10 persons (2003) Though
24 large outbreaks occurred, it is also important to note that most SARS patients transmitted the virus to no
25 others. In Singapore it was noted that after the institution of intensive infection-control measures, 81% of
26 probable SARS patients had no evidence of transmission to other persons (Peck et al. 2004). Despite
27 numerous unprotected exposures, there was no serologic evidence of healthcare-related SARS-CoV
28 transmission in the US, which may have been related to the relative absence of high-risk procedures or
29 patients and prompt institution of bio-safety practices (Peck et al. 2004). The transmissibility of SARS-
30 CoV is comparable to that of 1918 pandemic influenza (Mills et al. 2004; Dowell and Bresee 2008) and
31 lower than that of the measles virus (each patient with measles spread it to an average of 15–18 other
32 individuals prior to wide scale immunization) (Anderson et al. 2004).

1 An important lesson learned from the SARS outbreak was the high occupational risk posed to healthcare
2 workers from patients that were not yet recognized to have SARS and inadequate infection prevention
3 practices. Sixty three percent of SARS cases in Hanoi hospitals, 46% in Hong Kong, 76% in Singapore
4 and equally high rates in Toronto were in healthcare workers (Low and Wilder-Smith 2005). An increased
5 awareness of SARS among the public and healthcare workers coupled with a high index of suspicion for
6 possible cases led to the prompt institution of universal bio-safety practices; this resulted in dramatically
7 reduced transmission and infections during the course of the epidemic from Asia to North America and
8 Europe. The most effective public health and bio-safety strategies were respiratory isolation of
9 symptomatic patients, quarantine of exposed asymptomatic individuals, appropriate personal protective
10 equipment for healthcare workers and good hand hygiene practices.

11
12 The natural route of SARS-CoV transmission to humans is initially thought to have occurred by
13 inhalation of aerosolized blood and body fluids from infected mammals, primarily *Paguma larvata*, the
14 Himalayan palm civet cat (Feng and Gao 2007; Shi and Hu 2008). Direct human-to-human transmission
15 is thought to have occurred via respiratory droplets, infected bodily fluids, and fomites (Weiss and Navas-
16 Martin 2005; Lo et al. 2006). Aerosol transmission was considered responsible for rapid human-to-human
17 transmission in medical facilities, high density residential facilities, and aircraft, with rapid spread
18 internationally (McDonald et al. 2004).

19
20 There is no specific medication for prophylaxis or treatment available for SARS-CoV infection at the
21 present time; there is also currently no vaccine available for this virus. Several pharmacologic and
22 biologic regimens had been tried during the 2003 outbreak, though there are no controlled trials to judge
23 their usefulness; similarly researchers are working on several vaccine candidates and approaches against
24 the virus to either prevent and treat the disease (Groneberg 2005 Lancet Infectious Diseases, 5:147-155).

25 26 **Disease in Medically Vulnerable Subpopulations**

27 In reviewing the data from the 2003 worldwide outbreak of SARS, young adults in the age group 20-39
28 years and older individuals greater than 75 years of age were the most affected in terms of illness and
29 fatalities. Children less than 10 years of age accounted for 0.9% of probable cases of SARS. The median
30 age of those who became ill was 33 years. The relative risk (RR) of becoming ill with SARS was highest
31 in those 20–39 years of age, with their risk being nearly twice as high as younger and older age groups.
32 Overall, male patients had similar rates of illness as female patients, but the risk differed significantly in
33 certain age groups: among those 10–19 years of age and in those greater than 75 years of age, the RR for
34 SARS in male patients was nearly twice as compared to females (Liang and Xue 2004).

There are no peer-reviewed published data on differential vulnerability or disease severity to SARS-CoV in those with diabetes, HIV/AIDS or other immune-compromised conditions. There are no published studies discussing the differential impact of this virus on lower socio-economic groups.

Several countries reported confirmed cases of SARS among pregnant women in 2003. The largest case series from Hong Kong reported a case fatality rate of 25% among 12 pregnant women admitted to hospital ((Wong et al. 2004). In the US, two pregnant women were among the 8 laboratory confirmed cases (Robertson et al. 2004; Stockman et al. 2004). The numbers are too small to make any inferences regarding susceptibility or disease severity of SARS in pregnancy.

With regard to asthma, there is one report that concludes that there was no increase in exacerbations of asthma among children during the SARS outbreak (Van Bever et al. 2004). There are no published reports of any association of SARS and asthma in adults.

Human Infectious Dose

The human infectious dose for SARS-CoV is not known. There are no direct human dose response data for SARS-CoV. A review of the published literature reveals one detailed dose response modeling study of SARS-CoV (Watanabe, 2010). This study consists of an analysis of multiple data sets generated by others from experiments on mice that have been proposed as relevant models for human SARS-CoV infection. The best fitted dose response model to these data results in an estimated ID₅₀ of 280 PFU (95% confidence interval 130 to 530 PFU), ID₁₀ of 43 PFU (95% confidence interval 20 to 81 PFU), and ID₁ of 4 PFU (95% confidence interval not reported, but estimated 2 to 8 PFU).

Laboratory Acquired Infections

There is a potential for transmission of the virus to laboratory workers during routine laboratory activity (Normile 2004; Orellana 2004). It is important to note that during the 2003 outbreak, clinical and research laboratories around the world handled large numbers of specimens from confirmed SARS patients and there were no reports of any transmission among laboratory workers during that time. Once the large human epidemic subsided, several clinical and research laboratories retained SARS-CoV isolates that had been adapted to human transmission.

There have been three laboratory accidents reported involving SARS-CoV. In 2003, in Singapore, the first incident was reported in a BSL-3 laboratory at a research institute in Singapore (Ayats et al. 2011). A

graduate student working on a virulent New York strain of West Nile Virus (WNV) became sick with fever and myalgia after making several passages of the WNV in Vero E6 cells which were also used to grow SARS-CoV. The student had minimal training and help from an Institute technician. On Sept. 3, he was admitted to the hospital with a dry cough and signs of respiratory distress. He was placed in isolation precautions and subsequently developed a moderately severe case of confirmed SARS. The technician was not infected. Surveillance and quarantine was maintained on several dozen contacts of the graduate student; no secondary infections occurred. An investigation of the laboratory proved that the WNV was contaminated with the SARS-CoV.

Also in 2003, in Taiwan, a senior research scientist working with SARS in a Class III bio-safety cabinet at The National Defense University in Taipei, Taiwan, cleaned up waste fluid that leaked from a tightly docked transfer chamber connected to the main cabinet (Lim et al. 2006). From the main cabinet, he sprayed alcohol into the chamber, waited 10 minutes, opened the chamber to spray more and finally physically cleaned it up. The next day he attended a SARS meeting in Singapore. On December 10, 2003, he noted fever and fatigue, which progressed to a dry cough and severe muscle aches. He was hospitalized on December 16, and experienced moderately severe clinical illness which was confirmed to be SARS. Contacts, especially plane co-passengers, were monitored or quarantined; no secondary infections occurred. An investigation of the laboratory revealed that SARS-CoV nucleic acid was on the handle of an alcohol bottle in the transfer chamber and on the light switch in the Class III cabinet.

In 2004, after the worldwide epidemic had subsided, two researchers working with SARS at The National Institute of Virology in Beijing, China, became ill and were diagnosed with SARS 2 weeks apart in April 2004 (World Health Organization 2004, Cooper 2009). The significance and identity of these infections was not recognized until the mother of one of the researchers became ill as well. The mother died and six other persons in contact with the two index researchers were also subsequently diagnosed with SARS. An intense laboratory investigation revealed that two other workers had experienced SARS-compatible illnesses in Feb. 2004 and were found to have antibodies to SARS-CoV in their blood, indicating that they had been exposed to the virus. The investigation also revealed that the infections did not occur in BSL-3; however, the infections involved failure of BSL-3 policy and practice. Viral material was released to lower level labs without testing the effectiveness of the inactivation procedure used by the BSL-3 lab. This laboratory accident is the only reported incident that resulted in the initial laboratory workers secondarily transmitting SARS to contacts in the community.

1 There are several lessons learned from a review of these laboratory accidents. Laboratory associated
2 infections can occur from laboratory accidents leading to clinical infection in the worker. There is a
3 potential for spread in the community from direct person-to-person spread from the index patient
4 (laboratory worker). Laboratory worker education and training is an important component of SARS-CoV
5 bio-safety, as well as encouraging prompt reporting and seeking medical attention when symptomatic.
6

7 **Summary**

8 SARS-CoV is a virus that emerged to cause a newly recognized human infection in 2003. The virus is
9 highly transmissible from person-to-person via respiratory aerosols and direct contact. The disease it
10 causes, SARS, was responsible for a large number of illnesses and an overall high death rate of nearly
11 10% among those confirmed to have the illness. There was a rapid spread across countries and continents
12 due to air travel of exposed individuals and lack of knowledge among medical personnel of the pathogen
13 and the way it was spread (transmission characteristics). The worldwide epidemic was extinguished due
14 to sharing of knowledge of the virus and prompt institution of infection prevention and mitigation
15 strategies in hospitals and the community, despite the fact that there were no specific medications or
16 vaccines against the virus. Laboratory accidents have occurred with this pathogen, resulting in infections
17 in the laboratory workers and secondary transmission reported in a limited number of close contacts
18 following one accident.
19

20 There are currently no medications or vaccines to prevent or treat the infection caused by SARS-CoV.
21 This virus is expected to be studied in BSL-3 high containment laboratories worldwide, including
22 NEIDL, with the objective of understanding its biology and to develop countermeasures for future
23 outbreaks.
24

25 For the purposes of this RA, SARS-CoV will be analyzed in detail with regard to (1) Possible event
26 sequences that could lead to loss of bio-containment at NEIDL resulting in exposure of laboratory
27 workers and general public to SARS-CoV; (2) Estimates of the amount of virus the laboratory workers
28 and general public would be exposed to as a result of those event sequences; (3) Probabilistic estimates of
29 initial infection in those exposed to those amounts of SARS-CoV and (4) Transmission modeling of the
30 potential for secondary transmission of SARS-CoV among the general public in the case of a laboratory
31 worker or member of the public experiencing an initial infection.
32

3.5.1.6 Rift Valley Fever Virus (RVFV)

Introduction

Rift Valley fever virus (RVFV) is the pathogen that causes Rift Valley fever (RVF), which is potentially a severe disease among humans and animals. For this RA, RVFV was selected for analysis based on its characteristic of transmission by vectors that are relevant to potential NEIDL sites (Mahmoud 2008). The primary route of transmission of RVFV to humans is via arthropod vectors. Transmission of the pathogen can also occur after contact and/or exposure to infected animal products, especially products of conception, blood or other fluids (White et al. 1996). Based on a review of the epidemiologic literature, there is no evidence of direct spread of RVFV from a person infected with this pathogen to another person. The human infectious dose for RVFV is not known. The potential for LAI involving RVFV exists and infections have been reported; all were prior to 1980 and all of them occurred in the absence of appropriate bio-containment precautions (Meadors et al. 1986).

RVFV was first described in 1930 from an outbreak of sudden death and abortions in sheep along the Lake Naivasha in the greater Rift Valley of Kenya (reviewed in (Pepin et al. 2010)). It was described in humans soon after. The geographic distribution of the virus has increased over the years to currently include all of Africa and the Arabian Peninsula. The pathogen causes widespread morbidity and mortality among livestock and can be devastating to the areas affected. With the availability of competent arthropod vectors in many part of the world including Europe and the US and movement of animals, there is concern for importation of this virus to RVFV-free areas.

Rift Valley fever virus is an enveloped RNA virus of the genus *Phlebovirus*, family *Bunyaviridae* (Shimshony and Barzilai 1983; Meegan 1989; Murphy et al. ; Bird et al. 2009). The virus family *Bunyaviridae* includes viral hemorrhagic viruses in other genera such as Crimean-Congo hemorrhagic fever (genus *Nairovirus*) and Hantaan viruses (genus *Hantavirus*) (LeDuc 1989).

The natural reservoirs of RVFV are animals, mostly ruminants which have a high mortality from the disease. The host range for RVFV is broad and many species of vertebrates are affected by this pathogen, including rodents, domesticated animals such as dogs and cats, to non-human primates (Shimshony and Barzilai 1983).

RVFV has adapted to a large array of arthropod vectors including mosquitoes and ticks. This is in contradistinction to many arboviruses that are adapted to a narrow range of vectors. Transmission of

RVFV to animals is via biological vectors in whose bodies the pathogenic organism develop and multiply before being transmitted to the next host. . Many species of mosquitoes are competent to carry RVFV; more than 23 species in 5 genera including *Aedes*, *Anopheles*, *Culex*, *Coquillettidia*, *Eretmapodites*, *Mansonia* have been described (Meegan and Bailey 1989; Bird et al. 2009). *Rhipicephalus* ticks have also been noted to be biologic vectors (Meegan and Bailey 1989). RVFV has been isolated from mechanical vectors such as *Culicodes* (biting gnats or midges), *Simulium* (black flies); these vectors are not essential to the life cycle of the parasite. RVFV contaminates the mouth parts of these arthropods when they feed on a viremic host, the pathogen does not reproduce in the arthropod, but may be transmitted via pathogen-contaminated mouth parts when the arthropod subsequently feeds on another host.

During interepidemic periods, the virus is maintained in nature via transovarial transmission in mosquitoes, as was shown in *Aedes lineatopennis* in Kenya and in *Aedes vexans* in Senegal (Flick and Bouloy 2005).

BSL-3 is required for work RVFV (Chosewood et al. 2009). RVFV possession in the United States requires a USDA permit, and is a USDA restricted, USDA high consequence agent. A Department of Commerce permit is required, and vaccination is recommended (Weinbren 2008).

Human Disease and Outbreaks

Rift Valley fever in humans has been reported from an ever increasing geographic area (Pepin et al. 2010). Within Africa, it has now reported from almost all nations. The pathogen crossed a large natural barrier (Sahara desert) and appeared in Egypt in 1977. Later, in 1979, it was first reported outside continental Africa in the island nation of Madagascar across the Indian Ocean where the virus is now endemic. In 2000, the virus crossed over the Red Sea to the Arabian Peninsula and caused a large outbreak of RVF in both animals and humans. There is concern that RVF will spread even wider in the future.

The reported outbreaks of RVF have involved large numbers of humans, estimated to be in the thousands. In 1977, in the Egypt outbreak, it is estimated that there were 20,000 human clinical cases with 598 deaths; the overall case fatality rate was 3 percent, in hospitalized patients, the fatality rate was 14 percent. The true prevalence of disease was estimated to be many fold higher than reported as there are sub-clinical infections (Meegan and Bailey 1989).

1 An outbreak in 1987 in Senegal and Mauritania was reported to have a higher mortality rate, with 400
2 confirmed cases and 224 deaths (Meegan 1989; Swanepoel and Coetzer 1994; Flick and Bouloy 2005).

3
4 The largest outbreak to date was reported from Kenya during 1997–1998. It was estimated that there were
5 nearly 90,000 human cases, fortunately with a very low case fatality rate (478 deaths) (Centers for
6 Disease Control and Prevention 1998) Recent outbreaks have been smaller; in 2007, Sudan reported 125
7 human cases including 60 deaths (Gerdes 2002; Gerdes 2004; Bird et al. 2009).

8
9 Overall human fatality rate from RVF has been estimated at 0.5–2.0 percent of those infected; the rate is
10 much higher among those with severe disease (Pepin et al. 2010).

11
12 The disease is considered to be mild and sub-clinical in a majority of patients and presents frequently as a
13 self-limiting influenza-like syndrome without any severe sequelae (Bird et al. 2008) (Pepin et al. 2010).

14
15 The manifestations of severe RVF are variable. After a short incubation period, humans may experience
16 hepatitis, retinitis, delayed-onset encephalitis and, in the most severe cases, hemorrhagic disease.

17
18 The primary route of transmission of RVFV to humans is via arthropod vectors. Transmission of the
19 pathogen can also occur after contact and/or exposure to infected animal products, especially products of
20 conception, blood or other fluids (White et al. 1996). The viral load among these animal products is
21 exceedingly high and aerosolization of pathogen is considered to be very common. There are anecdotal
22 reports of human cases of RVF with no clear history of exposure, other than being in the vicinity of an
23 animal that was being slaughtered (Hoogstraal 1979). There is also a potential of transmission via
24 ingestion of raw milk from infected animals (Flick and Bouloy 2005).

25
26 Based on a review of the available literature from epidemiologic investigations on outbreaks of RVFV,
27 there does not appear to be evidence for direct spread of RVFV from a person infected with this pathogen
28 to another person; especially during an epidemic (Centers for Disease Control and Prevention (U.S.)
29 1998; Centers for Disease Control and Prevention (U.S.) 2007a; Centers for Disease Control and
30 Prevention (U.S.) 2007b). Recent studies have shown a high prevalence of seropositivity to RVFV among
31 populations during inter-epidemic periods; the natural reservoir for RVFV and the mechanism by which
32 humans become infected during interepidemic periods are unknown (LaBeaud et al. 2008; LaBeaud et al.
33 2010).

1 The diagnosis of RVF is based on clinical presentation and epidemiological history involving appropriate
2 exposure or travel to endemic areas. The differential diagnosis is large and includes other viral
3 hemorrhagic fevers; hence laboratory confirmation is required for diagnosis of RVF caused by RVFV.
4 Laboratory tests include PCR-based rapid tests, including virus isolation, antigen detection and detection
5 of specific antibodies to the pathogen (Pepin et al. 2010). The availability of these different modalities of
6 testing varies, especially in resource poor endemic regions.

7
8 Supportive therapy remains the mainstay of the management of patients with RVF. There are no specific
9 anti-viral medications for RVFV. The utility of ribavirin is not proven; however, there is a
10 recommendation of its use in mass casualty situations (Sidwell and Smee 2003).

11
12 Vaccines are widely used for livestock in endemic areas. There is an experimental human vaccine that is
13 available for use in at-risk laboratory workers and military personnel (LaBeaud et al. 2007). Recently,
14 researchers from the US have developed two recombinant RVFV vaccines using vaccinia virus (VACV)
15 as a vector for use in livestock (Papin et al. 2011). Testing in animal models showed that the vaccines are
16 safe and efficacious; protective levels of antibody titers were noted in vaccinated mice and baboons.

17 18 **Disease in Medically Vulnerable Subpopulations**

19 There are no specific reports of adverse outcomes or increased susceptibility in medically vulnerable
20 Subpopulations. There are concerns of RVFV causing abortions in humans as it occurs in animals (Abdel-
21 Aziz et al. 1980; Niklasson et al. 1987). In the 2000 RVF outbreak in Saudi Arabia, among 683 patients
22 reported with disease, it was noted that young children, pregnant women and neonatal infants were
23 relatively spared of the disease and there were no deaths reported in any patient younger than 10 years
24 (Balkhy and Memish 2003).

25 26 **Human Infectious Dose**

27 There are no human dose-response data available. Animals of several species have been infected by low
28 doses of RVFV by the inhalational route, as detailed in Appendix J. These data, as well as cases of
29 humans acquiring the disease in the vicinity of animal products and in laboratories (prior to
30 implementation of modern bio-safety precautions) suggest that RVFV infection by the aerosol route in
31 humans might be a concern.

Laboratory Acquired Infections

There have been no reports of accidental or intentional exposures to RVFV. Laboratory-acquired infections were frequently reported from exposure to RVFV, all of them prior to 1980 and all of them in the absence of appropriate bio-containment precautions (Meadors et al. 1986). There were at least 47 infections in laboratory workers described with 1 death during this period (Hanson et al. 1967; Pike 1979) (Subcommittee on Arbovirus Laboratory Safety of the American Committee on Arthropod-Borne Viruses 1980)

There have been limited reports of laboratory incidents involving RVFV after institution of appropriate biosafety practices (NRC (National Research Council) 2011) As noted in the Biosafety Review (Appendix D), during the period 2000-2010, there was one incident reported of a laboratory spill involving RVFV in 2009.

Summary

Rift Valley fever virus is an RNA virus in the larger family of viral hemorrhagic fevers and causes Rift Valley fever. The disease causes high morbidity and mortality in animals and is a potentially serious illness of humans. There have been large outbreaks of RVF in humans reported from Africa and Arabian Peninsula involving several hundreds to nearly 90,000 cases. The pathogen is transmitted to humans via arthropod vectors or direct contact/exposure to infected animal products. There is no specific treatment for RVF and case fatality rates are generally less than 2 percent. For severe cases of RVF involving bleeding, the mortality is higher. The geographic area for RVF is ever expanding and this pathogen is expected to be continued to be studied in laboratories around the world, including the US.

For the purposes of this RA, RVFV virus will be analyzed in detail with regard to: (1) Possible event sequences that could lead to loss of biocontainment at NEIDL resulting in exposure of laboratory workers and the general public to RVFV virus; (2) Estimates of the amount of pathogen the laboratory workers and general public would be exposed to as a result of those event sequences and (3) Probabilistic estimates of initial infection in those exposed to those amounts of RVFV virus.

There is no direct person-to-person transmission of RVFV; transmission to humans is via arthropod vectors or by contact with infected animal products. There is a limited literature on disease transmission models of RVFV involving animals, arthropod vectors and human hosts. Several models have addressed other complex variables such as climate conditions and livestock in the prediction and transmission of RVFV in endemic areas (Clements et al. 2006; Favier et al. 2006; Anyamba et al. 2009; Metras et al.

2011; Mpeshe et al. 2011). The applicability of these published models and epidemiologic, climate and livestock data to conditions in the US, specifically to NEIDL sites under study in the RA is unknown. Furthermore, epidemiologic data on ruminants and mosquito vectors are not uniformly available in a format suitable for use in secondary transmission modeling. The risk analysis for RVFV will include a qualitative discussion of transmission of RVFV and will not include detailed mathematical modeling of transmission of RVFV in the community.

3.5.1.7 Andes Virus (ANDV)

Introduction

Andes virus (ANDV) is the major etiological pathogen of Hantavirus Pulmonary Syndrome (HPS) that occurs in South America. For this RA, ANDV was selected for analysis based on its characteristics of being highly pathogenic with a high case fatality ratio despite its poor transmissibility (Mahmoud 2008). Inhalation of aerosolized virus by humans from contact with contaminated rodent feces, saliva, and urine, and contact with contaminated fomites are considered the primary routes of transmission of ANDV (CDC 2008). Direct person-to-person transmission of ANDV has been documented; though the extent of this transmission is limited to close family contacts and has not resulted in large outbreaks of HPS. The human infectious dose for ANDV is not known. The potential for LAI with ANDV exists though no reports of LAI have been reported with this pathogen. LAI have been reported with related hantaviruses, all reported prior to 1994 (reviewed in (Schmaljohn and Hjelle 1997)).

ANDV is maintained in rodent reservoirs and causes 50-80 cases of this potentially fatal disease annually, mostly in Chile and Argentina, when humans come into contact with rodent excrement (Mertz et al. 2006). ANDV is the only hantavirus that has been shown to be transmitted directly from person-to-person.

Andes virus is one of nearly 40 hantaviruses that have been described to date, of the Genus *Hantavirus*, family *Bunyaviridae* (CDC 2008). Hantaviruses are classified as either New World strains that cause HPS or Old World strains that cause Hemorrhagic Fever with Renal Syndrome. Apart from Andes virus, other New World hantaviruses are Choclo, Laguna Negra, and Sin Nombre viruses which are distributed in North and South America. Old World strains include the prototypic Hantaan, Puumala, and Seoul hantaviruses (Jonsson et al. 2010). The natural reservoir of Andes virus is the long-tailed pygmy rice rat, *Oligoryzomys longicaudatus*, and other species of genus *Oligoryzomys* (CDC 2008). The rodents are in the sub-family *Sigmodontinae* within the family *Muridae*, order *Rodentia* with which the hantaviruses have evolved for thousands of years (Toro et al. 1998; McCaughey and Hart 2000; Mertz et al. 2006). The

1 natural reservoir is maintained by chronic infection of the rodent with the virus, with no overt signs in the
2 rodent.

3
4 BSL-4 biocontainment precautions are recommended for ANDV when infecting rodent species
5 permissive for or susceptible to chronic infection. Otherwise, BSL-3 biocontainment precautions are
6 recommended. (Chosewood et al. 2009).

7 8 **Human Disease and Outbreaks**

9 HPS caused by Andes virus occurs in regions where the rodent reservoir is common, namely in Argentina
10 and Chile. Several hundred cases have been reported in these countries since the disease was first
11 described (Mertz et al. 2006). Between the years 2001 and 2005, the number of cases of HPS in Chile
12 ranged from a low of 56 cases in 2004 to a peak of 81 cases in 2001.

13
14 HPS is characterized by a prodromal phase after a variable incubation period that includes headache,
15 backache, abdominal pain, nausea, and diarrhea (CDC 2008). The cardiopulmonary phase starts abruptly
16 and usually results in respiratory failure, requiring ventilator support. Most patients also develop
17 cardiogenic shock. Overall case fatality rates for HPS patients is in the range of 30-40 percent as reported
18 in most outbreaks, with one report from Argentina reporting a higher case fatality rate of 55 percent
19 (Lazaro et al. 2007).

20
21 The route of transmission of ANDV to humans was by exposure to rodent excrements, not necessarily
22 direct contact with the rodent. Inhalation of aerosolized virus from contaminated rodent feces, saliva, and
23 urine, and contact with contaminated fomites are considered the primary routes of transmission of ANDV
24 (CDC 2008). Human activities that increase the chances of coming into contact with rodent excrements
25 such as cleaning out old, unused sheds or cabins are associated with infection with New World
26 hantaviruses in general, thus accounting for the spring and summer time increase in reports of cases.
27 There are rare reports of rodent bites transmitting ANDV (Merino et al. 2002). There are no known
28 arthropod vectors in the transmission of ANDV.

29
30 A unique feature of ANDV is that direct person-to-person transmissions of ANDV have been reported.
31 There are reports of HPS in close contacts with genetic evidence of person-to-person transmission, from
32 earlier outbreaks in the 1990s to more recent cases. In these circumstances, transmission generally
33 occurred in close family contacts who exchanged bodily fluids, with evidence of ANDV RNA found in
34 saliva of patients. (Enria et al. 1996; Padula et al. 1998; Martinez et al. 2005; Castillo et al. 2007; Lazaro

et al. 2007). A recent study that prospectively studied 476 household contacts of 76 index patients with HPS in Chile found 16 contacts developed confirmed HPS (3.4%) (Ferres et al. 2007). A third of all the cases occurred in family clusters. Person-to-person transmission was definite in only 3 household contacts and probable in another 9. Sexual contacts were at the highest risk for HPS in this study. In summary, direct person-to-person transmission of ANDV has been documented; though the extent of this transmission is limited to close family contacts and has not resulted in large outbreaks of HPS.

In other reports from Argentina, 16 cases of HPS were suspected to be due to person-to-person transmission, though contact or exposure to rodents could not be completely ruled out for a majority of those patients (Wells et al. 1997; Cantoni et al. 2001).

There did not appear to be any hospital- or healthcare-associated person-to-person transmission in one outbreak in Chile (Castillo et al. 2004). Other reports have described cases in health care workers (Lopez et al. 1996; Wells et al. 1997; Toro et al. 1998; Mertz et al. 2006).

The diagnosis of ANDV is based on clinical presentation, epidemiological history of exposure to rodent excrements, travel to endemic areas, and laboratory confirmation. Serological assays for hantavirus specific IgG and IgM are the most commonly used tests for confirmation. Rapid PCR-based tests are also available in select laboratories. Immunohistochemistry on pathologic specimens is also performed in select cases to confirm hantavirus infection (Mertz et al. 2006; Jonsson et al. 2008).

Supportive therapy remains the mainstay of the management of patients with HPS caused by ANDV (Mertz et al. 2006; Jonsson et al. 2008). Intensive care support along with specialized procedures such as extracorporeal membrane oxygenation has been shown to be beneficial to patients. There is no specific antiviral that has been approved or is effective against ANDV.

Disease in Medically Vulnerable Subpopulations

In general, all age groups are affected. There are no specific reports of adverse outcomes or increased susceptibility to ANDV in medically vulnerable Subpopulations. There are reports of hantavirus infection in children, including those in Argentina; some have reported worse outcomes, others have reported clinical courses and outcomes being similar to those in adults (Pini et al. 1998; Ramos et al. 2001; Ferres and Vial 2004; Overturf 2005). There are no specific reports of ANDV infection in pregnancy. There appeared to be no difference in maternal or fetal outcomes in HPS caused by Sin Nombre virus in one study (Howard et al. 1999) and concern for worse outcomes in 2 patients (Gilson et al. 1994).

1 **Human Infectious Dose**

2 There are no human dose-response data available for ANDV. Epidemiological evidence suggests that
3 humans have become infected through inhaling aerosolized particles containing ANDV, but the amount
4 of virus inhaled by humans who became infected is not known. Data from animal models suggests that
5 the ANDV infectious dose for humans is low.

6
7 **Laboratory Acquired Infections**

8 There have been no laboratory incidents or laboratory-acquired infections reported with ANDV
9 (Biosafety Review, Appendix D). Laboratory-acquired infections have been reported with related
10 hantaviruses, all reported prior to 1994 (reviewed in (Schmaljohn and Hjelle 1997)). These were reported
11 prior to institution of modern biosafety practices and involved laboratory workers handling infected rats
12 obtained from breeders, wild-caught, naturally-infected rodents, or experimentally infected rodents.
13 Asymptomatic seroconversions have been reported among workers using cell-culture adapted
14 hantaviruses. There is one report of occupationally acquired hantavirus infection in a utility company
15 employee (Jay et al. 1996). He developed HPS from the Sin Nombre virus.

16
17 **Summary**

18 Andes virus is a New World hantavirus that causes a severe cardio-pulmonary syndrome (HPS) and is
19 restricted to Argentina and Chile. The risk factor for humans is exposure to rodent excrements that are
20 contaminated with ANDV. Inhalation of aerosolized virus is the primary route of transmission to humans.
21 The mortality from HPS can be significant and in the range of 30-55 percent. There are no specific
22 treatment modalities for HPS; supportive therapies including intensive care are the main stay of
23 management of HPS patients. ANDV is unique among hantaviruses in that there is documented direct
24 person-to-person transmission; the extent of this transmission is limited to close family contacts and has
25 not resulted in large outbreaks of HPS.

26
27 There is a possibility of infection if an individual is exposed directly to ANDV. Direct person-to-person
28 transmission of ANDV is possible; based on natural outbreaks, this risk is limited to close household
29 contacts and the attack rate is low.

30
31 For the purposes of this RA, Andes virus will be analyzed in detail with regard to: (1) possible event
32 sequences that could lead to loss of biocontainment at NEIDL resulting in exposure of laboratory workers
33 and the general public to Andes virus; (2) estimates of the amount of pathogen the laboratory workers and
34 general public would be exposed to as a result of those event sequences and (3) probabilistic estimates of

initial infection in those exposed to those amounts of Andes virus. As there is a low risk of direct-to-person transmission of Andes virus amongst members of the public and low risk for such transmission to cause large outbreaks, secondary transmission modeling of the spread of this virus in the community following an initial infection will not be performed. Moreover, there are limited studies available to provide epidemiologic data for detailed secondary transmission modeling and no published mathematical models for this pathogen.

3.5.2 BSL-4 Biocontainment Precautions: Pathogens

3.5.2.1 Ebola Virus (EBOV)

Introduction

Ebola virus is the common designation for a group of closely related viruses that cause Ebola hemorrhagic fever (EHF). For this RA, EBOV was selected for analysis based on its characteristics of being highly pathogenic with a high case fatality ratio despite its poor transmissibility (Mahmoud 2008). The exact mode and route of transmission of Ebola viruses are not known. The pathogen is believed to be transmitted to humans via contact with infected animals. Direct person-to-person transmission of Ebola viruses from index cases to family and community contacts has been described via close contact with bodily fluids from infected patients. The human infectious dose of EBOV is not known. The potential for LAI with EBOV exists. There have been several laboratory incidents involving Ebola viruses, though no LAI have been reported.

EHF is characterized by a severe illness with bleeding and very high mortality. The first description of these viruses was from two natural outbreaks in 1976 from the Democratic Republic of the Congo (DRC, formerly Zaire) and southern Sudan (Hartman et al. 2010; Feldmann and Geisbert 2011). The viruses are named for the Ebola River located in northwestern DRC where the first outbreak occurred.

Ebola viruses are RNA viruses of the genus *Ebolavirus* of the family *Filoviridae*. These pathogens are closely related to Marburg virus and there are concerns of co-circulation of these viruses in their reservoir hosts (Bausch et al. 2006; Pourrut et al. 2009; Hartman et al. 2010). Currently, there are 5 known closely-related strains of Ebola virus; Ebola-Zaire, Ebola-Sudan, Ebola-Côte d'Ivoire, Ebola-Reston and Ebola-Bundibugyo (Towner et al. 2008; Normile 2009; 2009; Wamala et al. 2010; Feldmann and Geisbert 2011).

The natural reservoir of Ebola viruses is thought to be bats of various species, namely fruit bats, Old world fruit bats, and flying foxes in three genera of *Pteropus* (Leroy et al. 2005; Leroy et al. 2009). There are no known insect vectors for these pathogens. Several laboratory animals including mice (requires

1 adapted viral strains), guinea pigs, and non-human primates can be infected with the pathogen and have
2 been used as animal models of Ebola virus infections. BSL-4 biosafety practices are required for all work
3 with Ebola viruses (Chosewood et al. 2009).

5 **Human Disease and Outbreaks**

6 The human disease caused by Ebola viruses is the prototypical hemorrhagic fever that has received
7 considerable media attention and is of concern to the public (Leffel and Reed 2004). EHF is characterized
8 by an abrupt start of the illness with non-specific flu like symptoms such as fever, chills, muscle aches,
9 and general malaise. This is often followed by gastro-intestinal symptoms and more severe illness with
10 low blood pressure. Contrary to popular belief, hemorrhagic manifestations are variable among patients
11 and usually occur at the peak of the illness. These include bleeding from all mucous membranes and other
12 body sites.

14 Of the five related strains, the Ebola-Zaire virus strain has been responsible for the largest number of
15 outbreaks. There have been 12 outbreaks from 1976 through to 2008, with large numbers of cases and a
16 fatality rate between 25-90% (Hartman et al. 2010). Attack rates in these outbreaks have varied between 5
17 percent among the community and 20 percent in close relatives of patients (Feldmann et al. 1996). The
18 Zaire strain is generally considered the most virulent of the Ebola virus strains.

20 The Ebola-Sudan virus strain was responsible for the largest outbreak described to date in Uganda during
21 2000-2001, with 425 cases and an overall case fatality rate of 53% (2001; Okware et al. 2002). Attack
22 rates in this and prior outbreaks have varied between 2.5 and 12 percent.

24 The Ebola-Cote d'Ivoire virus strain has only been reported to cause a single nonfatal infection acquired
25 during the necropsy of a dead chimpanzee (Formenty et al. 1999; Le Guenno et al. 1999).

27 The Ebola-Reston virus strain was discovered in 1989 from cynomolgus macaques imported from the
28 Philippines for medical research in the United States in Reston, Virginia. An unusually large number of
29 monkeys died in quarantine and investigations led to the isolation of the new strain of Ebola virus. There
30 were no human cases; however, 21 animal handlers at the Philippine exporter and four employees of the
31 quarantine facility were found to have antibodies to the virus, indicating that they had been infected
32 (Normile 2009). Reston virus strain can infect humans but no serious illness or death in humans have
33 been reported to date (Towner et al. 2008; Normile 2009; 2009; Wamala et al. 2010; Feldmann and
34 Geisbert 2011).

1 The Ebola-Bundibugyo virus strain is the most recent to be described from an outbreak in Uganda, with
2 over 100 persons ill and a 40% fatality rate (Towner et al. 2008; MacNeil et al. 2010).

3
4 The exact mode and route of transmission of Ebola viruses are not known. The pathogen is believed to be
5 transmitted to humans via contact with infected animal hosts (Pourrut et al. 2005; Swanepoel et al. 2007).
6 Some recent outbreaks have been attributed to the consumption or handling of bush meat (Leffel and
7 Reed 2004). Human infections have also been documented via handling of infected dead and living
8 chimpanzees, gorillas, and forest antelopes (Peterson et al. 2004). Recent evidence suggests that fruit bats
9 might have a reservoir role; it is unclear as to whether other species of bats are involved or how
10 transmission to humans or apes occurs (Groseth et al. 2007). Fruit bats are eaten by local populations in
11 outbreak areas and could be the source of human infections (Leroy et al. 2005). One route of infection is
12 presumably to be by inhalation of the aerosolized virus, though this has only been noted in experimental
13 conditions (Leffel and Reed 2004). There have been no insect vectors reported in the transmission of
14 Ebola viruses.

15
16 Direct person-to-person transmission of Ebola viruses from index cases to family and community contacts
17 has been described. Secondary attack rates have varied among different outbreaks and strains. It has been
18 shown that the viruses are shed in a wide variety of bodily fluids during the acute period of illness and
19 this contributes to the person-to-person spread in the setting of the cultural practice of touching and close
20 contact with ill patients in Africa (Bausch et al. 2007). Though this is postulated to be the major route of
21 transmission, other routes are possible such as by droplets, airborne particles, or contaminated objects
22 (fomites); these came to light after several patients reported no direct contact or exposure during a large
23 outbreak in the Congo (Roels et al. 1999).

24
25 An important aspect of filovirus outbreaks in general (Ebola and Marburg viruses) is the amplification
26 that often occurs in hospitals by transmission of the viruses from patients to family or health care workers
27 (Fisher-Hoch 2005; Hartman et al. 2010). This is postulated to have occurred in the setting of poor
28 sanitary conditions, lack of personal protective equipment, and reuse of injection needles. Close contact
29 with a severely ill patient, during care at home or in hospital, and certain burial practices are common
30 routes of infection in Africa. Transmission via contaminated injection equipment or through needle-stick
31 injuries is associated with more severe disease, rapid deterioration, and possibly higher fatality. The risk
32 of transmission of Ebola viruses from fomites in an isolation ward and from convalescent patients is low
33 when recommended infection control guidelines for the viral hemorrhagic fevers are followed (Bausch et
34 al. 2007).

Based on analysis of the larger outbreaks, several estimates of the reproductive number (R_0) for Ebola viruses have been generated. Estimates range from a low of 1.34 to as high as 2.7 (Chowell et al. 2004; Lloyd-Smith et al. 2005; Lekone and Finkenstadt 2006). This indicates that in the right social and community setting where there is close contact with severely ill patients and the dead, especially in hospital settings, there is a possibility of direct person-to-person transmission and this could lead to large outbreaks. This situation is considered unlikely in the US.

The diagnosis of Ebola virus infection is based on epidemiological history of exposure to a patient during a known outbreak or travel history. Laboratory diagnostic methods include antibody detection by ELISA, antigen detection by PCR, and virus isolation by culture. Electron microscopy is also employed for detection and identification of the viruses. Laboratory confirmation is available only in specialized laboratories such as the CDC (Hartman et al. 2010).

There are no effective medications or vaccines for the treatment or prophylaxis of Ebola virus infection (Hartman et al. 2010). Vaccine and therapeutic drug candidates are an active area of research for both Ebola and Marburg viruses (Geisbert et al. 2010; Falzarano et al. 2011).

Disease in Medically Vulnerable Subpopulations

EHF has been diagnosed in all age groups; though the large African outbreaks were noted to be predominantly in the elderly. Children are thought to be relatively resistant to infection (Dowell 1996). There are no specific reports of increased susceptibility to Ebola virus infection in medically vulnerable Subpopulations. There are reports of increased attack rates among women in one outbreak (Okware et al. 2002). In one large outbreak in the Congo (Mupapa et al. 1999), it did not appear the incidence of EHF was increased in pregnant women; there was a loss of nearly all pregnancies and the mortality rate among these women was higher, though not statistically higher, than that in the general population (95% vs 77%).

Human Infectious Dose

The human infectious doses of Ebola viruses are not known. Epidemiological evidence suggests that humans have become infected through inhaling aerosolized particles containing EBOV, but the amount of virus inhaled by humans who became infected is not known. From animal data, the infectious dose for Ebola viruses it is postulated to be low (Pratt et al. 2010).

Laboratory Acquired Infections

There have been several laboratory incidents involving Ebola viruses (Biosafety Review, Appendix D). A fatal Ebola infection occurred in a laboratory worker in Russia in 2004. The worker had suffered a needle stick injury with the Ebola-Zaire strain while working with a guinea pig model of the pathogen. Another accident in Germany in 2009 involved a laboratory researcher wearing protective gloves who experienced a needle stick from a syringe suspected to contain Ebola virus (Tuffs 2009). The researcher was isolated and provided an experimental vaccine along with supportive measures. There was no evidence of clinical infection.

In the US, a significant incident occurred in 2004 at U.S. Army Medical Research Institute For Infectious Diseases (USAMRIID) when a researcher sustained a needle stick injury through a gloved hand when handling and injecting mice with an antibody (Kortepeter et al. 2008). The exposure to the virus was considered probable and the risk of infection was low as the mice did not yet have Ebola virus in their blood. The worker was placed in isolation and subsequently did not develop either asymptomatic disease or clinical illness. Another incident in 2005 involved both Ebola and Marburg viruses where a sharp object punctured a boot with no skin penetration.

As with other high-containment pathogens, laboratory-acquired infections with Ebola virus are a concern and laboratory personnel education and training should be reinforced while dealing with this BSL-4 pathogen.

Summary

Ebola viruses cause a hemorrhagic fever that is highly fatal to humans. The virus was discovered as a pathogen in 1976 and since then, three major strains have been responsible for the large outbreaks, all in Africa. The natural reservoir of the pathogen appears to be fruit bats in Africa. There is no known insect vector. There is a possibility of infection if an individual is exposed to Ebola viruses. There is evidence of direct person-to-person transmission via close contact with bodily fluids from infected patients. There are no effective medications or vaccines for these pathogens. These pathogens are expected to be continued to be studied in BSL-4 maximum biocontainment laboratories worldwide, including the US. There have been laboratory-acquired infections involving Ebola viruses, though none in the US.

For the purposes of this RA, Ebola viruses will be analyzed in detail with regard to (1) possible event sequences that could lead to loss of biocontainment at NEIDL resulting in exposure of laboratory workers and the general public to Ebola viruses; (2) estimates of the amount of pathogen the laboratory workers

and general public would be exposed to as a result of those event sequences; (3) probabilistic estimates of initial infection in those exposed to those amounts of Ebola viruses and (4) estimates of secondary transmission of Ebola viruses in the community in the event of an initial infection in a laboratory worker.

3.5.2.2 Marburg Virus MARV

Introduction

Marburg virus is a member of a group of hemorrhagic fever viruses that was first described in laboratory workers, as opposed to a natural outbreak. For this RA, MARV was selected for analysis based on its characteristics of being highly pathogenic with a high case fatality ratio despite its poor transmissibility (Mahmoud 2008). The mode of transmission of Marburg virus is direct exposure to bats and/or their secretions or excrement. Direct person-to-person transmission of MARV from index cases to family and community contacts has been described via close contact with bodily fluids from infected patients. The human infectious dose of MARV is not known. MARV was first described as a laboratory acquired infection and thus the potential exists. There have been no reports of laboratory incidents or infections involving Marburg virus in the US.

The first cases involving this virus were described in Marburg, Germany (thus the name) and Belgrade, Yugoslavia in 1967 in workers who had handled infected African green monkeys (*Chlorocebus sabaues* [formerly, *Cercopithecus aethiops*]), imported from Uganda. There were primary and secondary infections in these incidents and detailed studies led to the discovery of this new pathogen. Since then, through 2005, there have been several natural outbreaks reported, with two large ones reported from Africa.

Marburg virus is an RNA virus of the genus *Marburgvirus* of the family *Filoviridae*. This pathogen is closely related to Ebola virus and there are concerns of co-circulation of these viruses (Bausch et al. 2006; Pourrut et al. 2009; Hartman et al. 2010).

Despite the discovery of this pathogen in 1967, the natural reservoir was not known till recently, when it was shown to be a common species of fruit bat, *Rousettus aegyptiacus*, and possibly the insectivorous bats *Miniopterus inflatus* and *Rhinolophus eloquens* (Swanepoel et al. 2007; Towner et al. 2007; Kuzmin et al. 2010).

1 Since its discovery, Marburg virus has been studied extensively in maximum biocontainment laboratories
2 around the world, including the US. BSL-4 is required for all work with Marburg virus (Chosewood et al.
3 2009).

4 5 **Human Disease and Outbreaks**

6 Marburg virus causes a rapidly progressive illness that starts abruptly with severe headache, malaise, and
7 muscle pains. Fever is followed by other non-specific symptoms and within a week, patients develop the
8 characteristic features of ‘hemorrhagic fever’ with bleeding from body openings, often from multiple
9 sites. Case fatality rates are generally high, though there appears to be some variation between strains.
10 The Angolan strain is reported to have the highest case fatality rates approaching 100% with other strains
11 being less pathogenic (Mahanty and Bray 2004; Jeffs 2006; Bausch et al. 2008; Hartman et al. 2010).

12
13 Human outbreaks were rare between the discovery of the virus in 1967 and 1998 with only three cases
14 reported, each involving either a single person (Kenya, 1987) or an index case and the infection of a
15 traveling companion, medical personnel, or both (Zimbabwe–South Africa, 1975, and Kenya, 1980)
16 (Feldmann 2006; Towner et al. 2006). Between 1998 and 2005, there have been two large natural
17 outbreaks in Africa. All outbreaks have been associated with humans coming into contact with bats and
18 their secretions/excreta either by visiting caves (which is a popular tourist attraction), working in mines,
19 or sleeping in areas with bats. In all outbreaks, there have been secondary infections in family members
20 and in the local community from the index cases.

21
22 One large outbreak occurred in the Democratic Republic of the Congo during the period 1998-2000,
23 which involved gold miners. A total of 154 cases (with 83% case fatality rate) were reported with
24 multiple genetic variants of the virus, indicating that there was ongoing introduction of the virus to
25 humans over a period of time. In this outbreak, the index cases were in miners and with secondary cases
26 in their family members and in the general community (Bausch et al. 2006; Feldmann 2006). An
27 interesting point to note was the low numbers of infections in health care workers caring for these
28 patients, which is unusual for a filovirus infection.

29
30 The largest natural outbreak of Marburg virus occurred in Angola in 2004-2005 (Feldmann 2006; Towner
31 et al. 2006). This was an extension from the usual territory of filoviruses to Western Africa and is a matter
32 of concern. It is postulated that this outbreak started with one index case, with secondary transmission to
33 family and community members. The outbreak was further amplified in hospital settings as is typical for
34 filoviruses. The Angolan outbreak was unique in several ways and this may represent a new strain of

1 Marburg virus: in the illness which has a shorter incubation period, many children were affected and the
2 100% case fatality rate was higher than reported even in the Zaire outbreak of Ebola virus.

3
4 The most recent outbreak was reported in 2007, with Ugandan miners being affected; the likely source
5 was fruit bats in the cave mine (2007).

6
7 The mode of transmission of Marburg virus is direct exposure to bats and/or their secretions or
8 excrement; presumably by inhalation of the aerosolized virus, though this has only been noted in
9 experimental conditions (Leffel and Reed 2004). There have been no insect vectors reported in the
10 transmission of Marburg virus.

11
12 Direct person-to-person transmission of Marburg virus from index cases to family and community
13 contacts has been described in the 1967 outbreak and the two large outbreaks in Africa. Secondary
14 transmission is associated with close contact with the ill patient or their bodily fluids, mainly blood
15 (Bausch et al. 2006; Feldmann 2006; Towner et al. 2006). Other body fluids from infected humans (feces,
16 vomitus, urine, saliva, and respiratory secretions) with high virus concentrations, especially when these
17 fluids contain blood, have also been implicated in transmission. Transmission is known to occur only
18 during the symptomatic phase of the illness and not during the incubation period.

19
20 An important aspect of filovirus outbreaks in general (Ebola and Marburg) is the amplification that often
21 occurs in hospitals by transmission of the virus from patients to family or health care workers (Fisher-
22 Hoch 2005; Hartman et al. 2010) . This is postulated to have occurred in the setting of poor sanitary
23 conditions, lack of personal protective equipment, and reuse of injection needles. Close contact with a
24 severely ill patient, during care at home or in hospital, and association with certain burial practices, are
25 common routes of infection in Africa. Transmission via contaminated injection equipment or through
26 needle-stick injuries is associated with more severe disease, rapid deterioration, and possibly higher case
27 fatality rates.

28
29 There have been two recent reports of travel-related Marburg virus infection in those who visited the
30 same mine in Uganda. The first case was discovered in the Netherlands (Timen et al. 2009) and the
31 second was diagnosed in Colorado (2009). These cases highlight the importance of increasing awareness
32 of the risks associated with travel and specific activities such as cave exploration in areas where filovirus
33 outbreaks have been reported.

The diagnosis of Marburg virus is based on epidemiological history of exposure to a patient during a known outbreak or travel history. Laboratory diagnostic methods include antibody detection by ELISA, antigen detection by PCR, and virus isolation in culture. Electron microscopy is also employed for detection and identification of the virus. Laboratory confirmation is available only in specialized laboratories such as the CDC (Hartman et al. 2010).

There are no effective medications or vaccines for the treatment or prophylaxis of Marburg virus infection (Hartman et al. 2010). Vaccines and medications are an active area of research for filoviruses (Ebola and Marburg virus).

Disease in Medically Vulnerable Subpopulations

All age groups are susceptible to infection, but most cases have occurred in adults. Prior to the 2004 outbreak in Angola, pediatric cases were considered extremely rare. In the large outbreak that occurred in the Democratic Republic of the Congo from late 1998 to 2000, only 12 (8%) of the cases were under the age of 5 years (Feldmann 2006; Towner et al. 2006). There are no reports of increased susceptibility in medically vulnerable Subpopulations including pregnant women.

Human Infectious Dose

The human infectious dose of Marburg virus is not known. Epidemiological evidence suggests that humans have become infected through inhaling aerosolized particles containing the pathogen, but the amount of virus inhaled by humans who became infected is not known. From animal data, the human infectious dose for Marburg virus is postulated to be low.

Laboratory Acquired Infections

Marburg virus was first described as a laboratory-acquired infection in 1967 in Marburg, Germany and Belgrade, Yugoslavia, when laboratory workers handled infected African green monkeys or their tissues. The infected monkeys consigned from Uganda to Europe were caught on the shores of Lake Victoria and on islands where fruit bats are prevalent (Towner et al. 2007). The outbreaks involved 25 primary infections, with 7 deaths, and 6 secondary cases, with no deaths. The primary infections were in laboratory staff exposed to Marburg virus while working with monkeys or their tissues. The secondary cases involved two doctors, a nurse, a post-mortem attendant, and the wife of a veterinarian. All secondary cases had direct contact, usually involving blood, with a primary case. Both doctors became infected through accidental skin pricks when drawing blood from patients.

1 There have been 4 incidents reported from a maximum biocontainment laboratory in Johannesburg, South
2 Africa involving Marburg virus (Biosafety Review, Appendix D); these resulted in no infections. In two
3 separate incidents in a BSL-4 laboratory in Russia involving exposure of workers to Marburg virus, both
4 resulted in infections, with one death. There have been no reports of laboratory incidents involving
5 Marburg virus in the US.

6
7 As with other high-containment pathogens, laboratory-acquired infections with Marburg virus are a
8 concern and reinforce laboratory personnel education and training while dealing with this BSL-4
9 pathogen.

10 11 **Summary**

12 Marburg virus causes a hemorrhagic fever that is highly fatal to humans. The virus was discovered as a
13 pathogen in 1967 from laboratory primates and did not pose a major threat to humans till large outbreaks
14 were noted starting in 1998. There appears to have been a shift in the natural history of the disease with
15 the Angolan outbreak in 2004. The natural reservoir of the pathogen appears to be fruit bats in Africa.
16 There is no known insect vector. There is evidence of direct person-to-person transmission via close
17 contact with bodily fluids from infected patients that contain high concentrations of the virus, such as
18 blood.

19
20 There is a possibility of infection if an individual is exposed to Marburg virus. There are no effective
21 medications or vaccines for this pathogen. This pathogen is expected to be continued to be studied in
22 BSL-4 maximum biocontainment laboratories worldwide, including the US. There have been laboratory-
23 acquired infections involving Marburg virus, though none in the US.

24
25 For the purposes of this RA, Marburg virus will be analyzed in detail with regard to (1) possible event
26 sequences that could lead to loss of biocontainment at NEIDL resulting in exposure of laboratory workers
27 and the general public to Marburg virus; (2) estimates of the amount of pathogen the laboratory workers
28 and general public would be exposed to as a result of those event sequences and (3) probabilistic
29 estimates of initial infection in those exposed to those amounts of Marburg virus.

30
31 There is a possibility of person-to-person transmission of Marburg virus via close contact; however the
32 risk is low and requires close contact that may be culture- and region-specific. The closely related Ebola
33 virus is being analyzed by secondary transmission modeling for the spread of infection in the community,
34 the results of which will be broadly applicable to the risk analysis of Marburg virus. For these reasons,

secondary transmission modeling of the spread of Marburg virus infection in the community will not be performed as part of this RA.

3.5.2.3 Lassa Virus (LASV)

Introduction

Lassa viruses are the causative pathogens of Lassa fever, which is a viral hemorrhagic fever. For this RA, LASV was selected for analysis based on its characteristics of being highly pathogenic with a high case fatality ratio despite its poor transmissibility (Mahmoud 2008). The mode of transmission of Lassa viruses to humans is from direct contact with *Mastomys natalensis*, and African rodent species. Direct person-to-person transmission of Lassa viruses has been described, especially in hospital settings and is associated with direct contact with the blood or other bodily fluids containing virus particles from infected individuals. The human infectious dose of LASV is not known. The potential for LAI with LASV exists; though there are no reports of laboratory-acquired infections with Lassa viruses after institution of appropriate biosafety practices.

Lassa viruses were first described in 1970 after a small outbreak in Nigeria and were named for a village there (Geisbert and Jahrling 2004; Gunther and Lenz 2004). The disease is endemic in several countries of West Africa. A staggering number of cases and deaths are reported annually; estimates of cases are in the range of 300,000 to 500,000, with 5000 deaths yearly across West Africa (Ogbu et al. 2007; Idemyor 2010). It is concerning that the geographic region for these pathogens is considered to be expanding (Gunther and Lenz 2004).

Lassa viruses are members of the genus *Arenavirus*, family *Arenaviridae* and are RNA viruses (Gunther and Lenz 2004). There are four strains of Lassa virus described to date; these are *Josiah*— Sierra Leone, *Nigeria*, *LP-Nigeria*, and *AV*, imported to Germany by a traveler who had visited Ghana, Côte D'Ivoire, and Burkina Faso (Ogbu et al. 2007).

Lassa viruses are considered to be in the Old World complex of the *Arenaviridae* family that includes the prototype *arenavirus* lymphocytic choriomeningitis virus (LCMV), Mopeia virus, Mobala virus, and Ippy virus. The larger New World (Tacaribe) complex of the family of viruses includes Tacaribe virus, Pichinde virus, Junín virus, Machupo virus, Sabia virus, and Guanarito virus. It is interesting to note that the majority of viruses in this family are not known to cause disease in humans. However, Lassa virus, Junín virus, Machupo virus, Guanarito virus, and Sabia virus can cause a viral hemorrhagic fever (VHF) upon transmission to humans.

1 The natural reservoir of Lassa viruses is the rodent of the genus *Mastomys* (multimammate rat) that is
2 endemic to sub-Saharan Africa. The infection in rodents is considered life-long (Fisher-Hoch 2005) and
3 are likely infected *in-utero* (McCormick and Fisher-Hoch 2002). In Guinea and Sierra Leone, the
4 reservoir is likely to be *M. natalensis* where there is evidence of vertical (rodent to offspring) as well
5 horizontal (rodent-to-rodent) transmission of the virus (Lecompte et al. 2006). BSL-4 biosafety practices
6 are required for all work with Lassa viruses (Chosewood et al. 2009).

8 **Human Disease and Outbreaks**

9 The human disease caused by Lassa viruses is a type of hemorrhagic fever (Lassa fever). The disease is
10 endemic in several countries of West Africa, including Sierra Leone, Guinea, Liberia, and Nigeria. The
11 territory is expanding and disease has been reported also in Ghana, Ivory Coast, and Burkina Faso
12 (Drosten et al. 2003). Estimates of annual disease cases range from 100,000 (Ehichioya et al. 2010), to
13 between 300,000 – 500,000 (Ehichioya et al. 2010) , to over a million (Idemyor 2010). Fatalities are
14 estimated to be between 5,000 and 10,000 annually. The peak season for Lassa fever is the dry season
15 from February through May and it is estimated that 5–20 percent of susceptible persons are infected each
16 year (McCormick and Fisher-Hoch 2002), thus accounting for the large and varying estimates of burden
17 of disease. The rodent reservoirs are present both in agricultural and domestic settings. This increases the
18 possibility of coming into contact with rodents, contributing to the high incidence of disease among the
19 population.

21 Lassa fever is characterized by a wide range of clinical manifestations (Gunther and Lenz 2004). Fever is
22 a hallmark, accompanied by flu-like illness and gastrointestinal symptoms. These features make Lassa
23 fever indistinguishable from other fevers in West Africa, including other hemorrhagic fevers. Pharyngitis
24 is an early sensitive indicator and bleeding is a late specific symptom in Lassa fever patients.

26 Lassa fever is mild in about 80 percent of people infected with the viruses. Fatality rates from Lassa
27 viruses are significant at 10-20 percent in hospitalized patients and low for the general population at 1-2
28 percent. These are lower than that of other hemorrhagic fever viruses such as Ebola and Marburg viruses.
29 In untreated cases, however, mortality from Lassa fever may approach 60 percent.

30 There have been cases of Lassa fever reported in returning travelers from Africa from the 1970s in
31 Europe and in the US. A recent case in a traveler was the sixth imported case diagnosed and reported in
32 the US (Macher and Wolfe 2006; Amorosa et al. 2010).

1 The mode of transmission of Lassa viruses is from direct contact with rodents. Primary infection is
2 postulated to occur via breaks in the skin, by mucosal contact, ingestion of food contaminated by rodent
3 feces, and by consumption of the infected rodent (Curtis 2006). Though it is possible that aerosolization
4 of viruses from rodent droppings may cause human infection via the respiratory tract, this is considered
5 an infrequent event (McCormick and Fisher-Hoch 2002). The aerosol route has been shown to cause
6 infections in laboratory animals (Peters et al. 1987). Lassa viruses are not known to be vector-borne.

7
8 Direct person-to-person transmission of Lassa viruses occurs, especially in hospital settings. Person-to-
9 person transmission is associated with direct contact with the blood or other bodily fluids containing virus
10 particles from infected individuals. Airborne transmission has also been postulated to occur. Contact with
11 objects contaminated with virus, such as medical equipment (reused needles), is also associated with
12 transmission in healthcare settings (Simonsen et al. 1999). The viruses are generally not known to be
13 spread through casual contact, including skin-to-skin contact without exchange of bodily fluids (Ogbu et
14 al. 2007). These hospital-associated transmissions can be prevented with modern day practices such as
15 patient isolation, strict barrier precautions, personal protective equipment, sterilization of medical
16 equipment, and appropriate disposal of contaminated supplies.

17
18 The diagnosis of Lassa fever is based on epidemiological history of exposure to a patient during a known
19 outbreak or travel. Rapid diagnostic testing includes PCR-based methods (Drosten et al. 2002; Panning et
20 al. 2010). Other methods include serologic testing for IgM and IgG antibodies by enzyme immunoassay
21 or immunofluorescent antibody assay and antigen detection by enzyme immunoassay. Viral isolation by
22 cell culture remains the gold standard. The availability of these different modalities of testing is variable,
23 with some restricted to national and international reference laboratories.

24
25 The management of Lassa fever includes supportive therapy and the anti-viral medication, ribavirin, has
26 been shown to be effective, especially if given early in the course of the illness (Bausch et al. 2010;
27 Charrel et al. 2011). There is currently no vaccine available for Lassa fever and vaccine development
28 remains an active area of research (Geisbert et al. 2005; Kotturi et al. 2009).

Disease in Medically Vulnerable opulations

31 In general, all age groups are affected. The clinical presentation and outcomes in children are different
32 from those of adults, though there is no indication of increased incidence among children (Monson et al.
33 1987). There are no reports of increased incidence or susceptibility in specific medically vulnerable

Subpopulations. Lassa fever in pregnancy results in loss of the fetus in over 90% of patients. The risk of death is also higher for pregnant women, especially in their third trimester (Price et al. 1988).

Human Infectious Dose

There are no human dose-response data available for Lassa viruses. Epidemiological evidence suggests that humans have become infected through inhaling aerosolized particles containing Lassa viruses; however, the amount of virus inhaled by humans who became infected is not known. The human infectious dose is presumed to be low.

Laboratory Acquired Infections

Prior to 1979, there were three occupational infections reported with Lassa viruses (Pike 1979). One was a fatal infection in the researcher who described the first outbreak. She contracted it while doing an autopsy on a victim. There were two infections in laboratory workers in 1969 in the US, one was fatal.

There have been several laboratory incidents involving Lassa viruses, including three incidents at U.S. Army Medical Research Institute For Infectious Diseases (USAMRIID) (Biosafety Review, Appendix D). One of these incidents involved a needle and syringe loaded with a Lassa virus strain and posed a significant exposure (reported in 1979). None of the incidents resulted in clinical infection or asymptomatic disease (seroconversion).

There are no reports of laboratory-acquired infections with Lassa viruses or any other BSL-4 pathogens after institution of appropriate biosafety practices; this is a reflection of modern biosafety practices and awareness of risks associated with maximum biocontainment settings (National Research Council (U.S.). Committee to Review the Health and Safety Risks of High-Biocontainment Laboratories at Fort Detrick. 2010).

Laboratory-acquired infections with Lassa viruses are a concern and laboratory personnel education and training should be reinforced while dealing with this BSL-4 pathogen.

Summary

Lassa virus strains cause a hemorrhagic fever that is fatal to humans, especially if untreated. The incidence of Lassa fever is high in West Africa, where 5-20 percent of the population is at risk and numerous people contract the disease annually. The virus strains are transmitted to humans by close contact with rodents, their excretions, consuming food contaminated by rodents, or consuming the

1 infected rodents. The illness is characterized by a wide variety of symptoms including fever, flu-like
2 illness, gastro-intestinal symptoms, severe illness, and bleeding. Supportive and specific therapy with
3 ribavirin is effective. The overall case fatality rate is 1-2 percent in the general population and 10-20
4 percent in hospitalized patients. The case fatality rate may approach 60 percent in untreated patients.
5 There have been no recent laboratory-acquired infections with Lassa virus strains. Infections in travelers
6 returning from endemic areas have been reported.

7
8 There is a possibility of infection if an individual is exposed directly to Lassa virus strains. There is also a
9 possibility of person-to-person transmission of Lassa viruses; though the risk is low and requires close
10 contact with blood or bodily fluids with the viruses, especially in hospital settings.

11
12 For the purposes of this RA, Lassa viruses will be analyzed in detail with regard to: (1) possible event
13 sequences that could lead to loss of biocontainment at NEIDL resulting in exposure of laboratory workers
14 and the general public to Lassa viruses; (2) estimates of the amount of pathogen the laboratory workers
15 and general public would be exposed to as a result of those event sequences and (3) probabilistic
16 estimates of initial infection in those exposed to those amounts of Lassa viruses. As the risk of direct
17 person-to-person transmission of Lassa viruses is low and there are limited published mathematical
18 models of such transmission, secondary transmission modeling of Lassa viruses in the community will
19 not be performed for this RA.

3.5.2.4 Junín virus (JUNV)

Introduction

Junín virus is the causative pathogen of Argentine hemorrhagic fever (AHF) and was first described in the 1950s in Argentina. For this RA, JUNV was selected for analysis based on its characteristics of being highly pathogenic with a high case fatality ratio despite its poor transmissibility (Mahmoud 2008). The primary route of transmission to humans is inhalation of aerosolized virus through the respiratory tract from rodent urine, feces, saliva, and contaminated fomites). There is potential for direct person-to-person transmission of JUNV; however it is to be noted that there have been no reports of person-to-person transmission of this pathogen. The human infectious dose of JUNV is not known. The potential for LAI with JUNV exists and several such infections have been reported, all prior to 1980 and the institution of modern biosafety practices.

JUNV is endemic to central Argentina, where there are annual outbreaks of AHF during the agricultural season when humans come into contact with rodents that harbor the virus.

Junín virus is a member of the family *Arenaviridae*, genus **Arenavirus**, and belongs to the Tacaribe complex (New World arenaviruses) (LeDuc 1989).

The natural reservoir hosts for Junín virus are different species of vesper field mice, mainly *Calomys musculinus* (dry lands vesper mouse) and *Calomys laucha* (small vesper mouse). Virus antigens have been found in other species of mice including *Bolomys obscurus* (dark bolo mouse), *Mus musculus* (house mouse), and *Oligoryzomys flavescens* (yellow pigmy rice rat) (Carballal et al. 1988; LeDuc 1989; Ambrosio et al. 2006) (Mills et al. 1994). Experimental infection and animal models for Junín virus include wild rodents such as *Calomys musculinus* and laboratory-bred animals such as mice, rats, guinea pigs, and non-human primates. The guinea pig model most closely resembles human disease (Gomez et al. 2011).

Since its discovery, Junín virus has been studied extensively in maximum biocontainment laboratories, including in the US. BSL-4 is required for all work with Junín virus (Chosewood et al. 2009).

Human Disease and Outbreaks

Argentine hemorrhagic fever is endemic in a large area of fertile land in Argentina, termed the "humid pampas". An estimated 200 to 2,000 cases of Argentine hemorrhagic fever are reported annually in this

1 region, with a distinct seasonal peak in the fall (February to May) during the agricultural harvest when
2 humans come into contact with the rodent reservoir (Jay et al. 2005). It is important to note that there
3 have been uninterrupted annual outbreaks noted since the discovery of the virus in 1950. The geographic
4 region from which AHF is reported has been expanding in north-central Argentina, such that today,
5 nearly 5 million individuals are considered at risk for the disease (Gomez et al. 2011).

6
7 Human disease is characterized by fever, malaise, and headache, progressing to vascular, renal, and/or
8 hematologic/hemorrhagic disease and death. The hallmarks of the condition are impaired hemostasis,
9 endothelial cell dysfunction, and low platelet counts resulting in bleeding and death; hence AHF is
10 considered one of the ‘hemorrhagic fever viruses’. Overall, the case fatality rate is reported to be in the
11 range of 15-30 percent (Harrison et al. 1999; Colebunders et al. 2002; Enria and Barrera Oro 2002; Enria
12 et al. 2008; Gomez et al. 2011).

13
14 Junín virus is transmitted to humans from bodily secretions and excretions from persistently-infected
15 rodents. This could occur via aerosol, ingestion, fomites, and bites. The primary route of transmission to
16 humans is inhalation of aerosolized virus through the respiratory tract from rodent urine, feces, saliva, and
17 contaminated fomites (Carballal et al. 1988; LeDuc 1989; Enria and Barrera Oro 2002; Enria et al. 2008).

18
19 As with other hemorrhagic fever viruses in the Family *Arenaviridae* (Lassa fever virus and the New
20 World arenaviruses), there is potential for direct person-to-person transmission of Junín virus, postulated
21 to occur via close contact with infectious blood and body fluids (Borio et al. 2002). It is to be noted that
22 there have been no reports of person-to-person transmission of Junín virus from patients to health care
23 workers, despite the several hundred patients with hemorrhages cared for each year in Argentina (Charrel
24 and de Lamballerie 2003). The closely related Machupo virus has been confirmed to be responsible for
25 outbreaks in hospitals.

26
27 The diagnosis of Junín virus infection is based on the clinical presentation, laboratory data, and an
28 epidemiological history including appropriate travel (Colebunders et al. 2002). Laboratory confirmation
29 is by serology and PCR-based tests for rapid diagnosis (Gomez et al. 2011).

30
31 General supportive measures are an important component of the care of patients with viral hemorrhagic
32 fevers. The individual patient level management of patients with Junín virus infection has been greatly
33 improved with the use of immune plasma (or convalescent serum) containing antibodies to the virus. This
34 has resulted in decrease of mortality rates to less than 1% from an average of 20% in those who have no

1 treatment. Ribavirin has also been shown to be effective for this pathogen. At the population level, a live
2 attenuated vaccine, Candid-1, has been shown to be effective in decreasing incidence of Argentine
3 hemorrhagic fever (Enria and Barrera Oro 2002; Enria et al. 2008; Gomez et al. 2011).

5 **Disease in Medically Vulnerable Subpopulations**

6 There are no reports of any particular age groups being affected, nor any increased susceptibility in
7 medically vulnerable Subpopulations, including pregnant women, specifically for Junín virus. In general,
8 for viral hemorrhagic fevers, the presentation of illness is similar in adults and children and there is an
9 increase in fetal loss if pregnant women get infected.

11 **Human Infectious Dose**

12 The human infectious dose of Junín virus is not known. Epidemiological evidence suggests that humans
13 have become infected through inhaling aerosolized particles containing the pathogen, but the amount of
14 virus inhaled by humans who became infected is not known. From animal data, the human infectious dose
15 for Junín virus it is postulated to be low.

17 **Laboratory Acquired Infections**

18 There are several reports of laboratory-acquired infections (LAI) with Junín virus. The potential for
19 aerosolization of the virus is postulated to be the reason behind infections acquired in the laboratory.
20 There were at least 21 cases of LAI with Junín virus with one death up to 1980 (Scherer et al. 1980).
21 There was one incident reported from the USAMRIID in 1982 where during autopsy, a bone fragment of
22 a monkey infected with Junin virus punctured the finger of the worker. Immune plasma was used and no
23 clinical or subclinical infection ensued. In another incident in 2009 at the University of Texas Medical
24 Branch in Galveston, a scientist dropped a plate containing Junín virus on the floor. The spill was
25 decontaminated and reported after proper procedures were performed. There appeared to be no exposure
26 to virus and no infections were noted. (Biosafety Review, Appendix D).

28 From these incidents, it is concluded that laboratory-acquired infections are a concern with Junín virus.
29 All infections though were noted to be prior to 1980 when knowledge of biology and transmission of the
30 virus and biosafety precautions were rudimentary.

32 **Summary**

33 Junín virus is the causative pathogen of Argentine hemorrhagic fever and was first described in the 1950s.
34 Several hundred cases continue to occur in an endemic area of Argentina every year and an expanding

geographic region of the rodent reservoir places a large number of individuals at risk. The virus is transmitted from secretions and excretions of rodents via aerosolization to humans. A vaccine and the availability of specific treatment measures such as immune plasma and ribavirin have greatly reduced the risk, incidence, and mortality due to this virus. There is a potential for direct person-to-person transmission of viral hemorrhagic fevers; however, there are no specific reports of this occurring with Junín virus.

There is a possibility of infection in an individual exposed to Junín virus. There are effective treatment modalities available for this pathogen, along with supportive measures. A vaccine is available (in Argentina) that is used for prophylaxis. This pathogen is expected to be studied in BSL-4 maximum biocontainment laboratories worldwide, including the US. There have been reports of laboratory incidents and infections involving Junín virus; though all of these were from before 1980 when laboratory procedures and safety protocols were less rigorous.

For the purposes of this RA, Junín virus will be analyzed in detail with regard to (1) possible event sequences that could lead to loss of biocontainment at NEIDL resulting in exposure of laboratory workers and the general public to Junín virus; (2) estimates of the amount of pathogen the laboratory workers and general public would be exposed to as a result of those event sequences and (3) probabilistic estimates of initial infection in those exposed to those amounts of Junín virus.

Though the potential exists, there is a very low possibility of person-to-person transmission of Junín virus and there have been no specific reports documenting this; thus secondary transmission modeling of the spread of Junín virus infection in the community will not be performed as part of this RA.

3.5.2.5 Tick-borne Encephalitis Virus, Far Eastern Sub-type (TBEV-FE)

Introduction

Tick-borne encephalitis virus, Far Eastern sub-type (TBEV-FE) was formerly known as Russian spring-summer encephalitis. This virus is one member of the tick-borne encephalitis virus complex. For this RA, TBEV-FE was selected for analysis based on its characteristics of being highly pathogenic with a high case fatality ratio and transmitted via arthropod vectors (Mahmoud 2008). The virus is transmitted to humans through the bite of an infected tick. There is no known direct person-to-person transmission of TBEV-FE other than the rare cases of vertical transmission described from mother to fetus and via breast milk. The human infectious dose of TBEV-FE is not known. The potential for LAI with TBEV-FE exists

1 and several such infections have been reported, all prior to 1980 and the institution of modern biosafety
2 practices.

3
4 TBEV-FE is one of the causative pathogens of tick-borne encephalitis (TBE) (Lindquist and Vapalahti
5 2008). As the name implies, the disease is transmitted to humans by ticks, causes encephalitis and
6 is endemic in a large area from Western Europe to the eastern coast of Japan, and. The disease is
7 characterized by acute meningoencephalitis with or without myelitis, with varying morbidity and
8 mortality. The first description of TBE as a clinical entity was in Austria in 1931 and the causative
9 pathogen was isolated in the far eastern region of Russia in 1937.

10 Once considered a local health issue in certain regions of Russia and Central/Eastern Europe, TBE is now
11 an international health problem with expansion of endemic areas and rapidly increasing numbers of cases
12 due to travel to and pursuit of leisure activities into high-risk areas (Banzhoff et al. 2008).

13
14 The TBE complex of viruses are members of the genus *Flavivirus*, family *Flaviviridae* (Lindquist and
15 Vapalahti 2008; Mansfield et al. 2009). Medically important flaviviruses include mosquito-borne viruses
16 such as yellow fever, dengue Japanese encephalitis, and West Nile viruses; tick-borne flaviviruses include
17 those in the mammalian group such as tick-borne encephalitis virus, Central European encephalitis virus,
18 louping ill virus, Powassan virus, Kyasanur Forest disease virus, Omsk hemorrhagic fever virus, and
19 Langat virus (Lasala and Holbrook 2010). There are three subtypes of TBEV: (1) European (TBEV-Eu);
20 (2) Siberian (TBEV-Sib) and (3) Far Eastern (TBEV-FE). This risk analysis will focus on the Far Eastern
21 sub-type (TBEV-FE).

22
23 The natural reservoir of TBEV-FE is the tick *Ixodes persulcatus*, which also acts as the primary vector for
24 the virus (Lasala and Holbrook 2010). This tick is endemic to a large area extending from eastern Europe
25 to China and Japan. The virus can chronically infect ticks and is transmitted both transtadially (from larva
26 to nymph to adult ticks) and transovarially (from adult female tick through eggs. Ticks remain infected
27 throughout their life cycle and transmit the virus to uninfected ticks when co-feeding on small wild
28 rodents, such as the red vole (*M. rutilus* Pallas) which is indigenous to the area (Gritsun et al. 2003).
29 Currently, there are no effective animal models of the disease.

30
31 Since its discovery, virus has been studied extensively in maximum biocontainment laboratories around
32 the world, including the US. BSL-4 is required for all work with TBEV-FE virus (Chosewood et al.
33 2009).

Human Disease and Outbreaks

Several thousand human cases of TBE occur in Europe annually with Russia bearing the largest burden. As the older name suggests, the disease occurs during the summer and spring time when the ticks are active. During the period 1990-2006, Russia reported an average of 6,000 cases every year (adapted from data from The International Scientific Working Group on Tick-borne Encephalitis reported in (Lindquist and Vapalahti 2008)). The country with the next highest reported cases in the year 2006 was the Czech Republic with nearly 1000 cases. During this period, the annual incidence has been steadily increasing in all European countries except Austria, with an ever-expanding geographic area where the ticks are found. Humans are accidental hosts for TBEV-FE in that they can be infected by the virus and the virus can be detected in the blood; however, they do not participate in the circulation of the virus (Suss 2003). The virus is transmitted to humans through the bite of an infected tick. Following the tick bite and a median incubation period of 8 days, the first stage of illness appears. The prominent symptoms at this stage are fever, fatigue, general malaise, and headache/body pain (Lindquist and Vapalahti 2008). Following a symptom-free period, the second stage of the illness causes the most morbidity. The spectrum of illness includes mild meningitis to severe encephalitis, with or without spinal paralysis or myelitis. Altered consciousness or seizures may also be noted. One of the most concerning features is a flaccid poliomyelitis-like paralysis that preferentially affects the upper part of the body.

There is a long-term morbidity associated with TBE that includes residual spinal paralysis, a post-encephalitic syndrome, and cognitive problems. The case fatality rate is highest among patients with TBEV-FE, and of up to 20-40 percent.

Other than via ticks, TBEV has been reported to be transmitted to humans following consumption of raw milk from infected goats, sheep, or cows; consumption of imported goat cheese; vertical transmission from mother to fetus; and via breast milk (Randolph 2008).

There is no known direct person-to-person transmission of TBEV-FE other than the rare cases of vertical transmission from mother to fetus and via breast milk mentioned above. There have been cases of TBE reported in the US from travelers returning from Europe, especially Russia (2010). There were 2 cases reported prior to the year 2000 and between 2000-2009, there were 5 confirmed cases. Risk of acquiring TBEV while traveling to endemic areas remains a risk for tourists.

The diagnosis of TBEV-FE is based on clinical presentation and laboratory confirmation (Lindquist and Vapalahti 2008; Lasala and Holbrook 2010; Ruzek et al. 2010). A clinical and epidemiological history is

important along with an awareness of travel history to endemic areas. Laboratory testing includes TBEV-FE specific IgM and IgG that is detected during the second phase of the illness when central nervous system symptoms are prominent. The virus can also be detected by PCR from the blood during the first phase of the illness. Antibody detection in cerebrospinal fluid and antigen detection in the blood by enzyme immunoassay are also available. There is some cross-reactivity of these tests with other flaviviruses and this has to be noted while interpreting results.

There are no specific treatment modalities for TBEV-FE. The management of TBEV-FE infection is largely supportive; with intensive care being an important component. There is an effective vaccine available to prevent TBE by active immunization. There are Russian vaccines and also 2 vaccines based on the Siberian sub-type that are licensed in Europe. The success of mass vaccination campaigns in decreasing TBE has been well demonstrated in Austria, where the rate of protection is estimated to be 95 percent (Kunz 2002; Kunz 2003). Passive immunization using hyperimmune IgG against TBEV has fallen out of favor due to the lack of documented efficacy.

Disease in Medically Vulnerable Subpopulations

In general, all age groups are affected. The extremes of ages are affected adversely with a higher severity of illness noted in preschool children and a substantial increase in morbidity is seen in elderly people (Lindquist and Vapalahti 2008). There are no reports of increased susceptibility to TBEV-FE in specific medically vulnerable Subpopulations or in pregnant women.

Human Infectious Dose

There are no human dose-response data available for TBEV-FE virus. Animal models do not effectively reproduce human aspects of disease and so it is a challenge to interpret and extrapolate animal infectious dose data to humans. The human infectious dose for TBEV-FE is not known.

Laboratory Acquired Infections

Laboratory infections with TBEV were common before the advent of modern biosafety practices that prevented exposure to aerosols and vaccines. A total of 26 infections and 2 deaths have been reported in the literature, all prior to 1980. Risk factors appeared to be needle stick injuries and aerosolization of virus from breakage of glass-ware (Hanson et al. 1967; Pike 1979; Scherer et al. 1980; Subcommittee on Arbovirus Laboratory Safety of the American Committee on Arthropod-Borne Viruses 1980; Pedrosa and Cardoso 2011). Laboratory-acquired infections with TBEV-FE virus are a concern and reinforce laboratory personnel education and training while dealing with this BSL-4 pathogen.

Summary

The TBEV-FE sub-type causes TBE and is transmitted to humans via the bite of infected ticks of the species *Ixodes persulcatus*. Several thousand cases of TBE are reported from Europe every year; the bulk of the disease burden is in Russia. The disease has a case fatality rate of 20-40 percent and a high morbidity in terms of neurological sequelae. There is no specific treatment for TBE, however, it can be prevented with effective vaccines that are available in Europe. There is a possibility of infection if an individual is exposed directly to TBEV-FE. There is no direct person-to-person transmission of TBEV-FE, other than rare cases of transmission from mother to child and via breast milk (Randolph 2008).

For the purposes of this RA, TBEV-FE virus will be analyzed in detail with regard to: (1) possible event sequences that could lead to loss of biocontainment at NEIDL resulting in exposure of laboratory workers and the general public to TBEV-FE virus; (2) estimates of the amount of pathogen the laboratory workers and general public would be exposed to as a result of those event sequences and (3) probabilistic estimates of initial infection in those exposed to those amounts of TBEV-FE virus. As there is no direct-to-person transmission of TBEV-FE, secondary transmission modeling of the spread of this virus in the community following an initial infection will not be performed.

3.5.2.6 Nipah Virus (NIPV)

Introduction

Nipah virus is an emerging pathogen that was first described in 1998 from an outbreak of encephalitis in Malaysia and Singapore (1999). For this RA, NIPV was selected for analysis based on its characteristics of being highly pathogenic with a high case fatality ratio (Mahmoud 2008). Humans contract the virus when they come into contact with animals infected with the virus (such as pigs or domestic animals) or items contaminated with the virus by bats that serve as a reservoir for NIPV. Evidence from epidemiologic investigations of outbreaks in Bangladesh and India indicates that NIPV can be transmitted directly from person-to-person. The human infectious dose of NIPV is not known. The potential for LAI with NIPV exists; there are no reports of laboratory-acquired infections with Nipah virus.

Infections with Nipah virus were noted in workers with exposure to pigs such as pig farmers and abattoir workers. It was initially thought to be Japanese encephalitis that is known to occur in the region; subsequent detailed investigations and virologic studies revealed a new virus in the family *Paramyxoviridae*. The virus was named for the Nipah village in Malaysia where a fatal human case was first described in 1999 (Chua et al. 2000). Since the descriptions of the initial outbreaks, there have been several human outbreaks noted in Bangladesh (Hsu et al. 2004; 2004; Luby et al. 2009; Homaira et al.

2010). There are two outbreaks reported from areas in India that are close to the border with Bangladesh (Luby et al. 2009).

The Nipah virus, and its close relative, Hendra virus, belong to the family of paramyxoviruses, which have a single stranded non-segmented RNA virus that is fully encapsulated by protein (Lo and Rota 2008; Weingartl et al. 2009).

The natural reservoir hosts for Nipah virus appear to be several species of fruit bats of the genus *Pteropus*, as well as non-*Pteropus* species (Lo and Rota 2008; Blum et al. 2009; Luby et al. 2009; Weingartl et al. 2009; Chua 2010). Apart from bats in Malaysia, there is evidence for Nipah or Nipah-like viruses in bats from Cambodia and Thailand (Reynes et al. 2005; Wacharapluesadee et al. 2005). Nipah virus is able to infect a range of hosts, including swine, humans, and, to a minor extent, cats and dogs (Middleton et al. 2002; Mills et al. 2009; Weingartl et al. 2009).

Since its discovery in 1998 and description in 1999, Nipah virus has been studied extensively in maximum biocontainment laboratories, including in the US. BSL-4 is required for all work with Nipah and Hendra viruses (Chosewood et al. 2009).

Human Disease and Outbreaks

There appear to be two distinct clinical presentations of patients infected with Nipah virus. Neurological manifestations of encephalitis were noted in Malaysian pig farmers (Chua et al. 1999; Goh et al. 2000). Abattoir workers in Singapore demonstrated neurological and respiratory manifestations including pneumonia (Chew et al. 2000). Patients in the Bangladesh and Indian outbreaks primarily exhibited respiratory symptoms with evidence of pneumonia (Hossain et al. 2008). The case fatality rate is also different between the Malaysian and Bangladeshi outbreaks; higher in Bangladesh at 73%, as compared with 39% from Malaysia. This is postulated to be due to differences in availability of modern ICU care in Malaysia, rather than true differences in the biology and pathogenicity of the virus in the two outbreaks (Luby et al. 2009).

There have been no further outbreaks in Malaysia and Singapore after the initial outbreaks described in 1998 and 1999. Since then, there have been at least 10 large outbreaks described in Bangladesh and India in the period 2001-2008 and 17 minor transmission events involving one to four human cases (Luby et al. 2009).

1 The mode of transmission of Nipah virus has changed between the Malaysian/Singapore outbreaks and
2 those in Bangladesh/India. In the Malaysian/Singapore outbreaks, it is postulated that the virus was
3 transmitted from bats (natural reservoir) to pigs, causing an outbreak in pigs, which subsequently led to an
4 outbreak in humans in close contact with the pigs (abattoir workers and pig farmers).

5
6 In Bangladesh, the transmission from bats to humans appears to be ongoing and via at least three different
7 routes (Luby et al. 2006; Luby et al. 2009). The most frequent mode is food-borne through ingestion of
8 Nipah-virus-contaminated date palm sap which is a staple food source in that region. The sap from the
9 date palm tree is harvested in pots left hanging overnight on the trees after ‘tapping’ the tree. There is
10 evidence that bats that harbor Nipah virus in their saliva and urine lick the sap at night and Nipah virus is
11 known to survive in raw sap for several days.

12
13 A second mode of transmission appears to be via domestic animals that feed on contaminated fruits or
14 date palm sap that have been licked or partially eaten by fruit bats infected with Nipah virus. Cows, pigs,
15 and goats have been implicated in transmission of the virus to humans. A third route of transmission is
16 when humans come directly into contact with Nipah virus-infected bat secretions or excretions (saliva,
17 urine, feces). There do not appear to be any arthropod vectors in the transmission of Nipah virus.

18
19 Evidence from epidemiologic investigations of outbreaks in Bangladesh and India indicates that Nipah
20 virus can be transmitted directly from person-to-person. This has occurred in patients with respiratory
21 illness. Close physical contact with a known Nipah virus patient who later died was found to be the
22 strongest risk factor for direct person-to-person transmission (Gurley et al. 2007). Nipah virus has been
23 found in respiratory secretions of infected patients (Chua et al. 2001). Though direct transmissions have
24 occurred and are known to be responsible for many of the Bangladeshi outbreaks, the risk of direct
25 transmission appears to be low and requires close contact that may be culture- and region-specific (to
26 Bangladesh) (Luby et al. 2009). Given the limitations of conducting field investigations in rural areas of
27 developing countries, this study (Luby et al. 2009) estimated that only a few individuals transmitted to
28 others and the generations of transmissions rarely exceeded two. The overall number of secondary cases
29 resulting from an infected person was expected to be less than 0.5, indicating that it was unlikely that any
30 one chain of transmission would result in a large outbreak.

31
32 With regard to accidental or occupational exposure to Nipah virus and risk of transmission and infection,
33 there are differences between the Malaysian/Singapore outbreaks and those in Bangladesh and India.

1 From a study in Singapore, looking at Nipah virus infection in several different exposed groups including
2 abattoir workers and health care workers, there were no illnesses reported, however serologic studies
3 suggested evidence of asymptomatic infection in those directly exposed to pigs (Chan et al. 2002).
4 Similarly, in a study of 1412 military personnel who were involved in culling of pigs in Malaysia, 6
5 (0.4%) were noted to be seropositive (Ali et al. 2001). Of these, 4 were reported to be well with no
6 symptoms.

7
8 In a study of 338 health care workers who cared for Nipah patients at 3 Malaysian hospitals and, a
9 combined 89 episodes of exposure to Nipah virus from patient blood or body fluid directly contacting
10 bare skin, 39 splash exposures of blood or bodily fluid into their eyes, nose, or mouth, and 12 needle stick
11 injuries were reported and none developed clinical illness associated with Nipah virus infection (Mounts
12 et al. 2001).

13
14 In a Bangladesh hospital, there was no evidence of transmission of Nipah virus within the hospital,
15 despite substantial exposures and minimal use of personal protective equipment (Gurley et al. 2007).

16
17 In an outbreak in India, a patient not previously identified as having Nipah virus was admitted to a
18 hospital in Siliguri District. This patient transmitted the virus to 11 other patients who were then
19 transferred to other facilities. In two of those other facilities, a total of 25 staff and 8 visitors were infected
20 with Nipah virus from the transferred patients (Chadha et al. 2006).

21 There are differences noted in outcomes of accidental and occupational exposure to Nipah virus.
22 Variations in the virus and contact patterns between patients and health care workers are possible factors
23 leading to these differences.

24
25 The diagnosis of Nipah virus infection is based on epidemiological history of exposure or travel history.
26 Laboratory confirmation is by acute and convalescent serum antibody tests by ELISA (IgG and IgM), real
27 time polymerase chain reaction (RT-PCR) from various body fluids, and virus isolation attempts in
28 specialized laboratories. (Centers for Disease Control and Prevention (U.S.) 2011).

29
30 There are no effective medications for the treatment or prophylaxis of Nipah virus infection. Ribavirin has
31 been shown to be effective *in vitro*. There are currently no vaccines available for this pathogen (Centers
32 for Disease Control and Prevention (U.S.) 2011).

Disease in Medically Vulnerable Subpopulations

The initial outbreaks of Nipah virus infection occurred in male abattoir workers in Malaysia and Singapore. Subsequent outbreaks have been described in families and close contacts in Bangladesh and India. There are no reports of any particular age groups being preferentially affected, nor of any increased susceptibility in medically vulnerable subpopulations, including pregnant women.

Human Infectious Dose

The infectious dose of Nipah virus for humans is not known. From data from animal models and epidemiological data from outbreaks, it is postulated that the human infectious dose of Nipah virus is low.

Laboratory Acquired Infections

There are no reports of laboratory-acquired infections with Nipah virus.

Summary

Nipah virus is an emerging pathogen that causes a highly fatal disease in humans. There is a reservoir of this pathogen in fruit bats and though there are no further reports of outbreaks from Malaysia and Singapore where it was first discovered, there are reports of human outbreaks in Bangladesh and India as recently as 2007. There is a potential for this pathogen to be used in malevolent, intentional release scenarios as it is viable in certain high-sugar foods for several days. There is evidence of direct person-to-person transmission via respiratory secretions among close contacts who share food and/or bodily fluids with ill patients.

There is a possibility of infection in an individual is exposed to Nipah virus. There are no effective medications or vaccines for this pathogen. This pathogen is expected to be studied in BSL-4 maximum biocontainment laboratories worldwide, including the US. There have been no reports of laboratory incidents involving Nipah virus.

For the purposes of this RA, Nipah virus will be analyzed in detail with regard to (1) possible event sequences that could lead to loss of biocontainment at NEIDL resulting in exposure of laboratory workers and the general public to Nipah virus; (2) estimates of the amount of pathogen the laboratory workers and general public would be exposed to as a result of those event sequences, and (3) probabilistic estimates of initial infection in those exposed to those amounts of Nipah virus.

1 There is a possibility of person-to-person transmission of Nipah virus via respiratory secretions; however
2 the risk is low and requires close contact that may be culture- and region-specific (Luby et al. 2009).
3 Moreover, there are limited studies available to provide epidemiologic data for detailed secondary
4 transmission modeling and no published mathematical models for this pathogen. For these reasons,
5 secondary transmission modeling of the spread of Nipah virus infection in the community will not be
6 performed as part of this RA.

C. PATHOGEN CHARACTERISTICS

C.1 INTRODUCTION

The following data are selected findings from literature searches that were conducted by TetraTech scientists and subject matter experts on the Health and Human Ecology team, using methods and materials as described in Chapter 3. Results were sorted by pathogen and by biosafety level (BSL) designation, with references provided such that questions or needs for additional information by the Tetra Tech team could be efficiently addressed. These carefully documented data were organized and updated as a set of working notes for internal use by TetraTech in preparing the Risk Assessment. The data are presented here in the form used by the scientists and subject matter experts, and are presented solely for purposes of contributing to transparency of the Risk Assessment process. These data have not been substantially edited or reorganized for the lay reader. Instead, for that purpose, Chapter 3 has been constructed as a summation of key points about pathogen characteristics, and interested readers are directed there for representative information that has been selected and presented in a format that, in general, is more easily understood by the lay reader. Data are representative of the open literature as of January 2009. A cursory systematic update from the open literature was performed in April, 2010. Other information subsequently was added as needed. Any additional relevant data that might exist under classified status were not available to TetraTech.

C.1.1 BSL-3 Pathogens

C.1.1.1 Bacillus anthracis (B. anthracis)

Host range

a. Field

Natural reservoir is soil (typically pH >6) (Turnbull et al. 1998) (Hugh-Jones and Blackburn 2009). No animal reservoirs are known (Turnbull et al. 1998).

Grazing herbivores, especially cattle, sheep, goats, and horses are particularly susceptible; pigs are more resistant (Beyer and Turnbull 2009).

Not typically communicable between animals except through consumption (i.e. consumption by predators or scavenger, and those species are relatively resistant to infection) (Beyer and Turnbull 2009).

Birds are resistant with some exceptions such as the ostrich (Beyer and Turnbull 2009).

Outbreaks recently in Canada (Kumor, Bates, and Stephens; Center for Infectious Disease Research & Policy 2006).

Outbreaks in chimpanzees in Ivory Coast and gorilla in Cameroon (Leendertz et al. 2006; Leendertz et al. 2004).

b. Experimental

Mice, rats, guinea pig, and NHPs have been used for experimental models of disease (Welkos, Keener, and Gibbs 1986; Goossens 2009)

Prevalence/incidence/ attack rate

26,954 human cases in Turkey between 1960 and 2005 (Doganay and Metan 2009). Incidence per 100,000 ranged from 0.38–1.08 yearly (yearly data available 1990–2005) (Doganay and Metan 2009). 426 of those were reviewed: 96.9 percent were cutaneous, 1.9 percent were GI (1 case intestinal, 7 cases OP), 1.2 percent were meningitis (Doganay and Metan 2009).

2,000 to 20,000 human infections annually in Africa, the Middle East, and Southeast Asia. Most are cutaneous in settings of ruminant disease.

Largest human epidemic, 10,000 cases, occurred in Zimbabwe (1979–1985) (Mwenye, Siziya, and Peterson 1996).

71 naturally occurring inhalational human infections documented in the last century (Holty et al. 2006).

In the United States, from 1996 to 2001, 21 outbreaks in animals resulting in 1,862 deaths (Johnson 2008)

1 Anthrax is enzootic in several counties in southwestern Texas near the border of Mexico
2 (Johnson 2006) and in pockets in South Dakota, Nebraska, and Oklahoma (McBride et al. 1998).

3
4 Endemic in the Middle East, equatorial Africa, Mexico and Central America, Argentina,
5 Cambodia, Chile, China , Myanmar, Papua New Guinea, Peru, Thailand, Vietnam .

6
7 One million sheep deaths in Iran in 1945 (Amidi et al. 1974).

8
9 Attack rate among 170 postal mail personnel for letter sorting incident was 1.2 percent (Greene
10 et al. 2002; Inglesby et al. 2002).

11
12 Historical circumstantial evidence from at-risk industrial occupations suggests that humans are
13 relatively resistant to infection from naturally occurring exposures (Turnbull 1998).

14
15 **R_0 /incubation period/infectious period/infectious dose**

16 No human-to-human spread ($R_0 = 0$) with GI or inhalational disease (Inglesby et al. 2002;
17 Meselson et al. 1994; Turnbull 1998).

18
19 Very rare spread to caregiver (cutaneous infection from changing dressings) (Weber and Rutala
20 2001).

21
22 Incubation period for inhalational anthrax is suggested by modeling to be dose dependent and
23 that the relatively long period of the Sverdlovsk outbreak was related to exposure level
24 (Wilkening 2006). That contrasts with evaluations of natural environment in goat hair mills
25 where workers inhaled > 500 *B. anthracis* particles in an 8-hour shift (Dahlgren et al. 1960).

26
27 Cutaneous disease develops 1–12 days after infection and is characterized by ulcer and
28 ultimately eschar with significant swelling (Smyth 1941; Kunanusont, Limpakarnjanarat, and
29 Foy 1990; Gold 1955; Bravata et al. 2007; Fair et al. 2007; Amidi et al. 1974).

1 Incubation period for cutaneous anthrax in humans ranges from 9 hours to 2 weeks, but it mostly
2 is 2 to 6 or 7 days (Turnbull 1998).

3
4 GI/OP symptoms appear 2–5 days after ingestion (Ndyabahinduka et al. 1984; Sirisanthana and
5 Brown 2002; Sirisanthana et al. 1984).

6
7 Incubation period 1–13 days (Doganay and Metan 2009).

8
9 Cynomolgus monkeys, incubation periods are 7–18 days (Brachman, Kaufman, and Dalldorf
10 1966).

11
12 Incubation period in experimental animals is 36–72 hours regardless of the route of infection
13 (Beyer and Turnbull 2009).

14
15 Infectious doses for humans have not been established (Turnbull 1998).

16
17 ID₅₀ for pulmonary infection in humans is estimated at 8,000 to 50,000 spores (Franz et al.
18 1997).

19
20 Extrapolations suggest: LD₅₀ is 2,500 to 55,000 spores (Defense Intelligence Agency 1986);

21
22 LD₁₀ as low as 100 spores; LD₁ of as low as 1–3 spores (Peters and Hartley 2002).

23
24 Mathematical modeling of airborne anthrax infection (based on the USPS 2001 experience)
25 suggests exposures ranging from 18 to 863 spores and perhaps as low as 2–9 spores (Fennelly et
26 al. 2004).

27
28 One model of the Sverdlovsk outbreak suggests 50 percent of victims were infected by doses of
29 ~2 spores (Wilkening 2006).

30
31 One estimate of the human ID₅₀ is 8,600 spores (Wilkening 2006).

Infectious dose for cutaneous disease is unknown. Spores will germinate 1–3 hours after inoculation (Bischof, Hahn, and Sohnle 2007).

Infectious dose for GI anthrax is unknown. In animal models (guinea pigs, rabbits and monkeys) researchers were unable to induce infection using an inoculum of 10^8 spores (Beatty et al. 2003).

As few as 100 spores can be sufficient to cause infection in monkeys (Brachman, Kaufman, and Dalldorf 1966), but the amount needed to cause infection and death in 50 percent of monkeys was 4,130 (1,980–8,630) spores (Glassman 1966).

Morbidity/case fatality ratio

a. Humans

In the 2001 U.S. outbreak, no evidence of mild form of the disease was detected through follow up serologic testing of exposed persons (Baggett 2005).

Untreated patients can infrequently progress to sepsis and, ultimately, death.

CFR for untreated infection varies by cutaneous (5–20 percent) (Smyth 1941), GI/OP (25–60 percent), and inhalational (85–100 percent).

Zimbabwe, 19 cases were reported with a case fatality rate of 26 percent (95 percent CI 5–47 percent) (Mwenye, Siziya, and Peterson 1996).

Turkey, CFRs were 0.96 percent for cutaneous infection, 37.5 percent for GI infection, 100 percent for meningitis, and 2.8 percent overall (Doganay and Metan 2009).

Appropriate antimicrobial therapy reduced reported CFR to < 1 percent (Gold 1955), 12.5 percent (Beatty et al. 2003; Sirisanthana and Brown 2002), and 45–75 percent (Jernigan et al. 2001; Holty, Kim, and Bravata 2006), in the most recent outbreaks. Patients with later symptom onset after exposure (e.g., >30 days) had better survival.

CFR was lower among patients in the United States 2001 outbreak who received antibiotics during the prodromal phase (< 4.7 days) compared to patients who received antibiotics later (40 percent versus 75 percent) (Holty, Kim, and Bravata 2006). Available data from a pediatric review is limited but showed a similar CFR (Bravata et al. 2007).

b. Animals

Species-specific mortality during a 1971 epizootic in Louisiana was 4.3–9.1 percent (cow) and 12.5–22.5 percent (horse) (Johnson 2006).

1974 epizootic in Texas, species-specific mortality of 10.5 percent (cattle), 40 percent (horses), 50 percent (mules), and 0 percent (pigs) (Johnson 2006).

Cynomolgus monkeys incurred mortality rates (percent) of 7.1, 10.0, 11.8, 22.5, and 43.8, respectively for five experiments (overall mortality rate of 23.5 percent) (Brachman, Kaufman, and Dalldorf 1966).

Aerosol infection/routes of transmission

Infection following laboratory exposure has been described, including a recent cutaneous case in a laboratory worker (Brachman 1980)(Centers for Disease Control and Prevention 2002).

Human disease is acquired by three routes: cutaneous, inhalation, and GI. More recently, injection infections have been reported following illegal drug use (heroin) (ProMED mail 2010). Cutaneous anthrax results from introducing the spore through the skin; inhaling anthrax via the respiratory tract; and GI anthrax (abdominal or OP) through ingestion. Cutaneous disease (~95 percent) characterized by ulcer and ultimately eschar with significant swelling (Smyth 1941; Kunanusont, Limpakarnjanarat, and Foy 1990; Gold 1955; Bravata et al. 2007; Fair et al. 2007; Amidi et al. 1974).

GI/OP infection follows ingestion and accounts for less than 5 percent of cases (Ndyabahinduka et al. 1984; Sirisanthana and Brown 2002; Sirisanthana et al. 1984).

Inhalation/pulmonary infection historically occurs rarely in manufacturing settings or, more recently, after accidental or deliberate release of weaponized spores (Meselson et al. 1994). Germination of spores is followed by rapid hemorrhage, edema and necrosis of surrounding tissue from release of bacterial toxins. Meningitis is a frequent complication of inhalational disease (Rangel and Gonzalez 1975; Sejvar, Tenover, and Stephens 2005).

Naturally occurring disease in the United States is rare. No GI/OP cases were recorded in the last century, and 18 inhalational cases were reported between 1900 and 1976 (Brachman 1980). A single inhalational case with exposure to dried animal hides in 2006 was the first naturally occurring in United States since 1976 (CDC 2006; Walsh et al. 2007). Only 225 cutaneous cases occurred between 1944 and 2000.

Two naturally occurring cases of cutaneous infection since 2006 were related to Djembe drums (Centers for Disease Control and Prevention 2008).

A 2009 case of GI infection in the United States was linked to animal hide drums (Centers for Disease Control and Prevention 2010; Goodnough 2009; Brooks 2010).

Infection can occur from contact with infected tissues (butchering, contaminated meat) (Woods et al. 2004), consumption of undercooked meat (Sirisanthana et al. 1984), and contact with contaminated hair, wool, hides (Wattiau et al. 2008).

Bacterial concentrations/pathogenesis

Source cultures for animal experimentation are usually 10^9 CFU/mL (Abalakin and Cherkasskii 1978; Keppie, Smith, and Harris-Smith 1955; Welkos, Keener, and Gibbs 1986).

Culture concentration of 10^9 CFU/mL comprise of 90% spores (Welkos, Keener, and Gibbs 1986).

In naturally infected animals and in the laboratory, bacteremic animals achieve 10^7 to 10^8 CFU/mL (Turnbull 1998).

Certain organs of infected animals can have even higher concentration (e.g., 10^9 CFU/g in spleen) (Welkos, Keener, and Gibbs 1986).

10 mL of 5×10^9 as inoculum for mouse challenges created by filtration (Osorio et al. 2009; Pickering et al. 2004).

Pathogen stability

Spores seeded into a plant/soil model had survival ratio at day 2 and day 4 of approx. 60% and 53%, respectively, and the percentage of cells that were vegetative was 47% and 43% , respectively (Saile and Koehler 2006).

Vegetative bacteria have poor survival outside the host (Johnson 2006)(Titball, Turnbull, and Hutson 1991).

Spores resist drying, heat, ultraviolet (UV) light, and some disinfectants (Turnbull 1998).

Anthrax spores can remain viable after standard DNA purification procedures (Rantakokko-Jalava and Viljanen 2003).

Heating to 121 °C for 45 minutes and gamma irradiation appear to eliminate viability (Fasanella et al. 2003; Dauphin et al. 2008).

Anthrax spores can survive in soil for months or even decades depending on pH, temperature, and nutrients in the soil (Montville et al. 2005; Manchee et al. 1990).

Animal data suggest that anthrax spores can survive in lungs for 60 days, or even more than 100 days in the lymph nodes of a monkey (Henderson, Peacock, and Belton 1956).

The spore surface is highly hydrophobic, and spores in soil can be transported in clumps of organic matter by water runoff. Evaporation of water redistributes spores onto vegetation and are consumed by susceptible herbivores (Johnson 2006).

Seawater and formaldehyde used on contaminated soil (Inglesby et al. 2002). Chlorine dioxide fumigation used after 2001 attack in buildings (Wein, Craft, and Group 2005).

1 **Vectors**

2 Tabanid flies have been associated with rare cases of cutaneous disease (Turell and Knudson
3 1987).

5 **Other epidemiological/ecological data**

6 Spore germination occurs at temperatures of 8–45 °C, pH 5–9, when relative humidity (RH) is
7 greater than 95 percent, and adequate nutrients are present (Turnbull et al. 1998).

9 **Therapeutics/vaccines**

10 *B. anthracis* typically is susceptible to penicillin, doxycycline, fluoroquinolones. Penicillin is not
11 given as monotherapy. Initial IV therapy with multiple agents for inhalational disease with total
12 course of 60 days. Oral FQ or doxycycline for cutaneous disease (CDC 2001).

14 A human monoclonal antibody drug is available (raxibacumab) and was developed for the U.S.
15 government (Human Genome Sciences 2009).

17 Anthrax immune globulin is available (HHS 2006).

19 Prophylaxis: 60 day course of either doxycycline or ciprofloxacin recommended and effective in
20 the recent bioterrorism event with vaccination if available (CDC 2001).

22 Anthrax vaccine adsorbed (AVA), a precipitated preparation of protective antigen from
23 attenuated, non-encapsulated Sterne strain bacteria, affords protection for rhesus monkeys for
24 inhalational and cutaneous disease and a clinical trial for cutaneous disease among mill workers
25 (Gladstone 1946; Brachman et al. 1962; Mahlandt et al. 1966; Turnbull 1986).

27 A licensed vaccine for anthrax is available for at-risk personnel for preexposure or in post-
28 exposure situations (to be taken with antibiotic therapy) (CDC 2002; CDC and NIH 2007;
29 Wright et al.).

1 **Other remarks**

2 Although they may have limited applicability to animals, the findings as summarized by the
3 Working Group on Civilian Biodefense showed no significant threat to personnel from
4 aerosolization of settled spores (Inglesby et al. 1999).

5
6 Re-suspension of weapons grade anthrax can occur, but risk to exposed persons is unknown
7 (Weis et al. 2002).

8
9 In 1996, The United States Department of the Army reported its findings from field tests to study
10 the potential for reaerosolization of settled spores. Although they may have limited applicability
11 to animals, the findings as summarized by the Working Group on Civilian Biodefense showed no
12 significant threat to personnel from reaerosolization of settled spores (Inglesby et al. 1999).
13 BSL-3 biocontainment precautions are recommended for activities with a high potential for
14 creating aerosols (CDC and NIH 2007).

15
16 **Taxonomy/antigenic relationships/synonyms**

17 *B. anthracis* is a large (1–8 µm x 1–1.5 µm), gram-positive, non-motile, spore forming (1 µm),
18 bacterial rod that is responsible for both epizootics and enzootic disease and occasional human
19 disease (Johnson 2006).

20
21 *B. anthracis* has three primary virulence factors, which are all plasmid-mediated: edema toxin,
22 lethal toxin, and a poly-D-glutamic acid capsule (Turnbull 1998).

23
24 **C.1.1.2 Francisella tularensis (F. tularensis)**

25 **Host range**

26 **a. Field**

27 Infections have been reported in more than 200 species of terrestrial and aquatic
28 mammals (esp. *Sylvilagus-cottontail* in United States) such as ground squirrels, rabbits,
29 hares, voles, muskrats, water rats and other rodents, as well as reptiles, birds, and fish
30 (Gelman 1961; Hopla 1974; Morner 1992; Dennis 1998; Sjostedt 2007).

1 Natural reservoirs are poorly understood (Keim, Johansson, and Wagner 2007).

2
3 **b. Experimental**

4 Primates (Lyons and Wu 2007; Sawyer et al. 1966; Day and Berendt 1972), mice, rats
5 (Lyons and Wu 2007), and rabbits (Lyons and Wu 2007) have been used in experimental
6 animal models.

7
8 **Prevalence/incidence/attack rate**

9 120 cases per year in the United States are recorded; Arkansas has the highest rate; Martha's
10 Vineyard has periodic outbreaks (Sjostedt 2007)(Centers for Disease Control and Prevention
11 2002; Matyas, Nieder, and Telford 2007). Endemic foci exist in Russia, Finland, and Sweden.

12
13 **R₀/incubation period/infectious period/infectious dose**

14 No, or minimal, human-to-human spread is reported ($R_0 = 0$) (Dennis et al. 2001).

15
16 Ulceroglandular form after a bite from a vector or handling infected meat (with a 3- to 5-day
17 incubation, and the range is 1–21 day) (Dennis 1998; Cross 2000; Dennis et al. 2001; Sanders
18 and Hahn 1968; Penn 2005; Evans et al. 1985)Incubation period averages 3–5 days (and the
19 range is 1–21 days) (Penn 2010).

20
21 Incubation period is 3–5 (1–14) days (Dennis et al. 2001).

22
23 Extremely low infective dose. ID₅₀ of 10-50 cells (SchuS4). As few as 10 cells skin inoculation
24 or 15 cells by aerosol as determined in human challenges (Franz et al. 1997; Saslaw et al. 1961).
25 200 aerosolized cells infected 2/2 volunteers (McCrumb 1961).

26
27 **Morbidity/case fatality ratio**

28 Human disease has three major clinical forms: Ulceroglandular is the most common (45–85
29 percent), usually after a bite of vector that fed on infected animal or handling infected meat
30 (Dennis 1998; Cross 2000; Dennis et al. 2001; Sanders and Hahn 1968; Penn 2005; Evans et al.
31 1985).

1 *F. tularensis* subsp. *tularensis*, (type A), is found almost exclusively in North America and is the
2 most virulent species (Clades 1 and 2) (Ellis et al. 2002; Petersen 2006; Penn 2005). *F. tularensis*
3 subspecies *novicida* is of low virulence (Penn 2005). Depending on strain, illness can be
4 relatively benign or even asymptomatic (Penn 2005).

5
6 Untreated CFR varies by strain/clinical presentation. CFR before antibiotics ~7 percent, but ~4
7 percent for ulceroglandular (Pullen 1945).

8
9 CFR can be as high as 50 percent for pneumonia (Dennis et al. 2001; Pullen 1945).

10
11 CFR for Type A-East (Clade1) is 14 percent, Type B is 7 percent, Type A-West (Clade 2) is 0
12 percent (Staples et al. 2006).

13
14 Antibiotics reduce CFR from severe disease in pre-antibiotic era to ~2 percent (Evans et al.
15 1985).

16
17 Poor outcome is associated with comorbid conditions, late presentation, delayed antibiotics
18 (Penn and Kinasewitz 1987; Rohrbach, Westerman, and Istre 1991).

19
20 Extremely low infective dose is reported. ID₅₀ of 10–50 cells (SchuS4). As few as 10 cells
21 through skin inoculation or 15 cells by aerosol as determined in human challenges (Franz et al.
22 1997; Saslaw et al. 1961).

23 24 **Aerosol infection/routes of transmission**

25 Tularemia is highly infectious for lab workers (1 infection/1,000 at-risk employee years in
26 *vaccinated* employees) (Pike 1976; Shapiro and Schwartz 2002; Burke 1977; Overholt et al.
27 1961).

28
29 Can be transmitted through apparently intact skin. Oculoglandular is a rare form (< 5 percent)
30 contracted through the conjunctiva (Lillie and Francis 1937). OP or enteral tularemia (< 5
31 percent) can result from ingestion of infected food or water. Pneumonic tularemia (< 5 percent)

1 can be primary (inhalation) or secondary (spread from other forms)(Stuart and Pullen 1945;
2 Syrjala et al. 1986; Lillie and Francis 1937). Typhoidal tularemia (< 5 percent) is a sepsis
3 presentation in the absence of a known point of entry.

4
5 Infected arthropods (Klock, Olsen, and Fukushima 1973; Markowitz 1985).

6
7 Handling infectious tissues (Young 1969).

8
9 Ingestion (Greco et al. 1987; Mignani et al. 1988; Reintjes et al. 2002; KuoLee et al. 2007).

10
11 Inhalation of aerosols (Dahlstrand, Ringertz, and Zetterberg 1971; Feldman et al. 2001; Feldman
12 et al. 2003).

13
14 Possibly direct contact with soil or water, or ingestion of water (Willke et al. 2009) (Greco et al.
15 1987; Meric et al. 2008; Keim, Johansson, and Wagner 2007).

16
17 **Bacterial concentrations/pathogenesis**

18 Heavy bacterial load occur in blood and tissues (Lyons and Wu 2007).

19
20 Most models use SCHU S4. Human challenge models from the 1950s and 1960s cutaneous and
21 aerosol used a challenge of 10^4 - 10^8 (Lyons and Wu 2007).

22
23 Concentrations used in primate models varied from 10^4 to greater than 10^8 (Lyons and Wu 2007;
24 Sawyer et al. 1966; Day and Berendt 1972).

25
26 Mouse/rat animal models used challenge doses of 10^2 to 10^4 CFU; tissue burdens of 10^{7-8} are
27 reported (Lyons and Wu 2007).

28
29 Rabbit models have used aerosol challenge ranging from 10^5 to 4×10^8 cells (Lyons and Wu
30 2007).

1 **Pathogen stability**

2 Viability of *F. tularensis* aerosols in a chamber ventilated with outdoor air ranged from 7% (45
3 minutes at 79-82% RH) [HL=11.7 min] to 25% (30 minutes at 73% relative humidity)
4 [HL=15min] (Hood 2009).

5
6 *F. tularensis* can persist in water, mud, and animal carcasses for months (Morner 1992).

7
8 Water mammals or protozoa might play role in persistence in water but are likely not required.
9 Chlorination protects municipal systems (Mitchell and Penn 2005; Greco et al. 1987).

10
11 Under natural conditions, *F tularensis* can survive for extended periods in a cold, moist
12 environment. The working group lacks information on survival of intentionally dispersed
13 particles but would expect a short half-life because of desiccation, solar radiation, oxidation and
14 other environmental factors (Dennis et al. 2001).

15
16 **Vectors**

17 A wide range of arthropod vectors is implicated in transmission between mammalian hosts
18 (Dennis 1998; Hopla 1974; Sjostedt 2007).

19
20 Tabanid flies (e.g., *Chrysops discalis*) are most important for *F. tularensis tularensis* Clade 2 in
21 Utah, Nevada, and California ; ticks [*D. variabilis*, *A. americanum* (Clade 1); *D. andersoni*
22 (Clade 2)] most important east of the Rocky Mountains (Farlow et al. 2005; Jellison 1950;
23 Olsuf'ev and Emel'ianova 1966).

24
25 In Russia, Central Asia, and Sweden, it is spread by mosquitoes (*Aedes*, *Culex*, and *Anopheles*)
26 (Sjostedt 2007) and *Ixodes* sp of ticks. Mosquitoes and tabinids are likely infected by a water
27 source.

28
29 Preservation in the fly gut for at least 56 hrs. is reported (Sjostedt 2007).

1 **Other epidemiological/ecological data**

2 Tularemia is primarily a rural disease, but natural infections can occur in suburban and even
3 urban areas as well (Dvorak 2005; Martone et al. 1979; Halsted and Kulasinghe 1978; Dennis et
4 al. 2001).

5
6 **Therapeutics/vaccines**

7 Doxycycline or ciprofloxacin are used for prophylaxis (Sawyer et al. 1966; Dennis et al. 2001).
8 Aminoglycosides are the treatment of choice for severe disease (Pediatrics 2006; Enderlin et al.
9 1994; Hassoun, Spera, and Dunkel 2006).

10
11 Fluoroquinolones are as effective as aminoglycosides in animal models and limited human
12 studies (Johansson et al. 2000; Perez-Castrillon et al. 2001; Limaye and Hooper 1999).

13
14 Tetracyclines are acceptable, but failures occur (Brouillard et al. 2006; Tarnvik and Chu 2007;
15 Overholt et al. 1961; Evans et al. 1985). Beta-lactams should not be used.

16
17 Live attenuated vaccine strain (LVS), not licensed in western countries, had been in use since
18 1959 for immunizing personnel at risk of lab infection, but its use in the U.S. has been
19 suspended (Penn 2005).

20
21 Partial protection against aerosol challenge (Griffin, Oyston, and Titball 2007; Burke 1977).
22 Improved LVS is in clinical evaluation (Pasetti 2008) Experimental formalin-inactivated,
23 attenuated, and recombinant vaccines might be efficacious or available for at-risk personnel, but
24 no licensed vaccines are available (Sjostedt 2003; Jia et al. 2009).

25
26 **Other remarks**

27 Fully virulent *F. tularensis* is a BSL-3 pathogen (Dennis et al. 2001; CDC and NIH 2007).
28 Conditionally virulent or attenuated *F. tularensis* is BSL-2.

Taxonomy/antigenic relationships/synonyms

Francisella species are small (0.2–0.5 µm x 0.7–1.0 µm), aerobic, catalase-positive, pleomorphic, gram-negative coccobacilli with four recognized subspecies (*tularensis*, *holarctica*, *mediasiatica*, and *novicida*) (Ellis et al. 2002; Wong 1999).

C.1.1.3 *Yersinia pestis* (Y. pestis)

Host range

a. Field

Approximately 215 mammalian species from 73 genera are naturally infected; rodents are the most important host (Butler 1991; Gabastou et al. 2000; Dennis and Meier 1997; Gage 1998).

Occasional spread to amplifying hosts (prairie dogs, ground squirrels, chipmunks) causes epizootics (Christie 1980; Gage et al. 2000; Dennis and Meier 1997; Reed et al. 1970; von Reyn et al. 1976; Wild, Shenk, and Spraker 2006; Gage and Kosoy 2005).

Occurs in rats, tarabagans (Pharaoh's rat), susliks (ground squirrel), ground squirrels, prairie dogs, field mice, bobcats, chipmunks, and camels (Dennis and Mead 2010).

Cats, when orally infected, develop buboes and bacteremia and transmit infection via scratches, bites, and close contact (Gage et al. 2000).

Occurs in great gerbils, Kazakhstan (Stenseth et al. 2006; Enscoe et al. 2002).

Partially resistant mammals (*Peromyscus* and *Microtus*) and their fleas responsible for enzootic maintenance (Christie 1980; Gage et al. 2000; Dennis and Meier 1997; Reed et al. 1970; von Reyn et al. 1976; Wild, Shenk, and Spraker 2006; Gage and Kosoy 2005).

Many mammals have high susceptibility and high CFR; others are more resistant (Christie 1980; Gage et al. 2000; Dennis and Meier 1997; Reed et al. 1970; von Reyn et al. 1976; Wild, Shenk, and Spraker 2006; Gage and Kosoy 2005).

Carnivores appear to be highly resistant (Salkeld et al. 2007; Boone, Kraft, and Stapp 2009).

b. Experimental

Guinea pigs are the most common historical experimental models for epizootic plague because of their high susceptibility.

Aerosol transmission in mice and guinea pigs is difficult to establish, but there is a rat model (Agar et al. 2009).

Mice are used for experimental study (Agar et al. 2008).

Prevalence/incidence/attack rate

In the United States, 415 cases were reported from 1970 to 2007 (Dennis and Mead 2010). About seven cases are recorded annually, most (~80 percent) bubonic (Centers for Disease Control and Prevention 1994, 2006, 1991).

Occurs in 17 of the contiguous western U.S. states (Dennis and Mead 2010).

80 percent of U.S. cases occur in New Mexico, Arizona, and Colorado; approximately 10 percent are in California (Dennis and Mead 2010).

Globally, 38 countries reported more than 80,000 cases over past 50 years. Annual reporters include Brazil, Democratic Republic of Congo (DRC), Madagascar, Myanmar, Peru, United States, Vietnam (Dennis and Mead 2010).

Outbreaks have occurred in Vietnam, India, Tanzania, and Madagascar (Dennis and Mead 2010). Recently, pneumonic outbreaks have occurred in Madagascar 1997, DRC 2006, and adjacent Uganda in 2007. Attack rate is 8 percent in untreated close contacts in Uganda (Begier et al. 2006). That is similar to the attack rate experienced in Madagascar (Ratsitorahina et al. 2000).

R₀/incubation period/infectious period/infectious dose

R₀ is estimated at 1.3 from model of 20th century pneumonic outbreaks (Gani and Leach 2004).

1 R_0 of 1.32 (90% confidence interval: (1.01-1.61)) estimated from six historical outbreaks
2 (Lloyd-Smith et al. 2005).

3
4 In rhesus and *C. philippinensis* primates, 120–270 cells caused infection (Meyer 1961).
5 Monkeys with pneumonic plague exhaling 20 or more CFU were able to infect other monkeys
6 (Meyer 1961).

7
8 Bubonic plague develops 2–6 days after infection (Butler 1972, 1991; Hull, Montes, and Mann
9 1987; McGovern and Friedlander 1997).

10
11 Primary pneumonic plague develops 1–3 days after droplet exposure (2-5 ft)(Kool 2005; Craven
12 et al. 1993; Meyer 1961; Doll et al. 1994; Gasper et al. 1993).

13
14 Plague's latent period has a mean and standard deviation of 4.3 and 1.8 days, respectively (Gani
15 and Leach 2004).

16
17 Incubation period is stated by others to be 1–3 days for primary pneumonic plague (Perry and
18 Fetherston 1997).

19
20 Incubation period is 2–6 days for the bubonic form (Winters et al. 2009).

21
22 Infectious period has a mean and standard deviation of 2.5 and 1.2 days, respectively (Gani and
23 Leach 2004).

24
25 Estimated dose is 100–500 CFU in humans (Perry and Fetherston 1997; Franz et al. 1997).

26 LD_{50} in mice has been determined to be 2.1×10^3 CFU (Agar et al. 2008; Agar et al. 2009).

27
28 Infectious dose is low—approximately 120–270 organisms in *Macaca rhesus* and *Cynomolgus*
29 *philippinensis* (*M. cynomolgus philippinensis*) (Meyer 1961).

30
31 LD_{50} is ~20,000 inhaled cells in *M. rhesus*.

LD₅₀ data in rats is 1.6×10^3 (Agar et al. 2009).

LD₅₀ determined for mice (Agar et al. 2008).

Morbidity/case fatality ratio

In the United States, 415 cases were reported from 1970–2007 with 59 deaths (Dennis and Mead 2010).

Three major clinical forms of human diseases exist: bubonic, septicemic, and pneumonic.

Asymptomatic or minimally symptomatic infections have not been reported (Dennis and Mead 2010). Secondary septicemia, pneumonia, and meningitis are the most common complications. Sub-clinical infections can occur in endemic areas (Ratsitorahina et al. 2000).

Bubonic plague (~85 percent of U.S. cases) are characterized by fever, headache, chills, swollen, tender lymph nodes (mainly inguinal and femoral in adults, mainly cervical or axillary in children) (Butler 1972, 1991; Hull, Montes, and Mann 1987; McGovern and Friedlander 1997).

Bacteremia or secondary sepsis is frequent with higher CFR (Butler et al. 1976; Dennis and Mead 2010).

Primary septicemic plague occurs without adenopathy (approximately 10–25 percent of U.S. cases) (Butler 1991; Hull, Montes, and Mann 1987; Sebbane et al. 2006; Dennis and Meier 1997).

Primary pneumonic plague is a rare (about 2 percent in the United States but higher in other areas) but deadly form of the disease (Kool 2005; Craven et al. 1993; Meyer 1961; Doll et al. 1994; Gasper et al. 1993).

Secondary pneumonia occurs in about 12 percent of U.S. cases (Doll et al. 1994).

CFR in untreated bubonic plague ranges from 40 to 60 percent (Dennis 1997).

1 Untreated septicemic form is uniformly fatal (Perry and Fetherston 1997; Crook and Tempest
2 1992).

3 Untreated pneumonic form is uniformly fatal (Dennis 1997).

5 In the United States, treated bubonic CFR is less than 5 percent (Butler 1991).

7 In the United States, overall CFR for plague is about 14 percent (Craven et al. 1993). However,
8 antibiotics used empirically for undifferentiated sepsis are not effective against *Y. pestis*, so the
9 CFR remains high.

11 Overall CFR for children in recent U.S. outbreaks is 15.8 percent (Mann, Shandler, and Cushing
12 1982).

14 **Aerosol infection/routes of transmission**

15 For the pneumonic form, inhalation of droplets (greater than 5 microns) from infected animals
16 such as cats can occur (Burmeister, Tigertt, and Overholt 1962).

18 Cats are a recent source, including 5/23 cases primary pneumonic (Eidson et al. 1988; Gage et al.
19 2000).

21 Inhalation of respiratory droplets from person with primary or secondary pneumonic plague
22 occurs (Burmeister, Tigertt, and Overholt 1962).

24 At least five laboratory-acquired infections have occurred in the U.S. (Inglesby et al. 2000)
25 Four of these occurred prior to availability of now-standard biocontainment technologies. The
26 fifth case occurred from an attenuated strain in an unsuspected immune-compromised host,
27 during work at biosafety level 2. In addition to being immune-compromised, the researcher
28 apparently did not always follow BSL-2 biocontainment requirements regarding the use of
29 personal protective equipment (gloves) (Centers for Disease Control and Prevention
30 2011)(Burmeister, Tigertt, and Overholt 1962).

1 Bubonic form of infection can occur from bites by flea vectors, or from bites or scratches by
2 infected animals such as cats (Gage et al. 2000).

3
4 Bubonic form can occur from direct contact with animal carcasses (Christie 1980; von Reyn et
5 al. 1976; Reed et al. 1970).

6
7 Pharyngeal infection can occur via ingestion of organisms (Bin Saeed, Al-Hamdan, and Fontaine
8 2005; Arbaji et al. 2005).

9
10 **Bacterial concentrations/pathogenesis**

11 Inocula for aerosol challenges in mice were in tenfold steps from 10^8 to 10^{10} CFU/mL (Agar et
12 al. 2008)(Torosian et al. 2009; Feodorova and Golova 2005).

13
14 In lab animals, bacterial concentrations reach 10^8 to 10^9 CFU/mL blood(Agar et al. 2008)
15 (Torosian et al. 2009; Feodorova and Golova 2005).

16
17 A rat model used 10 mL of 10^{10} CFU/mL as aerosol inoculum (Agar et al. 2009).

18 Bacteremic load of 10^4 to 10^7 CFU/mL reported from humans (Butler et al. 1976).

19
20 Routes of *Y. pestis* infection other than the aerosol route (i.e. i.p., s.c., i.v.) in
21 mice do not significantly alter 50% lethal doses (LD_{50} s) (Perry and Fetherston 1997).

22
23 **Pathogen stability**

24 *Y. pestis* can survive approximately 3 hours on flea mouthparts (Bibikova 1977).

25
26 Can survive days to weeks in flea feces, tissues of dead animals, and up to 40 weeks in some
27 soils (Ayyadurai et al. 2008; Eisen et al. 2008; Drancourt, Houhamdi, and Raoult 2006).

28
29 Survival up to 3 weeks has been noted in blood-contaminated soil (Mollaret 1963).

1 Stability on laboratory surfaces varies [steel (6 hours), glass (7 hours), polyethylene (24 hours),
2 and paper (5 days)] (Rose et al. 2003).

3
4 World Health Organization (WHO) estimates that aerosolized *Y. pestis* would remain viable for 1
5 hour (Borio and Hynes 2010).

6
7 An approximately 3-log decay over 90 minutes using an avirulent strain in aerosolized heart
8 infusion broth at conditions of 26 °C and RH varying from 20 to 50 percent is reported (Won and
9 Ross 1966).

10 11 **Vectors**

12 Of the 1,500 species of fleas, more than 200 are naturally infected, about 30 are proven vectors
13 of the plague (Perry and Fetherston 1997).

14
15 Squirrel fleas (*O. montanus*) are the most common source of human plague in the United States.
16 *O. montanus* and *X. cheopis* likely transmit early without complete blocking (Eisen et al. 2006).

17
18 Cat, dog, and so-called human fleas are very poor vectors (Eisen et al. 2006; Kartman, Quan, and
19 Stark 1962).

20
21 An accepted paradigm has been that *Y. pestis* proliferation in the flea causes gut blockage with
22 subsequent starvation, aggressive biting and regurgitation of *Y. pestis* into the bite site. In
23 contrast, *O. montanus* and *X. cheopis* likely transmit early without complete blocking of midgut
24 (Eisen et al. 2006).

25
26 Unblocked and occasional blocked fleas can live for many months or over a year in the wild
27 (Eisen et al. 2006; Kartman, Quan, and Stark 1962).

28
29 *Y. pestis* has been isolated from lice and ticks (Houhamdi et al. 2006).

Experimentally infected ticks can maintain plague bacilli for up to a year but cannot transmit (Thomas, Karstens, and Schwan 1990).

Other epidemiological/ecological data

For infection control, respiratory droplet isolation is recommended by using a surgical mask and eye protection when caring for symptomatic patient until 48 hours after initiating effective treatment (Weber and Rutala 2001). Quarantine of asymptomatic persons is not recommended.

Soil is suggested as a possible site for interepizootic maintenance, but it is not well supported (Baltazard 1964).

U.S. males and females are equally affected (Dennis and Mead 2010).

The last case of human-to-human in the United States occurred in the 1924 Los Angeles outbreak (Meyer 1961).

Three pandemics originating in Egypt 542; Italy 1347; China 1894. United States-via China in 1900 was originally urban in southern California and became endemic in wild animal populations (Kaufmann, Boyce, and Martone 1980). Since then, it occurs seasonally in warm months among persons in the southwestern United States with close contact to animals (about 7 cases annually, about 80 percent bubonic) (Centers for Disease Control and Prevention 1994, 2006, 1991).

Warm springs and wet summers increase its prevalence in great gerbils in Kazakhstan, which can also affect human disease frequency (Stenseth et al. 2006; Ensore et al. 2002).

Blocking in fleas was described in 1914. Many factors influence blocking and transmission including strain differences and transmission factors, flea species, proventricular morphology, and temperature (Gage and Kosoy 2005). Vector efficiency is defined as the product for infection potential, vector or infective potential, and transmission potential. Flea blood meal = 0.1–0.3 µL, therefore, must have at least 10^8 CFU/mL (Lorange et al. 2005; Hinnebusch 2003).

25,000–100,000 *Y. pestis* inoculated with flea bite (Reed et al. 1970). Vector index from multiplying blocking-survival potential and vector efficiency. *X. cheopis* is a classic and very effective vector (becomes blocked in as few as 5 days versus 2–3 weeks).

Therapeutics/vaccines

Streptomycin has been the treatment of choice. It can be efficacious for treatment, but gentamicin is as efficacious and more available (Inglesby et al. 2000; Heine 2007; Mwengee et al. 2006; Boulanger et al. 2004).

Doxycycline is also FDA approved and used, particularly when aminoglycosides are not available or cannot be used. Fluoroquinolones are as effective in animal models (Russell et al. 1996; Steward et al. 2004).

Resistance to imipenem, rifampin, and macrolides (Frean et al. 2003; Wong et al. 2000).

A multidrug resistant isolate was reported from Madagascar, but it was susceptible to fluoroquinolones, cephalosporins (Galimand et al. 1997; Welch et al. 2007).

Prophylactic tetracycline, doxycycline, sulfonamides, chloramphenicol, and FQ can be used for exposed asymptomatic individuals (Inglesby et al. 2000). In a 2,000-person review, no cases occurred among those receiving prophylaxis (Centers for Disease Control 1984).

In the United States, a licensed, formaldehyde–killed, whole bacilli vaccine was discontinued in 1999 (Titball and Williamson 2001).

The vaccine demonstrated efficacy in prevention and attenuation of bubonic disease, but was not helpful for primary pneumonic. Eight cases of plague occurred among vaccinated U.S. servicemen in Vietnam (equating to one case/10⁶ person years of exposure), versus (333 cases/10⁶ person years of exposure in non-vaccinated civilians (Titball and Williamson 2001).

Heat-killed vaccine was used by British in the Gulf War (Allen et al. 2006). F1/LcrV combination vaccine worked well in macaques, but showed limited usefulness in African green monkeys.

Other remarks

Fully virulent *Y. pestis* is a BSL 3 pathogen (CDC and NIH 2007). Conditionally virulent or attenuated *Y. pestis* is BSL-2 (CDC and NIH 2007; Sewell 2003).

Taxonomy/antigenic relationships/synonyms

Y. pestis is a gram-negative, non-motile, non-spore-forming coccobacillus (0.5–0.8µm x 1–3µm) responsible for epizootics and enzootic disease and intermittent human disease (Perry and Fetherston 1997). Three classic biovars are recognized: *antique*, *medievalis*, and *orientalis* (Dennis and Meier 1997).

C.1.1.4 1918 H1N1 influenza virus (1918 H1N1V)

NOTE: Information on the 1918 H1N1 virus is limited. Accordingly, information for other influenza strains is shown as well. Data points referring specifically to 1918 H1N1 are clearly marked.

Host range

a. Field

1918 H1N1 virus is known to be infectious humans, birds, and swine (Taubenberger and Morens 2006; Babiuk et al. 2010) .

Research indicates that descendants of the 1918 virus still persists enzootically in pigs (Taubenberger and Morens 2006).

The origin of the 1918 H1N1 virus remains unknown (Taubenberger and Morens 2006). Influenza A viruses cause chronic, asymptomatic infection in the GI tracts of wild birds but are also able to infect and cause disease in a variety of mammals. On rare occasions, an influenza A virus is introduced into human populations and spreads rapidly to cause a global pandemic. That can occur either when an avian virus with a novel hemagglutinin

(HA) protein adapts to human-to-human transmission, or when an avian virus undergoes genomic reassortment during co-infection of an influenza virus-infected mammal such as a pig. As a pandemic virus circulates, it undergoes progressive antigenic drift in its HA and neuraminidase (NA) proteins, permitting it to reinfect the same populations in regular outbreaks of *seasonal* influenza (Barnard 2009).

“Influenza A viruses have infected many different animals, including ducks, chickens, pigs, whales, horses, and seals. However, certain subtypes of influenza A virus are specific to certain species, except for birds, which are hosts to all known subtypes of influenza A. Subtypes that have caused widespread illness in people either in the past or currently are H3N2, H2N2, H1N1, and H1N2. H1N1 and H3N2 subtypes also have caused outbreaks in pigs, and H7N7 and H3N8 viruses have caused outbreaks in horses. Influenza A viruses normally seen in one species sometimes can cross over and cause illness in another species. For example, until 1998, only H1N1 viruses circulated widely in the U.S. pig population. However, in 1998, H3N2 viruses from humans were introduced into the pig population and caused widespread disease among pigs. Most recently, H3N8 viruses from horses have crossed over and caused outbreaks in dogs.”(Centers for Disease Control and Prevention 2005).

Wild, aquatic birds, predominantly dabbling ducks, appear to be the reservoir of influenza A viruses (Weber and Stilianakis 2008). Birds are hosts to all known subtypes of influenza A virus (Centers for Disease Control and Prevention 2005).

b. Experimental

The virus is able to infect and replicate in experimentally infected pigs, and the available data suggest that natural infections occurred widely in swine during the 1918 pandemic (Weingartl et al. 2009).

1918 H1N1V has low pathogenicity in birds (Babiuk et al. 2010). Data indicated that 1918 H1N1V does not replicate efficiently in experimentally infected chickens and, although the virus does replicate in ducks (as shown by serological testing), the level of

1 replication in most ducks was below the limit of detection (for nucleic acid-based
2 detection tests) (Babiuk et al. 2010).

3
4 1918 H1N1 virus does not spread from inoculated (10^6 PFU intranasal instillation) mice to
5 uninfected cagemates (Lowen et al. 2006; Tumpey 2008).

6
7 Mice are a poor model for 1918 H1N1 transmission, and ferrets are used instead
8 (Tumpey 2008)

9
10 10^6 PFU 1918 H1N1 is the highest concentration that can be given to mice in a 50 uL
11 volume; interferon-deficient mice exhibit 100 percent mortality. Ferrets exhibit 50
12 percent mortality (Tumpey 2008).

13
14 10^5 PFU 1918 H1N1 in outbred mice is not lethal (Tumpey 2008).

15
16 1918 H1N1 lethality in mice (LD_{50}) is $3.5 \log_{10}$ PFU or EID_{50} ; LD_{50} in ferrets is 10^6 PFU;
17 the same dose in a susceptible mouse strain (Mx1 gene deficient) give an LD_{100}
18 (intranasal inoculation) (Tumpey 2008).

19
20 Guinea pigs have been used as an animal model for 1918 H1N1 (Van Hoeven et al.
21 2009).

22
23 ID_{50} of H3N2 for guinea pigs was determined to be 5 PFU (Lowen et al. 2006).

24
25 ID_{50} of H0N1 for mice was determined to be 0.079 to 5 EID_{50} (Yetter et al. 1980).

26
27 H3N2 found to spread between guinea pigs by droplets; cages up to 91 cm apart (Lowen
28 et al. 2006).

29
30 Mice, ferrets, rats, pigs, and NHPs have been used as an animal model (regarding
31 influenza A) (Barnard 2009).

Prevalence/incidence/attack rate

1918 H1N1 virus is not circulating in humans, and is not known to be circulating in animals (Tumpey, Basler, et al. 2005).

At least 3 laboratory-acquired infections with non-1918 H1N1V have been reported, and 2 of these occurred in the ABSL-3 setting (Wentworth et al. 1997; Harding 2006). Figure C-1, below, shows 1918 H1N1 influenza plus pneumonia (P&I) (combined) age-specific incidence rates per 1,000 persons per age group (panel A), death rates per 1,000 persons, ill and well combined (panel B), and case-fatality rates (panel C, solid line), U.S. Public Health Service house-to-house surveys, 8 states, 1918 (36). A more typical curve of age-specific influenza case-fatality (panel C, dotted line) is taken from the U.S. Public Health Service surveys during 1928–1929 (37) (Taubenberger and Morens 2006).

Figure C-1. 1918 attack rates by age group.

The major epidemiological differences between 1918 and 2008 human populations include immunity to H1, immunity to N1, and co-circulation of H1N1 and H3N2; all humans older than 2–3 years have immunity to both H1N1 and H3N2 viruses (Murphy 2008).

1 Current vaccines can boost antibody to 1918 virus (Tumpey et al. 2004; Murphy 2008).

2
3 A 53 percent attack rate (9/17) among human volunteers for influenza A/Wisconsin 67/2005
4 H3N2 (Zaas et al. 2009).

5
6 For pandemic influenza A virus, not otherwise specified, using R_0 values of 1.6, 1.9, 2.1 and 2.4
7 percent, model-determined attack rates of 32.6, 43.5, 48.5, and 53.7 percent, respectively, were
8 found without interventions. School closures alone were projected to limit the attack rate to 1.0
9 but only if the R_0 did not exceed 1.6. The “model suggests that the combination of targeted
10 antiviral prophylaxis (TAP), school closure, and social distancing can be successful up to $R_0 =$
11 2.4, without any vaccination.” Success is defined as limiting the attack rate to that of annual
12 influenza epidemics (about 10 percent of the U.S. population). Various combinations of
13 interventions (including unlimited TAP, and excluding vaccination) resulted in projected attack
14 rates of 0.02, 0.07, 0.14, and 2.8 percent, respectively. However, it is noted that a supply of 20
15 million courses of targeted antiviral therapy courses would be exceeded if the R_0 were 1.8 or
16 greater (as of the publication date—April 2006—5 million courses were stockpiled nationally).
17 See table C-3 below by German et al “Simulated mean number of ill people (cumulative
18 incidence per 100) and for TAP, the number of antiviral courses required for various
19 interventions and R_0 ” (Germann et al. 2006).

20
21 Attack rate for H2N2 was predicted (by modeling) to be 33 percent without intervention and 2
22 percent with the use of targeted antiviral prophylaxis (Longini et al. 2004).

23
24 Attack rate for influenza A/Taiwan/1/86 (H1N1) during an outbreak at a naval base was 39
25 percent in those under 35 years old and 25 percent for all other ages (Klontz et al. 1989).

26
27 Attack rate for H1N1 in Seattle (December 15, 1978, through March 31, 1979) was 0.290
28 overall. For the age groups (years) 0–4, 5–19, and 20+, the attack rates were 0.346, 0.524, and
29 0.023, respectively (Longini et al. 1982).

Clinical attack rate of 34 percent for 1977-1978 H1N1 virus was reported among 200 males (98 percent were 20 years of age or younger) aboard a navy ship (Ksiazek et al. 1980). For the same virus and period, clinical attack rates of 2.36 percent and 0.62 percent were reported for age groups ≤ 23 years and ≥ 23 years, respectively, at a 38,000 student campus (Pons, Canter, and Dolin 1980).

R_0 /incubation period/infectious period/infectious dose

Literature analysis (1965–2005) indicates influenza generation time (cf incubation period) can be as short as 2.5 days on average (range 1.5–4.0 days) (Carrat et al. 2008). That value is substantially shorter than that assumed by Longini et al. 2004 (Longini et al. 2004; Germann et al. 2006).

The incubation period for the 2009 novel swine-origin influenza A H1N1 virus (S-OIV) infection appears to be 2–7 days; however, additional information is needed (Novel Swine-Origin Influenza et al. 2009).

“The incubation period for seasonal influenza is reported to average 2 days (range: 1–4 days) [but that is] not supported by high-quality evidence” (Carrat et al. 2008).

The infectious period for seasonal influenza is 1 day before the onset of symptoms through 5–7 days after onset of symptoms or until symptoms have resolved (Novel Swine-Origin Influenza et al. 2009).

The actual R_0 for 1918 H1N1 in Iceland was 2.2 (Dowell and Bresee 2008).

The estimated R_0 for 1918 H1N1 is as follows:

- Estimated to be approximately 2–3; median R_0 based on data from 45 U.S. cities is 2; “Initial R” = 2.0 (Interquartile range 1.7-2.3); “Extreme R” = 2.7 (Interquartile range 2.3-3.4); Maximum R = 6.5 (upper bound); estimate over 45 U.S. cities (Mills, Robins, and Lipsitch 2004);

- Estimated R_0 for England and Wales, assuming a 3 day generation interval, for Autumn wave: 1.39 (1.36–1.43); for winter wave: 1.39 (1.29-1.49). Assuming a 6 day generation interval the numbers are 1.84 (1.75-1.92) and 1.82 (1.61-2.05) respectively (Chowell et al. 2008);
- Estimated R_0 for Copenhagen and three other Scandinavian cities was substantially higher in summer (2.0–5.4) than in fall (1.2–1.6) (Andreasen, Viboud, and Simonsen 2008);
- Estimated R_0 for H2N2 (for modeling purposes) was 1.68 (Longini et al. 2004);
- R_0 estimated at 2.2 (95% C.I. 1.7-2.7) extreme at 3.5, Iceland (Gottfredsson et al. 2008);
- R_0 estimated at 2.1, England and Wales (Viboud et al. 2006);
- R_0 estimated at 1.49 (95% CI 1.45-1.53) spring wave; 3.75 (95% CI 3.57-3.93) fall wave, Geneva (Chowell et al. 2006);
- R_0 of 1.79 – 2.1, estimates from eight model variants over 16 U.S. cities; largest confidence interval 1.3-3.2 (Bootsma and Ferguson 2007);
- R_0 of 1.58 – 3.41 estimated for Prussia, Germany (Nishiura 2007);
- R_0 estimated at 1.3 – 3.1, New Zealand (Sertsou et al. 2006);
- R_0 of 2.68 estimated for Sao Paulo, Brazil (Massad et al. 2007);
- R_0 estimated at 1.7-2.0 for 83 cities in the U.K. (Ferguson et al. 2006);
- R_0 of 1.70 estimated for the UK and Wales (Gani et al. 2005);
- R_0 estimated at 2.4, 3.5 for San Francisco (Chowell, Nishiura, and Bettencourt 2007) .

Tables C-2 and C-3 below pertain to a pandemic influenza A virus, not otherwise specified. R_0 estimates of 1.6, 1.9, 2.1, and 2.4 have been used to model the spread of influenza and efficacy of intervention strategies (Germann et al. 2006).

Table C-1. Characteristics of simulated pandemic influenza in the United States without intervention

Basic reproductive number, R_0	1.6	1.9	2.1	2.4
Rate of spread: 1,000th ill person*	14	13	12	11
10,000th ill person*	29	24	22	19
100,000th ill person*	48	37	34	29
1,000,000th ill person*	70	52	46	39
Peak of epidemic*	117	85	75	64
Daily number of new cases at peak activity	2.3 M	4.5 M	6.0 M	7.9 M
Number of days with >100,000 new cases	86	68	60	52
Cumulative number of ill persons	92 M	122 M	136 M	151 M

M, million.
*Days after initial introduction.

Source: (Germann et al. 2006)

1 The typical incubation period is 2 days, with a range of 1–4 days (cites internal reference #28)
2 (Bridges, Kuehnert, and Hall 2003).

3
4 Compiled data from H1N1 volunteer challenge studies in the literature (1965–2005) show an
5 inoculum range of 10^3 – $10^{7.2}$ TCID₅₀, and an infection rate of 362 per 532 volunteers (68 percent),
6 but aerosol challenge was used in only one of those studies (Carrat et al. 2008).

7
8 A human infectious dose (HID₃₀) of 3 x TID₅₀ for influenza A2/Bethesda/10/63 was determined
9 for 23 male volunteers, 21–40 years of age (7/23 infected) (Alford et al. 1966).

10
11 Eleven of fifteen (73 percent) human volunteers were infected using an H1N1 inoculum of 10^4
12 TCID₅₀ instilled intranasally (Clements et al. 1986).

13
14 Nine of seventeen (53 percent) human volunteers were infected using H3N2 influenza A
15 (Wisconsin 67/2005) using inocula of either 10^2 , 10^3 , 10^4 , or 10^5 TCID₅₀ instilled intranasally
16 (Zaas et al. 2009).

17
18 Intranasal instillation of influenza virus in volunteers might not mimic real exposure/infection
19 (Carrat et al. 2008).

20
21 The HID₅₀ for 1918 H1N1 in humans is unknown but is estimated to be 1–10 virions (Subbarao
22 2008).

23
24 Data on HID₅₀ for other influenza viruses range from 3 TID₅₀ to $10^{7.2}$ TID₅₀ (Carrat et al. 2008;
25 Alford et al. 1966; Zaas et al. 2009).

26
27 **Morbidity/case fatality ratio**

28 Asymptomatic infection with 1918 influenza virus possibly could occur and would not be
29 detected by illness monitoring of lab personnel (Uyeki 2008; Monto 2008).

1 As many as one in three infections with influenza (non-1918 H1N1) are asymptomatic (Carrat et
2 al. 2008).

3
4 Although primary infection in young children is usually symptomatic, overall, approximately 50
5 percent of influenza infections can be asymptomatic. Nevertheless, infected persons with few or
6 no signs of illness can shed virus and, therefore, be infectious to others (cites ref #29). Infected
7 persons can become contagious (i.e., they can shed detectable amounts of influenza virus) the
8 day before symptoms begin. Adults usually shed virus for about 3–5 days (author cites refs #28,
9 30), whereas young children can shed the virus for up to 3 weeks (author cites refs #31–33)
10 (Bridges, Kuehnert, and Hall 2003).

11
12 Symptoms of seasonal influenza typically include high fever, chills, headache, sore throat, dry
13 cough, myalgia, anorexia, and malaise. Complications include primary viral pneumonia,
14 secondary bacterial pneumonia, or combined bacterial and viral pneumonia. Severe infections
15 are caused by the recently emerged avian influenza A H5N1 virus are characterized by rapid
16 development of diffuse interstitial pneumonia, viremia, and shock leading to death (Barnard
17 2009).

18
19 Morbidity data are pending from the 2009–2010 H1N1 pandemic [Update: morbidity &
20 mortality data are available from Lemaitre and Carrat 2009 (Lemaitre and Carrat 2010)].
21 Mortality attributed to 1918 H1N1 in Iceland was 2.8 percent (Dowell and Bresee 2008).
22 Case fatality rate in 1918 was about 2.5 percent (Taubenberger 2008).

23
24 “Age-specific death rates in the 1918 pandemic exhibited a distinct pattern that has not been
25 documented before or since: a W-shaped curve, similar to the familiar U-shaped curve but with
26 the addition of a third (middle) distinct peak of deaths in young adults about 20–40 years of age.
27 Influenza and pneumonia death rates for those 15–34 years of age in 1918–1919, for example,
28 were more than 20 times higher than in previous years” (Taubenberger and Morens 2006).

1 “Overall, nearly half of the influenza-related deaths in the 1918 pandemic were in young adults
2 20–40 years of age, a phenomenon unique to that pandemic year” (Taubenberger and Morens
3 2006).

4
5 “The 1918 pandemic is also unique among influenza pandemics in that absolute risk of influenza
6 death was higher in those < 65 years of age than in those > 65; persons < 65 years of age
7 accounted for > 99 percent of all excess influenza-related deaths in 1918–1919. In comparison,
8 the < 65-year age group accounted for 36 percent of all excess influenza-related deaths in the
9 1957 H2N2 pandemic and 48 percent in the 1968 H3N2 pandemic” (author cites a primary ref.)
10 (Taubenberger and Morens 2006).

11
12 In the 1918 pandemic, “[t]hose 5 to 14 years of age accounted for a disproportionate number of
13 influenza cases but had a much lower death rate from influenza and pneumonia than other age
14 groups” (Taubenberger and Morens 2006).

15
16 Histological and bacteriological evidence suggests that the vast majority of influenza deaths
17 during the 1918 pandemic resulted from secondary bacterial pneumonia (Morens, Taubenberger,
18 and Fauci 2008) (Klugman, Astley, and Lipsitch 2009). Antibiotics were not available in 1918,
19 and medical support services have improved dramatically in the past 90 years (Murphy 2008).

20
21 A model-predicted case fatality rate for H2N2 infections was 0.58/1,000 persons in the absence
22 of intervention and 0.04/1,000 persons if targeted antiviral prophylaxis is used (Longini et al.
23 2004).

24
25 Case fatality rates for adults (ages 14 years and older) in a large prepaid group practice (Portland,
26 Oregon) for the 1968-1969 and 1972-1973 H3N2 viruses were 13 percent and 12 percent,
27 respectively (Barker and Mullooly 1980).

28 29 **Aerosol infection/routes of transmission**

30 As of 2004, the CDC/NIH Influenza Agent Summary Statement Committee estimated the likely
31 infectious dose for 1918 H1N1 virus to be 1 to 10 [particles] (Subbarao 2008).

1 Droplet transmission of influenza viruses occurs when contagious droplets produced by the
2 infected host via coughing or sneezing are propelled a short distance and come into contact with
3 another person's conjunctiva, mouth, or nasal mucosa. Because the droplets generally are large
4 (110 μm) and do not stay suspended in the air, this mode of transmission is not affected by
5 special air handling or control of room pressures. Airborne transmission entails the production of
6 infectious droplet nuclei, generally $< 5 \mu\text{m}$ in diameter, which, in contrast to droplets, can remain
7 suspended in the air and be disseminated by air currents (Bridges, Kuehnert, and Hall 2003).

8
9 Evidence exists to support the transmission of influenza viruses by direct and indirect contact
10 and by droplet and droplet nuclei (i.e., airborne) transmission. However, experimental studies
11 involving humans are limited, and the relative contribution of each mode of transmission remains
12 unclear (Bridges, Kuehnert, and Hall 2003).

13
14 Transmission of H1N1 (strain Pan 99) by fomites was found to be inefficient using a guinea pig
15 model (Mubareka et al. 2009).

16
17 "Flu viruses are thought to spread mainly from person to person through coughing or sneezing of
18 people with influenza. Sometimes people [can] become infected by touching something with flu
19 viruses on it and then touching their mouth or nose" (Centers for Disease Control and Prevention
20 2010).

21
22 "The pathogenesis of H5N1 in mammals raises some new concerns about the waterborne route;
23 in cats" (Weber and Stilianakis 2008).

24
25 "The waterborne route of transmission is traditionally not considered to be relevant for
26 respiratory viruses. The emergence of highly pathogenic avian influenza virus H5N1 as a
27 perceived pandemic threat has changed this situation" (Weber and Stilianakis 2008).

28 29 **Virus titers/concentrations/pathogenesis**

30 The CDC in 2008 estimated the range of concentrations of 1918 H1N1 virus a laboratory might
31 work with to be 10^2 to 10^8 [virions] (Subbarao 2008).

Table C-3, Properties of recombinant influenza viruses used in this study

Virus ^a	Titer ^b		% Weight loss ^c	Lung titer (log ₁₀ EID ₅₀ /ml ± SE) ^d	LD ₅₀ ^e
	log ₁₀ EID ₅₀ /ml	PFU/ml			
Wild-type Tx/36/91	8.2	2.0 × 10 ⁷	0.7	3.3 ± 0.2	>6
Parental rTx/36/91	8.7	4.4 × 10 ⁷	0.1	3.6 ± 0.3	>6
Parental rWSN	8.2	2.2 × 10 ⁷	21.8	7.2 ± 0.2	2.75
1918 HA/NA:Tx/36/91	8.7	2.5 × 10 ⁷	15.9	6.0 ± 0.2	4.75
1918 HA/NA:WSN	8.5	2.1 × 10 ⁷	21.7	7.0 ± 0.3	2.25

^a All viral genomic segments derived from the WSN or Tx/91 virus unless otherwise indicated.
^b Calculated by the method of Reed and Muench (47) from titrations in eggs and MDCK cells.
^c Average percent weight loss on day 4 postinfection (five mice per group).
^d Average lung titers of four mice on day 4 postinfection.
^e Expressed as the log₁₀ PFU required to give 1 LD₅₀.

Source: (Tumpey, Garcia-Sastre, et al. 2005):

1918 virus challenge doses used in guinea pig model: 10⁶ EID₅₀ (i.e., the dilution that causes infection in 50 percent of eggs is the egg infectious dose – EID₅₀; the upstream dilution tube that is 10⁶ higher than the EDI₅₀ is the 10⁶ EID₅₀). Other challenge doses of 1918 H1N1 varied between 10³ and 10⁶ PFU of EID₅₀ (Van Hoeven et al. 2009).

The 1918 H1N1 peak titer in guinea pig nasal wash was greater than 10⁵ PFU/mL or EID₅₀/mL (Van Hoeven et al. 2009).

A concentration of 10⁸ PFU/ml for a recombinant virus containing the 1918 NS1 sequence achieved in Madin-Darby canine kidney (MDCK) cell culture within 36 hours (Jackson et al. 2008).

In experimental infections in healthy volunteers, influenza A viral replication peaks approximately 48 hours after inoculation into the nasopharynx, declining thereafter, with usually little or no virus shed after 6 days (Barnard 2009).

Human volunteers intranasally infected with H3N2 influenza A (Wisconsin 67/2005) had a median time to peak symptoms of 80 hours (range 50–110 hours) (Zaas et al. 2009).

1 Unpublished data show no transmission of 1918 H1N1 among caged mice over a 14-day period
2 (Tumpey 2008).

3
4 The 1918 H1N1 virus replicates effectively in both the upper and lower respiratory tract, in
5 contrast to other H1N1 viruses, and that is suspected to be a virulence factor for the strain
6 (Barnard 2009)(Watanabe et al. 2009).

7
8 Using a mouse model, it was shown that viruses engineered to contain four C-terminal residues
9 of the nonstructural, nonessential, NS1 gene from the 1918 (or HPAI as well) virus were more
10 virulent than wild type virus (Jackson et al. 2008).

11
12 The 1918 H1N1 virus is less lethal in mice than contemporary H5N1 isolates, requiring 63–500
13 times more virus to cause death (Tumpey 2008).

14 15 **Pathogen stability**

16 Human influenza viruses can survive on a variety of surfaces at 35–49 percent humidity and a
17 temperature of 28 °C. Both influenza A and B viruses were cultured from experimentally
18 contaminated, nonporous surfaces, such as steel and plastic, up to 24–48 hours after inoculation,
19 and from cloth, paper, and tissues up to 8–12 hours after inoculation (Bean et al. 1982).

20
21 Influenza viruses could be recovered from hands for only 5 minutes and only if the hands were
22 contaminated with a high viral titer. Viable virus could be transferred from nonporous surfaces to
23 hands for 24 hours and from tissues to hands for 15 minutes. Those data support the feasibility of
24 spread of influenza by indirect contact (Bean et al. 1982). However, the importance of that mode
25 of transmission probably depends on the type of surface and the amount of virus present
26 (Bridges, Kuehnert, and Hall 2003).

27
28 Effects of humidity on the ability of influenza viruses to infect mice in a non-ventilated room
29 with constantly agitated air have been studied (Loosli et al. 1943). At an RH of 17–24 percent,
30 animals became infected with influenza as late as 24 hours after the virus was first aerosolized
31 into the room, although the proportion of animals infected decreased over time. Infectivity was

enhanced at 22 hours after influenza virus was introduced, when the floor was vigorously swept, suggesting that desiccation of the virus does not eliminate infectivity. Whether sufficient numbers of virus-laden particles can remain viable to infect humans in a similar setting is unknown (Bridges, Kuehnert, and Hall 2003).

The D_{37} value for influenza A virus was calculated to be 7.5 [HL=18 min at maximum solar conditions] (Lytle and Sagripanti 2005).

Solar radiation-induced infectivity reduction for influenza A virus has been reported to range from 0.1 to 7.5 \log_{10} /day in U.S. locations depending on latitude and season (Sagripanti and Lytle 2007).

“Study of the inactivation of influenza virus as a function of RH and temperature has produced contradictory results.” “Maximum survival times vary between 1 hour (80 percent RH) and 24 hours (20 percent RH)” (Weber and Stilianakis 2008).

Transmission of H3N2Pan/99 among guinea pigs in separate cages at 20 °C was 75–100 percent, 100 percent, 25 percent, 75 percent, and 0 percent, for RHs of 20 percent, 35 percent, 50 percent, 65 percent, and 80 percent, respectively (Lowen et al. 2007).

Absolute humidity (AH) was reported in 2009 to be more important than RH in determining survival and transmission (the conclusion stands that low humidity, whether measured by RH or AH, favors viral survival). Data derived by calculating AH from a previous study (Harper 1961) that examined RH and temperature showed an inverse linear correlation between survival and AH, with survival being greatest (about 80 percent, 63 percent, 62 percent, at 0, 6 and 23 hours, respectively) as AH nears zero (i.e., 2 mb). 50 percent of influenza virus transmission variability and 90 percent of influenza virus survival variability were explained by AH, whereas, respectively, only 12 percent and 36 percent were explained by RH (Shaman and Kohn 2009).

“Avian influenza viruses can be isolated from natural, open fresh water” (Weber and Stilianakis 2008).

Avian strains of H1N1 can be isolated from bodies of fresh water (Deboosere et al. 2011).

“The influenza-related risk posed by water resources, water supplies and sanitation has received some limited attention. There is apparently no quantitative information on the inactivation of human influenza A viruses in open, liquid water; H1 sequences have been isolated from Siberian lake water, but no further information on inactivation rates is provided (authors cites reference number 123). The most recent work on low- and high pathogenic avian influenza virus inactivation in water investigates 8 subtypes of low-pathogenic avian influenza (LPAI) viruses and two strains of high-pathogenic H5N1 (Anyang/01 and Mongolia/05) (author cites reference number 124). Virus inactivation depends on pathogenicity, salinity and temperature (see Table [C-5]): survival decreases with salinity and temperature and LPAI survive longer than HPAI. These results imply that avian influenza viruses can under circumstances of low salinity and low temperatures persist many weeks in water” (Weber and Stilianakis 2008).

Table C-4. Daily inactivation rates for LPAI and HPAI avian influenza viruses in water

T = 17 °C		T = 28 °C
Salinity Z 0 ppt	0.023 (LPAI)	0.116 (LPAI)
	0.051 (HPAI)	0.215 (HPAI)
Salinity Z 15 ppt	0.038 (LPAI)	0.184 (LPAI)
	0.053 (HPAI)	0.216 (HPAI)
Salinity Z 30 ppt	0.067 (LPAI)	0.220 (LPAI)
	0.063 (HPAI)	0.281 (HPAI)

The values for LPAI are the means of the values of 8 subtypes, the values for HPAI the mean of 2 strains of H5N1.

Vectors

No vectors exist for the 1918 H1N1V.

Other epidemiological/ecological data

A credible scenario leads to the conclusion that a 1918 influenza virus-infected (LAI) researcher could lead to an uncontained outbreak among the public (Osterholm 2008).

A bite from an infected ferret is considered the most likely exposure event for 1918 H1N1 (Osterholm 2008).

The pandemic potential of 1918 influenza virus is thought to be significant (Henkel 2008). Clinical impact of the 1918 H1N1 virus in 2008 would be much less than in 1918—even less than the H2N2 epidemic of 1957 (Murphy 2008).

1918 H1N1 virus should not be treated differently than other human influenza A viruses with pandemic potential (Murphy 2008).

“Findings [on] ...data on the timing of 19 classes of NPI in 17 U.S. cities during the 1918 pandemic... support the hypothesis that rapid implementation of multiple NPIs [non-pharmaceutical interventions] can significantly reduce influenza transmission, but that viral spread will be renewed on relaxation of such measures [6 weeks or less]” (Dowell and Bresee 2008; Hatchett, Mecher, and Lipsitch 2007; Markel et al. 2007; Bootsma and Ferguson 2007).

“An important component of the current pandemic planning strategies in the United States and many other countries is to keep ill persons out of the hospital and have large numbers of them cared for at home, with the idea of avoiding the amplification of infections in hospitals seen with SARS in 2003 and with a range of other modern epidemics (author here citing CDC 2007 - Community Strategy for Pandemic Influenza Mitigation)” (Dowell and Bresee 2008).

“Regardless of R_0 , unless drastic travel restrictions are imposed, the extent or duration of the pandemic [referring to influenza A, not otherwise specified] is insensitive to details of the amount and locations(s) of introductions of pandemic influenza virus in our simulations” (Germann et al. 2006).

Studies generally have shown that susceptibility to influenza infection, preexisting antibody titer, viral shedding, and symptomatic illness are related in the following ways (Bridges, Kuehnert, and Hall 2003):

- The higher a person's existing antibody titer against the same or a related influenza virus strains, the larger the inoculum of virus needed for infection and the less likely that clinical illness will develop (author cites refs 28, 36);
- The amount of viral shedding correlates with the severity of illness and temperature elevation (author cites ref 31);
- The amount of virus required to induce infection is inversely related to the size of infectious particles administered, with particles smaller than 10 nm in diameter more likely to cause infection in the lower respiratory tract (author cites ref 36).

In February 2007, CDC published a planning guidance document for non-pharmaceutical interventions (NPI). The rationale for NPI is, "[i]t is highly unlikely that the most effective tool for mitigating a pandemic (i.e., a well-matched pandemic strain vaccine) will be available when a pandemic begins." Furthermore, the pandemic could find populations "potentially without sufficient quantities of influenza antiviral medications. In addition, it is not known if influenza antiviral medications will be effective against a future pandemic strain." "The use of NPIs for mitigating a community-wide epidemic has three major goals: (1) delay the exponential growth in incident cases and shift the epidemic curve to the right in order to *buy time* for production and distribution of a well-matched pandemic strain vaccine, (2) decrease the epidemic peak, and (3) reduce the total number of incident cases, thus reducing community morbidity and mortality." "Communities, individuals and families, employers, schools, and other organizations will be asked to plan for the use of these interventions to help limit the spread of a pandemic, prevent disease and death, lessen the impact on the economy, and keep society functioning. This interim guidance introduces a Pandemic Severity Index to characterize the severity of a pandemic, provides planning recommendations for specific interventions that communities might use for a given level of pandemic severity, and suggest when these measures should be started and how long they should be used" (CDC 2007).

"The pandemic mitigation interventions described in this document include:

1 Isolation and treatment (as appropriate) with influenza antiviral medications of all
2 persons with confirmed or probable pandemic influenza. Isolation may occur in the home
3 or healthcare setting, depending on the severity of an individual's illness and/or the
4 current capacity of the healthcare infrastructure.

5
6 Voluntary home quarantine of members of households with confirmed or probable
7 influenza case(s) and consideration of combining this intervention with the prophylactic
8 use of antiviral medications, providing sufficient quantities of effective medications exist
9 and that a feasible means of distributing them is in place. Dismissal of students from
10 school (including public and private schools as well as colleges and universities) and
11 school-based activities and closure of childcare programs, coupled with protecting
12 children and teenagers through social distancing in the community to achieve reductions
13 of out-of-school social contacts and community mixing.

14
15 Use of social distancing measures to reduce contact between adults in the community and
16 workplace, including, for example, cancellation of large public gatherings and alteration
17 of workplace environments and schedules to decrease social density and preserve a
18 healthy workplace to the greatest extent possible without disrupting essential services.
19 Enable institution of workplace leave policies that align incentives and facilitate
20 adherence with the non-pharmaceutical interventions (NPIs) outlined above.
21 All such community-based strategies should be used in combination with individual
22 infection control measures, such as hand washing and cough etiquette" (CDC 2007).

23 24 **Therapeutics/vaccines**

25 Immunity induced by current influenza viruses or vaccines will restrict the replication of a 1918
26 H1N1 virus in current human populations (Murphy 2008, 2008).

27
28 Current vaccines can boost antibody to 1918 virus (Tumpey et al. 2004; Murphy 2008).
29 Immunization of mice with 1999 H1N1 vaccine reduced replication of 1918 virus by 50-fold
30 (Tumpey et al. 2004; Murphy 2008), and reduction would be expected to be greater if the mice,
31 like current 2008 humans, had been repeatedly infected with wild type H1N1 (Murphy 2008).

1 Oseltamivir (Tamiflu®) protects mice from a lethal challenge of 1918 influenza virus (Katz
2 2008).

3
4 “Recombinant viruses possessing the 1918 NA or both the 1918 HA and 1918 NA were inhibited
5 effectively in both tissue culture and mice by the NA inhibitors, zanamivir and oseltamivir
6 (Tumpey et al. 2002). A recombinant virus possessing the 1918 M segment was inhibited
7 effectively both in tissue culture and in vivo by the M2 ion-channel inhibitors amantadine and
8 rimantadine. These data suggest that current antiviral strategies would be effective in curbing the
9 dangers of a re-emergent 1918 or 1918-like virus” (Tumpey et al. 2002).

10
11 “Mice that received an intramuscular immunization of the homologous or Sw-Iowa-30-
12 inactivated vaccine developed HI and VN antibodies to the 1918 recombinant virus and were
13 completely protected against lethal challenge. Mice that received A-PR-8-34, A-Texas-36-91, or
14 A-New Caledonia-20-99 H1N1 vaccines displayed partial protection from lethal challenge”
15 (Tumpey et al. 2004).

16
17 Intranasal or intramuscular vaccination with 1918 influenza virus-like particles protect mice
18 from a lethal 8-gene 1918 influenza virus challenge (Tumpey 2008).

19
20 “Mice vaccinated with 1918 HA plasmid DNAs showed complete protection to a lethal
21 challenge from the 1918 virus” (Kong et al. 2006).

22
23 Four measures of influenza vaccine efficacy have been estimated in detail on the basis of
24 challenge studies in human volunteers from 1980 to 2008 (Basta et al. 2008).

25
26 Vaccines for influenza A : inactivated vaccines (Fluzone®, Fluvirin™) obtained from infected
27 chicken embryos are most commonly used. Attenuated vaccines include FluMist (Barnard 2009).

28
29 Approved therapeutics for seasonal influenza A virus infections include the neuraminidase
30 inhibitors oseltamivir phosphate (Tamiflu) and zanamivir (Relenza®) and the M2 ion channel
31 blockers amantadine (Symmetrel®) and rimantadine (Flumadine®) (Barnard 2009).

1 “Influenza-associated pneumonia patterns may now be influenced by the administration of
2 pneumococcus, *Hemophilus influenzae* b, and meningococcus vaccine, and cases have tended to
3 occur in elderly individuals” (Morens, Taubenberger, and Fauci 2008).

4
5 Modeling (based on the assumption that antiviral therapy would reduce the period of illness by 1
6 day) has predicted targeted antiviral prophylaxis to be nearly as effective as vaccinating 80
7 percent of the population and has potential as an effective measure for containing influenza until
8 adequate quantities of vaccine become available (Longini et al. 2004).

9
10 Modeling has projected that stockpiles sufficient to cover 20–25 percent of the population would
11 be sufficient to treat most of the clinical cases and could lead to 50–77 percent reductions in
12 hospitalizations (Gani et al. 2005).

13 14 **Other remarks**

15 “The 1918 H1N1 virus appears to be an avian-like influenza virus derived *in toto* from an
16 unknown source” [author cites two primary sources] (Taubenberger and Morens 2006).

17
18 Recommendations for work with 1918 influenza virus include enhanced BSL-3 and ABSL-3
19 practices, procedures and facilities; large laboratory animals such as NHPs should be housed in
20 primary barrier systems in ABSL-3 facilities (Henkel 2008).

21
22 Seasonal influenza vaccination for researcher working with 1918 influenza virus is
23 recommended by CDC (Uyeki 2008).

24
25 The current policy of the Division of Select Agents and Toxins regarding the 1918 influenza
26 virus requires oseltamivir (Tamiflu) preexposure prophylaxis in enhanced BSL-3
27 biocontainment; it is not required for work in BSL-4 biocontainment. That requirement was
28 based on a risk assessment conducted by Intragovernmental Select Agents and Toxins Technical
29 Advisory Committee (which advises the Division of Select Agents and Toxins) (Henkel 2008).
30 The NIH-RAC is considering whether to recommend this policy to the NIH (Corrigan-Curay
31 2008).

1 The RAC opinion, by the end of the December 2, 2008, meeting, was strongly against
2 recommending preexposure prophylactic use of antiviral agents for scientists working with 1918
3 H1N1 virus.

4
5 One view is that a series of incorrect assumptions led to the existing recommendation of
6 mandatory antiviral prophylaxis for work with 1918 H1N1 virus, and new data on restricted
7 replication of 1918 virus in H1N1 immune mice makes continuation of the policy unnecessary
8 and unwise (Murphy 2008, 2008).

9
10 The RAC is considering, “whether the public health objective should be to prevent [by requiring
11 preexposure prophylaxis] any researcher from developing an active case of 1918 H1N1
12 [infection] that could be spread to the public, or is it acceptable to be prepared to contain the
13 infection once in the community” (Shapiro 2008). Further, the RAC is considering whether “the
14 ethical obligation to protect the public [is] higher because this virus was recreated in the
15 laboratory” (Shapiro 2008). The CDC’s perspective is that, without a vaccine for the 1918 virus,
16 the public health objective is to prevent a case of illness in a lab worker by use of
17 biocontainment, training, seasonal influenza vaccination and oseltamivir preexposure
18 prophylaxis, and that there is a higher obligation to the public with regard to a recreated virus
19 (Uyeki 2008).

20
21 Pre-exposure prophylaxis with antiviral agents would not necessarily be 100 percent effective in
22 preventing infection with 1918 H1N1 virus (Uyeki 2008).

23
24 The Occupational Medicine response plan for NIH Division of Intramural Research Laboratory
25 of Infectious Diseases, Subbarao lab (SARS-CoV, HPAI, H2N2 viruses) (Subbarao 2008) is as
26 follows:

- 27 • If an employee reports a spill but had intact respiratory protection, the employee returns
28 to work, monitors symptoms and temperature and reports to Occupational Medicine
29 physician daily;
- 30 • If an employee reports a spill but had questionable respiratory protection or a
31 percutaneous exposure, the employee is sent home and is asked to stay home, started on

post-exposure prophylaxis, avoids contact with others and wears a surgical mask, monitors temperature and symptoms, and reports to Occupational Medicine physician twice a day;

- If an employee reports a fever (temp of more than 100.4 °F), the employee stays in place, dons a surgical mask, and notifies an Occupational Medicine physician. The Occupational Medicine physician obtains a medical history and a work and social history for the prior 14 days, consults with PI and infectious disease specialists. If indicated, an Occupational Medicine physician coordinates safe transport and appropriate hospital isolation and diagnostic laboratory testing.

The Select Agent Program requires work with 1918 virus be predicated on approval by the Division of Select Agents and Toxins of an [application] amendment, and this also requires a detailed inspection from the Division of Select Agents and Toxins group (Henkel 2008).

Antigenic relationships/synonyms

Influenza viruses are spherical or pleomorphic, single-stranded, negative-sense RNA enveloped viruses of the genus *Influenzavirus A* belonging to family *Orthomyxoviridae*. Influenza A and B viruses contain eight separate ribonucleoprotein (RNP) segments, while influenza C virus contains seven, each of which encodes 1 or 2 proteins. The internal antigens (M1 and NP proteins) are the type-specific antigens used to determine if a virus is A, B, or C, while the external hemagglutinin (HA) and neuraminidase (NA) are the subtype- and strain-specific antigens (Barnard 2009).

C.1.1.5 SARS-associated coronavirus (SARS-CoV)

Host range

a. Field

Coronaviruses are important pathogens of mammals and birds causing enteric or respiratory tract infections in a variety of animals including humans, livestock, and pets (Wang and Eaton 2007; Shi and Hu 2008).

1 Samples from wild animals sold as food in the local market in Guangdong, China,
2 yielded SARS-associated coronavirus from palm civets (*Paguma* sp.), but the animals did
3 not always show clinical signs (Wang and Eaton 2007; Shi and Hu 2008).

4
5 Virus crossed the animal-human barrier from palm civets to humans. More than 10,000
6 masked palm civets were destroyed in Guangdong Province (Wang and Eaton 2007).

7
8 Virus has been isolated from raccoon dogs (*Nyctereutes* sp.), Chinese ferret badgers
9 (*Melogale moschata*), and domestic cats (Wang and Eaton 2007; Shi and Hu 2008).
10 2005 two studies identified a number of SARS-like coronaviruses in Chinese bats (Wang
11 and Eaton 2007) (Shi and Hu 2008).

12
13 Phylogenetic analysis of bat viruses indicated a high probability that SARS-associated
14 coronavirus originated in bats and spread to humans either directly or through animals
15 held in Chinese markets. The bats did not show any visible signs of disease but are the
16 likely natural reservoirs (Wang and Eaton 2007; Shi and Hu 2008).

17
18 Bats are natural reservoirs of a very similar virus [bat SARS-CoV] and civet cats might
19 be involved in the virus's emergence (Feng and Gao 2007).

20
21 In China, original infected humans had a typical history of contacting animals in the food
22 industry (Feng and Gao 2007; Shi and Hu 2008).

23
24 In live-animal markets in Guangdong Province 13–40 percent of wild animal traders and
25 slaughterers were revealed to be seropositive (Feng and Gao 2007; Shi and Hu 2008).

26
27 Suspicion focused on palm civets because more than 70 percent of SARS seropositives
28 were among the traders who were primarily trading masked palm civets; SARS-CoV-like
29 viruses were isolated from Himalayan palm civets (*Paguma larvata*) [nasal samples], and
30 nasal and fecal samples were RT-PCR positive; and a raccoon dog (*Nyctereutes*
31 *procyonoides*) [virus isolates and RT-PCR from nasal and fecal samples] at an animal

1 market; neutralizing antibody in serums from *P. larvata*, *N. procyonoides*, and *Melogale*
2 *moschata* [Chinese ferret-badger] (Guan et al. 2003; Feng and Gao 2007).

3
4 A subsequent survey failed to support widespread infection in wild and/or farmed civets
5 (Feng and Gao 2007).

6
7 Civets may be the carrier source of SARS-CoV-like virus (Feng and Gao 2007).

8
9 Virus exists in civets and other common animals within wet-market systems. It might
10 reflect an *artificial* market cycle in native species rather than an indication of a natural
11 reservoir (Feng and Gao 2007).

12
13 Bats function as the natural reservoirs and rarely display clinical signs despite persistent
14 infections with multiple viruses (Feng and Gao 2007).

15
16 Bats or bat products in food and traditional medicine markets make it possible that
17 SARS-CoV-like viruses infect humans from bats, subsequently adapt to humans, and
18 trigger human-to-human transmission (Feng and Gao 2007).

19
20 Closely related coronaviruses isolated from horseshoe bat species of the genus
21 *Rhinolophus* within the family *Rhinolophidae* (Shi and Hu 2008).

22
23 High prevalence of antibodies observed in the lesser horseshoe bat *Rhinolophus pusillus* (
24 (Daddario-DiCaprio) 2/6), the great-eared horseshoe bat *Rhinolophus macrotis* (5/7) and
25 the Pearson's horseshoe bat *Rhinolophus pearsoni* (13/46) by a sandwich ELISA method
26 (Shi and Hu 2008).

27
28 Chinese horseshoe bat *Rhinolophus sinicus* (12/18 by Western blots, 31/37 positive by
29 enzyme immunoassay (EIA) with titer $\geq 1:400$, and 8/19 by a neutralization assay for
30 human SARS-CoV with titer $\geq 1:20$); very low percentage of positive samples were
31 detected in the fruit bat *R. leschenaultia* (1.2 percent) (Shi and Hu 2008).

1 Using RT-PCR, a low prevalence of viruses was detected in fecal swabs of *Rhinolophus*
2 *ferrumequinum* (1/8), *R. macrotis* (1/8) and *R. pearsoni* (3/30), as compared with a high
3 prevalence in *R. sinicus* (23/59); 39 percent of fecal swabs from wild Chinese horseshoe
4 bats, *R. sinicus*, contained genetic material similar to SARS-CoV (Shi and Hu 2008;
5 Wang et al. 2006).

6
7 In contaminated markets, red foxes, domestic cats, Lesser rice field rats, and others might
8 harbor the virus (Shi and Hu 2008).

9
10 The prime suspect as an animal reservoir host remains the civet cat (*Paguma larvata*),
11 and the foci for spread from this host to humans seems to be the animal markets in China
12 (Shi and Hu 2008).

13
14 Domestic cats living in the Amoy Gardens apartment block in Hong Kong, where more
15 than 100 residents contracted SARS (2003), were found to be infected with SARS-CoV
16 (Martina et al. 2003).

17
18 Investigations of SARS-CoV in animals are summarized in Table C-7 (Shi and Hu 2008).

Table C-7. Summary of investigations of SARS-CoV in other animal species (does not include masked palm civets and bats).

Species	Common name	Methods	Prevalence	Reference (as cited by Shi & Hu {Shi, 2008 #13541})
<i>Macaca mulatta</i>	Rhesus macaque	RT-PCR	0/20	Lau et al. (2005)
<i>Canis familiaris</i>	Dog	Antibody	0/20	Chen et al. (2005)
		Real-time RT-PCR	0/5	(Wang et al., 2005a) and (Wang et al., 2005b)
<i>Nyctereutes procyonoides</i>	Raccoon dog	RT-PCR, virus isolation	1/1	Guan et al. (2003)
		RT-PCR	15/15	Kan et al. (2005)
<i>Vulpes vulpes</i>	Red fox	Real-time RT-PCR	3/5	(Wang et al., 2005a) and (Wang et al., 2005b)
<i>Melogale moschata</i>	Chinese ferret-badger	Antibody	1/2	Guan et al. (2003)
<i>Arctonyx collaris</i>	Hog-badger	RT-PCT, antibody	0/3	Guan et al. (2003)
<i>Mustela vison</i>	Mink	Real-time RT-PCR	0/1	(Wang et al., 2005a) and (Wang et al., 2005b)
<i>Felis catus</i>	Domestic cat	RT-PCT, antibody	0/4	Guan et al. (2003)
		Real-time RT-PCR	4/20	(Wang et al., 2005a) and (Wang et al., 2005b)
		Real-time RT-PCR	0/13	(Wang et al., 2005a) and (Wang et al., 2005b)
		Real-time RT-PCR	0/3	(Wang et al., 2005a) and (Wang et al., 2005b)
		Antibody	0/11	Chen et al. (2005)
<i>Sus scrofa domestica</i>	Pig	Antibody, RT-PCR	2/108	Chen et al. (2005)
<i>S. scrofa</i>	Wild boar	Real-time RT-PCR	1/19	(Wang et al., 2005a) and (Wang et al., 2005b)
<i>Muntiacus reevesi</i>	Chinese muntjac	RT-PCT, antibody	0/2	Guan et al. (2003)

		Antibody	0/9	(Wang et al., 2005a) and (Wang et al., 2005b)
<i>Bos tarurs</i>	Cattle	Real-time RT-PCR	0/60	Chen et al. (2005)
<i>Capra hircas</i>	Goat	Real-time RT-PCR	0/3	(Wang et al., 2005a) and (Wang et al., 2005b)
<i>Oryctolagus cuniculus</i>	Rabbit	Real-time RT-PCR	0/6	(Wang et al., 2005a) and (Wang et al., 2005b)
		Real-time RT-PCR	0/5	(Wang et al., 2005a) and (Wang et al., 2005b)
<i>Lepus sinensis</i>	Chinese hare	RT-PCT, antibody	0/3	Guan et al. (2003)
<i>Castor fiber</i>	Beaver	RT-PCT, antibody	0/3	Guan et al. (2003)
<i>Niviventer fulvescens</i>	Chestnut spiny rat	RT-PCR	0/12	Lau et al. (2005)
<i>Rattus rattus flavipectus</i>	Buff-bellied rat	RT-PCR	0/4	Lau et al. (2005)
<i>Rattus sikkimensis</i>	Sikkim rat	RT-PCR	0/44	Lau et al. (2005)
<i>Rattus losea</i>	Lesser rice field rat	Real-time RT-PCR	1/6	(Wang et al., 2005a) and (Wang et al., 2005b)
		Real-time RT-PCR	0/16	(Wang et al., 2005a) and (Wang et al., 2005b)
<i>Anas domestica</i>	Duck	Antibody	0/30	Chen et al. (2005)
<i>Anas platyhynchos</i>	Spotbill duck	Real-time RT-PCR	0/13	(Wang et al., 2005a) and (Wang et al., 2005b)
		Real-time RT-PCR	0/9	(Wang et al., 2005a) and (Wang et al., 2005b)
<i>Anser anser</i>	Greylag goose	Real-time RT-PCR	1/10	(Wang et al., 2005a) and (Wang et al., 2005b)
		Real-time RT-PCR	0/14	(Wang et al., 2005a) and (Wang et al., 2005b)

<i>Gallus domestica</i>	Chicken	Antibody	0/11	Chen et al. (2005)
<i>Gallus gallus</i>	Red jungle fowl	Real-time RT-PCR	0/46	(Wang et al., 2005a) and (Wang et al., 2005b)
<i>Francolinus pintadeanus</i>	Chinese francolin	Real-time RT-PCR	0/31	(Wang et al., 2005a) and (Wang et al., 2005b)
		Real-time RT-PCR	0/2	(Wang et al., 2005a) and (Wang et al., 2005b)
<i>Phasianus colchicus</i>	Common pheasant	Real-time RT-PCR	0/8	(Wang et al., 2005a) and (Wang et al., 2005b)
<i>Pavo muticus</i>	Green peafowl	Real-time RT-PCR	0/2	(Wang et al., 2005a) and (Wang et al., 2005b)
<i>Columba livia</i>	Pigeons	Real-time RT-PCR	0/6	(Wang et al., 2005a) and (Wang et al., 2005b)

b. Experimental

A mouse-adapted strain has been used in BALB/c mice (Roberts et al. 2007; Day et al. 2009).

Replicates in cynomolgus macaques (Cinatl et al. 2005).

Replicates in the lungs of mice, hamsters and domestic cats; these animals remain asymptomatic (Perlman and Dandekar 2005).

Initial reports indicated that cynomolgus macaques (*M. fascicularis*) and ferrets develop clinically evident respiratory disease and would be useful animal models for studying SARS. But the results are not reproducible (Perlman and Dandekar 2005).

Experimental infection of civets with human isolates reproduced overt clinical signs similar to that of SARS patients. It is unlikely that civets play a role as natural reservoir hosts but are susceptible hosts (Feng and Gao 2007).

1 SARS-CoV infects a wide-range of hosts, including masked palm civets, monkeys
2 [common marmoset, *Callithrix jacchus*], cats, ferrets, mice, pigs, chickens, guinea pigs,
3 and golden Syrian hamsters (Shi and Hu 2008) (Wang and Eaton 2007).

4
5 Virus replicates in the respiratory tracts of African green monkeys (*Chlorocebus aethiops*
6 *sabaeus*) and rhesus (*M. mulatta*) and cynomolgus macaques (*M. fascicularis*) (titer of
7 infecting virus was $10^{6.3}$ CCID₅₀) but minimal to no clinical disease was observed.
8 Clinical disease was observed in cynomolgus macaques, but observations were not
9 uniformly reproducible (McAuliffe et al. 2004; Gillim-Ross and Subbarao 2006).

10
11 Virus replicates to high titers in the lungs and nasal turbinates of 6- to 8-week-old mice.
12 Viral nucleic acid is detected in the lungs and intestines (Gillim-Ross and Subbarao
13 2006).

14
15 Failure to isolate the virus and the lack of virus shedding indicate that neither pigs nor
16 chickens are likely to play a role as an amplifying host (Weingartl, Copps, et al. 2004).

17
18 Most reproducible data on virus replication obtained from inbred mice and from golden
19 Syrian hamsters that are not inbred but are of limited genetic heterogeneity (Subbarao
20 and Roberts 2006).

21
22 In golden Syrian hamsters, the virus replicates to a high titer in the respiratory tract, 10^8
23 CCID₅₀/gram of lung tissue following intranasal administration (Subbarao and Roberts
24 2006).

25
26 Ferrets (*Mustela furo*) and domestic cats (*Felis catus*) are susceptible to infection by
27 SARS-CoV and can efficiently transmit the virus to previously uninfected animals
28 housed with them (Wang et al. 2004).

29
30 In domestic cats and ferrets inoculated intratracheally with 10^6 CCID₅₀ obtained from a
31 patient who died from SARS and passaged 4 times on Vero cells: no clinical signs in

1 cats; 3/6 ferrets exhibited clinical signs and one died; all cats and ferrets shed virus from
2 pharynx, trachea, and lungs from 2–10 (cats)/–14 (ferrets) days after infection. SARS-
3 CoV was isolated from the trachea and lungs: cats $10^3 \pm 0.51 \text{CCID}_{50}/\text{mL}$; ferrets $10^6 \pm$
4 $0.70 \text{CCID}_{50}/\text{mL}$. In the GI and urinary tracts, SARS-CoV was detected by RT–PCR. All
5 animals seroconverted. All attempts to infect suckling mice through intracerebral
6 inoculation failed. Infection via non-direct contact was shown when uninoculated cats
7 and ferrets housed with inoculated cats and ferrets became infected with SARS-CoV
8 (Wang et al. 2004).

9
10 SARS-CoV injected intratracheally into chickens, turkeys, geese, ducks, and quail, or
11 into the allantoic sac of their embryonating eggs, failed to cause disease or replicate. That
12 suggests that domestic poultry are unlikely to have been the reservoir, or associated with
13 dissemination, of SARS-CoV in the animal markets of southern China (Swayne et al.
14 2004).

15
16 SARS animal model was established by inoculating SARS-CoV into rhesus macaques
17 (*M. mulatta*) through the nasal cavity; RNA was detected by nested RT-PCR in the
18 pharyngeal swab and nasal swab samples on the first day after infection and in all
19 monkeys from the 5th to 16th day post-infection (Qin et al. 2005).

20
21 Animal studies provide proof from experimental infection of cynomolgus macaques (*M.*
22 *fascicularis*) that SARS-CoV is the etiological agent of SARS (Fouchier et al. 2003).

23 24 **Prevalence/incidence/attack rate**

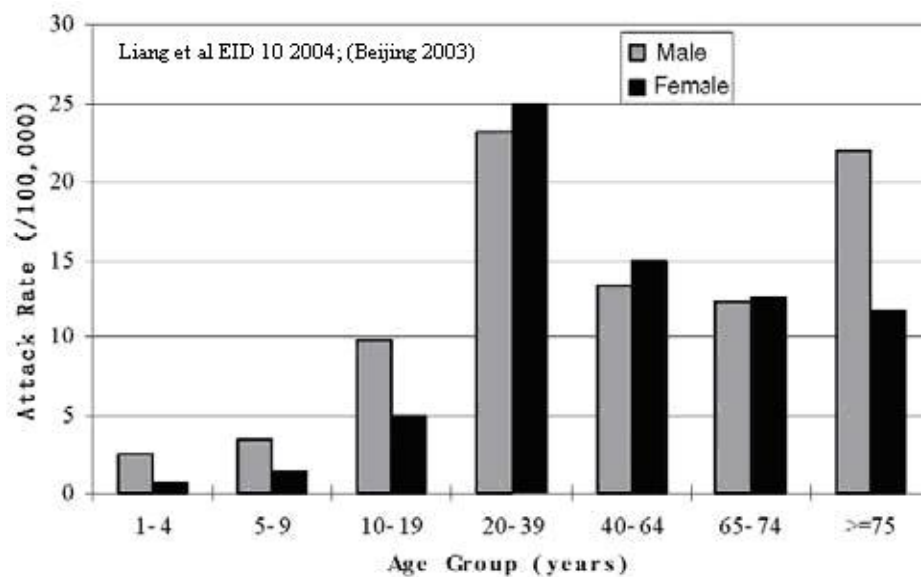

25 Seroprevalence rate was 88.9 percent (80/90) for healthcare workers with SARS and 1.4 percent
26 (15/1,057) for healthcare workers who were apparently healthy with seroprevalence in a
27 reference group at 0.4 percent (3/709); findings suggest that inapparent infection is uncommon in
28 humans (Chu et al. 2004).

29
30 Attack rate for probable SARS among healthcare workers in Beijing is estimated as 465 per
31 100,000 (Liang et al. 2004).

Highest attack rate in Beijing 2003 as 25 percent among males 20–39 y.o. (Liang et al. 2004).

Demographic characteristics of case-patients: children <10 years of age accounted for 0.9 percent of probable cases, median age of those who became ill was 33 years; age-specific attack rates were highest in those 20–39 years of age (relative risk [RR] 1.7, 95 percent confidence interval [CI] 1.53 to 1.89), as compared with those 40–64 years, and significantly lower in children (1–4 years of age, RR 0.12 [CI 0.05 to 0.28], 5–9 years, RR 0.17 [CI 0.09 to 0.31] and 10–19 years, RR 0.53 [CI 0.44 to 0.64]), as compared with those aged 40–64 years; overall, male patients had similar rates as female patients, but the risk differed significantly in certain age groups: among those 10–19 years of age, the RR for SARS in male patients was 1.96, 95 percent CI 1.36 to 1.83, as compared with that of females; and in those >75 years, RR for male patients was 1.88 (95 percent CI 1.08 to 3.29) (Liang et al. 2004).

Figure C-2. Attack rates (cases per 100,000 population) by age and sex, Beijing 2003.

Source: (Liang et al. 2004).

Attack rates were >50 percent in hospitals in China, Hong Kong, and Singapore (Goh et al. 2004).

1 Secondary household attack rates were 6.2 percent in Singapore and 4.6 percent in China (Goh et
2 al. 2004).

3
4 Secondary attack rate in households was 8 percent in Hong Kong (Lau et al. 2004).

5
6 Attack rates by percentage: male, 46.6, females, 53.4; 18–30 years, 46.6, 31–40 years, 15.3, 41–
7 50, 16.2, 51–60 years, 10.9, >60 years, 11.1; overall, 14.9 percent (Lau et al. 2004).

8
9 **R₀/incubation period/infectious period/infectious dose**

10 R₀ estimated between 2 and 3; because the transmission route for SARS-CoV superspreaders
11 were atypical of the disease in most cases estimates of R₀ have not included superspreaders to
12 not skew results; therefore, some R₀ values reported might not be a true indication of
13 transmissibility during the epidemic (Chan, Tang, and Hui 2006).

14
15 R₀ values/modeling reported by several investigators (Anderson et al. 2004; Chan, Tang, and Hui
16 2006; Riley et al. 2003; Lipsitch et al. 2003; Galvani, Lei, and Jewell 2003; Cauchemez et al.
17 2006; Fraser et al. 2004; Hufnagel, Brockmann, and Geisel 2004; Lloyd-Smith, Galvani, and
18 Getz 2003).

19
20 1.63 (90% confidence interval: 0.54-2.65) for first three generations of transmission in Singapore
21 2003; 2.55 (90% confidence interval: 0.50-4.50) for first two generations of transmission in
22 Singapore 2003. Third generation occurred before centralized control measures were in place,
23 but after WHO's global alert on SARS, so drop in R₀ estimate could be explained by informal
24 behavior changes or informal increased isolation of patients. These are direct estimates of R in
25 Singapore from contact tracing data (Lloyd-Smith et al. 2005).

26
27 1.88 (90% confidence interval 0.41-3.32) for first two generations of transmission in Beijing
28 2003; 0.94 (90% confidence interval 0.27-1.51) for only second generation of transmission in
29 Beijing 2003. The first generation consisted of a single infected individual who directly
30 transmitted to 33 others. These are direct estimates of R in Beijing from contact tracing data
31 (Lloyd-Smith et al. 2005).

3.6 (95% confidence interval 3.1-4.2) for Hong Kong; 2.4 (95% confidence interval 1.8-3.1) for Vietnam; 3.1 (95% confidence interval 2.3-4.0) for Singapore; 2.7 (95% confidence interval 1.8-3.6) for Canada: these are estimates inferred from epidemic curves and generation interval data from each city, using a likelihood-based estimation procedure (Wallinga and Teunis 2004).

Estimated 0.86 (0.24-1.18) for Toronto, 1.70 (0.44-2.29) for Hong Kong, 1.83 (0.47-2.47) for Singapore (Chowell, Castillo-Chavez, et al. 2004). Ranges are the inter-quartile range. These are model-based estimates assuming a portion of population is less susceptible, which explains why these are lower than other estimates. For example, with uniform susceptibility, estimate for Hong Kong increases to 2.6 (Bauch et al. 2005).

2.7 (95% confidence interval 2.2-3.7) for Hong Kong (Riley et al. 2003). This excluded super-spreading events. Including them may increase the estimate to about 3.2 (Bauch et al. 2005). Estimate was based on fitting stochastic spatial simulation to case-incidence data.

3.5 (90% confidence interval 1.5-7.7) for Singapore using Bayesian procedure. Range of 2.2-3.6 using deterministic model estimate (Lipsitch et al. 2003).

4.80 for Toronto; 3.60 for Hong Kong; 5.04 for Singapore; 4.91 for Beijing (Gumel et al. 2004): these are deterministic dynamic model-based estimates. The reason they are higher than other estimates may be because of unrealistic assumptions about the efficacy of control measures (Bauch et al. 2005).

4.2 for Taiwan (Hsieh, Chen, and Hsu 2004). May be higher than other estimates because of uncertainties in model infectiousness parameters and/or unusually high rate of hospital transmission in Taiwan.

2.1 for Hong Kong (Zhou and Yan 2003). Lower because estimate includes data from after implementation of control measures (Bauch et al. 2005).

1 1.5 for Toronto, 2.0 for Hong Kong (Choi 2003). Estimates are too low because of authors'
2 interpretation of generation time parameter. After adjusting for this, results are 2.5 for Toronto
3 and 3.4 for Hong Kong (Bauch et al. 2005).

4
5 1.1-3.3 for Beijing (Wang and Ruan 2004). Lower end of range assumes no transmission after
6 entering hospital, highly unrealistic (Bauch et al. 2005).

7
8 2.23 for Taiwan (Bombardt 2006) using approach similar to Wallinga and Teunis (Wallinga and
9 Teunis 2004).

10
11 2.87 for mainland China (Zhang 2007).

12
13 3 (range 1.5-5)) (Lloyd-Smith, Galvani, and Getz 2003).

14
15 2-3 (Anderson et al. 2004).

16
17 2.5-2.9 Hong Kong (Fang, Chen, and Hu 2005).

18
19 Hong Kong $R_0 = 2-3$, excluding superspreading events (Riley et al. 2003).

20
21 Main conclusion to draw from these estimates of R_0 is that SARS-CoV is of low transmissibility
22 by comparison with other directly transmitted viruses such as influenza A (R_0 of *ca* 7 or more)
23 and the measles virus (R_0 of *ca* 15–18 before widescale immunization) (Anderson et al. 2004).

24
25 Estimated that a single infectious case of SARS will infect about three secondary cases in a
26 population that has not yet instituted control measures (Lipsitch et al. 2003).

27
28 In Toronto, mean incubation period was 5 days (median 4 day; range 2–10 days)(Varia et al.
29 2003).

1 Incubation period: estimates of 2–12 days; range 4–5.3 days, mean 4.5–4.6 days from
2 China/Hong Kong data (Anderson et al. 2004).

3
4 Incubation period estimates of mean and median for patients in China, Hong Kong, Singapore
5 and Canada consistently ranged from 4 to 6 days (Donnelly et al. 2004).

6
7 Infectious period (Amoy Gardens, Hong Kong): range 5–15 days; peak viral load (nasopharyngeal wash) at day 10 (Peiris, Chu, Cheng, Chan, Hung, Poon, Law, Tang, Hon, Chan, Chan, Ng, Zheng, Ng, Lai, Guan, Yuen, et al. 2003).

10
11 Infectious dose for humans is unknown.

12
13 Infectious dose used in *M. mulatta* monkeys was 10^3 , 10^5 , and 10^7 CCID₅₀ ; optimal dose was
14 10^5 CCID₅₀ which produced serologic conversion in 5 of 8 animals (HID63).(Qin et al. 2005).

15
16 **Morbidity/Case fatality ratio**

17 Primary symptoms include fever, headache, myalgias and malaise, followed by a dry cough, and
18 shortness of breath in more severe cases. About 25 percent of patients developed severe disease
19 that progressed to adult respiratory distress syndrome (McIntosh and Perlman 2010).

20
21 Asymptomatic or minimally symptomatic infections apparently are exceedingly rare (~0.1
22 percent of people tested) (Leung et al. 2006; Yang et al. 2009).

23
24 One near pandemic between November 2002 and July 2003, with 8,096 known infected cases
25 and 774 deaths (a case-fatality rate of 9.6 percent) worldwide (Feng and Gao 2007; Lam, Zhong,
26 and Tan 2003).

27
28 Mortality by age group is less than 1 percent for people aged younger than 25, 6 percent for
29 those 25 to 44, 15 percent for 45 to 64 and more than 50 percent for 65 and older (Lam, Zhong,
30 and Tan 2003; Zhong and Wong 2004; Feng and Gao 2007).

1 Rapid transmission and high mortality rate (Feng and Gao 2007; Lam, Zhong, and Tan 2003).
2 Overall mortality rate is about 10 percent but the mortality varies with age; few children and
3 generally appeared to be milder in pediatric age group, mortality rate in the elderly was as high
4 as 50 percent (Cinatl et al. 2005).

5
6 By 2007, 8,400 cases with more than 812 fatalities in more than 30 countries (Feng and Gao
7 2007).

8
9 Case-fatality rate during early outbreaks was nearly 10 percent (range 0–40 percent) (Feng and
10 Gao 2007).

11
12 Case fatality rates, Hong Kong, age related, younger than 30 years, less than 1 percent; 30–44
13 years, males = 10–12 percent, females = 5 percent; 45–59 years, males = 20–22 percent, females
14 = 10 percent; 60–74 years, males = females = 40–45 percent; 75+ years, males = 65 percent,
15 females = 70 percent (Anderson et al. 2004).

16
17 Case fatality rate for SARS was less than 1 percent for patients aged 24 years or younger, 6
18 percent for 25–44 years, 15 percent for 45–64 years, and more than 50 percent for patients aged
19 65 years or older (Chan, Tang, and Hui 2006).

20
21 Mortality rates of mechanically ventilated patients ranged from 44.8 to 48 percent at 28 days
22 after ICU admission and 51.7 percent at 8 weeks; through discharge from the hospital, mortality
23 rate was 64 percent; global case fatality rate was 9.6 percent (Tai 2006).

24
25 As of May 20, 2003, case-fatality rate was 6.4 percent for probable SARS case-patients; case-
26 fatality rates increased with age (0.5 percent in younger than 20 year olds; 4.8 percent for those
27 20–64 years; and 27.7 percent for 65 years or older, $p < 0.001$); case fatality rate among probable
28 case-patients, excluding those still hospitalized, was 8.4 percent (Liang et al. 2004).

29
30 Overall complication rate of 23.7 percent and case-fatality rate of 19.7 percent (Wang et al.
31 2004).

Amoy Gardens mortality rate was 6.7 percent (Peiris, Chu, Cheng, Chan, Hung, Poon, Law, Tang, Hon, Chan, Chan, Ng, Zheng, Ng, Lai, Guan, and Yuen 2003).

Toronto, 2003, case-fatality rate was 2.9 percent among the 102 cases less than 60 years of age and 53.8 percent among the 26 cases 60 years or older; overall, 13.3 percent (Varia et al. 2003).

In Toronto nosocomial cases, death rate, 41.2 in females, 58.8 in males (Varia et al. 2003).

CFR in Hong Kong increased with age as in other parts of the world: 14.7 percent in persons under 44 years of age, 21.4 percent between 45 and 64 years and 63.9 percent over 64 years; experiences suggested that deaths were associated with pre-existing illnesses in the older age group (> 64 years)(Chan-Yeung and Xu 2003).

Case fatality rate for SARS-CoV infection in 2003 was estimated to be 13.2 percent for individuals younger than 60 years and close to 50 percent for individuals 60 years and older (Gillim-Ross and Subbarao 2006).

Average overall CFR for all countries increased from 10.4 percent on April 21, 2003, to 14.7 percent on May 12 (largely attributable to the sudden rise in CFRs in China and Taiwan) (Galvani, Lei, and Jewell 2003).

Table C-5. Summary of probable SARS cases with onset of illness from November 1, 2002 to July 31, 2003

Areas	Cumulative number of cases			Median age (range)	Number of deaths ^a	Case fatality ratio (%)
	Female	Male	Total			
Australia	4	2	6	15 (1-45)	0	0
Canada	151	100	251	49 (1-98)	43	17
China	2674	2607	5327 ^b	Not available	349	7

1 **Aerosol infection/routes of transmission**

2 Suspected SARS definition = sexual or casual contact with someone with a diagnosis of SARS
3 within the last 10 days and clinical symptoms (Anonymous 2007).

4
5 Diagnostic laboratory staff members most at risk handled respiratory samples and were exposed
6 to aerosols from leaking samples (Barkham 2004).

7
8 Transmission rate among health care workers high, 63 percent of cases in Hanoi hospitals, 46
9 percent in Hong Kong, 76 percent in Singapore, equally high rates in Toronto (Low and Wilder-
10 Smith 2005).

11
12 Transmission of most respiratory viruses is a combination of direct contact (touch), short-range
13 (large droplet; within 1 m) and long-range (droplet nuclei; beyond 1 m and farther) (Chan, Tang,
14 and Hui 2006).

15
16 High infectivity of the viral illness is supported by the fact that 138 patients (many of whom
17 were healthcare workers) were infected with SARS-CoV within 2 weeks after the admission of
18 this single index case from Hotel M; superspreading event is thought to be related to the
19 administration of a nebulized bronchodilator to the index case, together with overcrowding and
20 poor ventilation in the hospital ward (Chan, Tang, and Hui 2006).

21
22 Possible spread by long-range airborne transmission in a major community outbreak in a private
23 residential complex in Hong Kong; possible passive carriage of viruses by pests, drying up of U-
24 shaped bathroom floor drain, which allowed the backflow of contaminated sewage or its
25 aerosolized particles and creation of infectious aerosol current by the use of residential exhaust
26 fans in the toilet (Chan, Tang, and Hui 2006) (Verreault, Moineau, and Duchaine 2008).

27 Possible airborne transmission shown by air samples obtained from a room occupied by a SARS
28 patient, and swabs taken from frequently touched surfaces in rooms and at a nurse station were
29 positive for SARS-CoV by PCR (Chan, Tang, and Hui 2006).

* nosocomial transmission was the primary accelerator of SARS infections, accounting for 72 percent of cases in Toronto and 55 percent of probable cases in Taiwan (McDonald et al. 2004). Transmission appears to be primarily through exposure to respiratory droplets and direct contact with patients and their contaminated environment, especially if exposed during aerosol-generating procedures (McDonald et al. 2004).

Airborne droplets from infected patients might be the main route of transmission, with a secondary transmission route via blood and fecal-oral transmission (Weiss and Navas-Martin 2005).

Transmission other than by droplets, bodily fluids, and fomites is unknown (Lam, Zhong, and Tan 2003; Lim, Ng, and Tsang 2006).

Most respiratory pathogens transmitted by direct contact and short-range routes, with occasional instances where long-range transmission can be the only explanation, e.g., influenza; source for such transmission events is normally the infected patient's upper respiratory tract, and not via the hematogenous or fecal-oral routes (Chan, Tang, and Hui 2006).

In United States, under certain circumstances, SARS-CoV was not readily transmitted to close contacts, despite ample unprotected exposures (Peck et al. 2004).

Superspreading events, in which a single person spread the infection to many other people, were an important component of SARS-CoV transmission globally; in Singapore and Taiwan single case-patients might have transmitted the virus to >60 persons; for most SARS case-patients, transmission was limited—after the institution of intensive infection-control measures in Singapore, 81 percent of probable SARS patients had no evidence of transmission to other persons (Peck et al. 2004).

In United States, lack of virus transmission among 110 healthcare workers with exposure within droplet range (i.e., 3 feet) to six SARS-CoV-positive patients; 45 healthcare workers had exposure without any mask use, 72 had exposure without eye protection, and 40 reported direct

1 skin-to-skin contact; potential droplet- and aerosol-generating procedures were infrequent: 5
2 percent of healthcare workers manipulated a patient's airway, and 4 percent administered
3 aerosolized medication; despite numerous unprotected exposures, no serologic evidence of
4 healthcare-related SARS-CoV transmission; could be related to the relative absence of high-risk
5 procedures or patients (Park et al. 2004).

6
7 Transmitted primarily through direct mucous membrane contact with infectious respiratory
8 droplets and through exposure to fomites (Lo et al. 2005).

9
10 Amoy Gardens, 2003, high virus concentration aerosol spread from building plumbing through
11 floor drains; initial exposures in bathrooms from feces and urine, then spread via prevailing
12 winds to adjacent buildings, exposing additional humans; virus travelled hundreds of feet
13 between buildings/apartments (McKinney, Gong, and Lewis 2006; Verreault, Moineau, and
14 Duchaine 2008).

15
16 In Amoy Gardens, spread of the airborne, virus-laden aerosols generated by the index patient
17 was modeled with the use of airflow-dynamics studies, including studies performed with the use
18 of computational fluid-dynamics and multizone modeling (Yu et al. 2004).

19 Transmission mechanical, including airborne particles, contaminated equipment, and contact
20 (Anonymous 2007).

21
22 Transmission of SARS-CoV is similar to other respiratory viruses but with several important
23 differences: first international dissemination of SARS-CoV was related to a superspreader, a 64-
24 year-old physician from southern China who visited Hong Kong on February 21, 2003, and
25 stayed in Hotel M; died 10 days later with severe pneumonia; spread the virus to at least 16 hotel
26 guests or visitors who had visited the floor where he stayed and spread subsequently in Hong
27 Kong and to Vietnam, Singapore, and Canada (Chan, Tang, and Hui 2006; Verreault, Moineau,
28 and Duchaine 2008).

29
30 Hong Kong transmission study showed that the probability of transmission from index cases
31 whose date of symptom onset occurred before public health interventions imposed on March 26,

2003, was slightly higher during the first 2 days after symptom onset and peaked again on day 9 after symptom onset; probability of transmission from index patients whose LDH level was above the expected level was markedly higher than that from those whose LDH level was below the predicted level, peaking on days 8–9 of illness; index cases aged 60 years or older had a high probability of transmission as compared with younger index patients, approximately 3 times higher than in younger index patients during the first week of illness and remained high throughout the first 9 days of illness (Pitzer, Leung, and Lipsitch 2007).

Virus titers/concentrations/pathogenesis

In Vero cells, 10^6 – 10^7 CCID₅₀/mL produced in roller bottles/flasks (Johnson 2008).

In BHK-21 (baby hamster kidney) cells, titers of 10^8 PFU used as animal inoculum but no details are provided about whether this was artificially concentrated from culture (Weingartl, Czub, et al. 2004).

In A72 canine cells, canine coronavirus titers attain $3.14 \pm 0.58 \times 10^{6.0}$ CCID₅₀/mL (Amici et al. 2006).

In human lung epithelial cells [A549 cell line], SARS-CoV titers attain $4.39 \pm 1.2 \times 10^{3.0}$ CCID₅₀/mL (Amici et al. 2006).

In VERO cells, SARS-CoV titers attained 1.74×10^6 CCID₅₀/mL [titers in some tests attained $>10^7$ CCID₅₀/mL] (Amici et al. 2006).

In canine coronavirus-infected dogs, by RT-PCR, virus was excreted in feces to $10^{4.0}$ to $10^{5.0}$ RNA copies/ μ L, peaking at 2.11×10^5 copies/ μ L (Amici et al. 2006).

SARS-CoV from trachea and lungs of infected domestic cats, titers 1×10^3 CCID₅₀/mL (Weiss and Navas-Martin 2005).

In VERO cells and chicken embryo kidney epithelial cells, virus titers $10^{5.8}$ – $10^{6.0}$ PFU/ μ L (Weingartl, Copps, et al. 2004).

* Virus isolated retrospectively from stored clinical specimens that were RT-PCR positive for viral RNA; virus more readily isolated from the respiratory tract than from stool specimens, was most successful during the first 2 weeks of the illness, and was generally negative after day 22 of illness, even though virus [=signal=RNA] was detectable in the specimens by RT-PCR (Chan et al. 2004).

Macaques infected with 1×10^6 CCID₅₀ of SARS-CoV suspended in 5 mL phosphate-buffered saline, 4 mL was applied intratracheally, 0.5 mL intranasally, and 0.25 mL on each conjunctiva; shed SARS-CoV from sputum, nose, and pharynx from 2 days after infection through ≥ 6 days; virus isolated from the lung (1×10^5 CCID₅₀/g tissue) and kidney (1×10^3 CCID₅₀/g tissue) of 1 macaque, and from the lung of a second (1×10^4 CCID₅₀/g tissue), other samples RT-PCR positive (Kuiken et al. 2003).

In ferret (*Mustela furo*) females, infected intratracheally with 10^3 to 10^4 CCID₅₀ of SARS-CoV, produced $10^{2.6-4.0}$ CCID₅₀ and were RT-PCR positive (ter Meulen et al. 2004).

In African green monkeys, mean peak virus titers were $10^{3.1}$ and 10^3 CCID₅₀/mL in the upper and lower respiratory tract; no virus, but viral genome detected by RT-PCR in fecal samples (McAuliffe et al. 2004).

In African green monkeys, virus titered $10^{1.5-3.0}$ CCID₅₀/mL on nasal/throat swabs; $10^{3.7-5.5}$ CCID₅₀/g of turbinate tissue; $10^{0.5-3.2}$ CCID₅₀/mL in tracheal lavage fluid; $10^{2.5-4.2}$ CCID₅₀/g in tracheal tissue; $10^{1.5-7.2}$ CCID₅₀/g of lung tissue (McAuliffe et al. 2004).

In Rhesus monkeys, titers $10^{1.0-1.5}$ CCID₅₀/mL and in cynomolgus monkeys, $10^{1.0-2.2}$ CCID₅₀/mL [with both species, lower and upper respiratory tracts, respectively] (McAuliffe et al. 2004).

In several strains of laboratory mice, infection produces $10^{7.0}$ CCID₅₀/g lung tissue after intranasal infection (Glass et al. 2004).

In cynomolgus monkeys, infection produced up to 170 copies of RNA/ng of respiratory tissues; In Rhesus, up to 7120 copies RNA/ng in respiratory tissues (Rowe et al. 2004).

1 In ferrets, from early in the infection and up to 5 days post-infection, titers ranged from 4×10^3
2 to 1.4×10^4 PFU per pharyngeal swab; sensitivity of real-time RT-PCR titrated to be 0.1 PFU per
3 mL, while the classical RT-PCR showed sensitivity as low as 10^{-4} PFU per mL (Weingartl, Czub,
4 et al. 2004).

5
6 In *C. jacchus*, virus isolation and titration attempted, but no viral growth was detected in samples
7 that included oral swabs, rectal swabs, and tissue homogenates from the first group of six
8 monkeys; despite sample-processing limitations, viral RNA was detected with RT-PCR in tissue
9 homogenates from two of six animals (Greenough et al. 2005).

10
11 In a second group of *C. jacchus*, used RT-PCR only, because of the absence of titratable virus in
12 the first group; threshold values ranged from 2,500 to 17,000 copies/g of respiratory tissues to >
13 70×10^6 copies/g of tissue; average values from $10^{4.3-5.0}$ copies/g tissue to peak concentrations of
14 $10^{5.6-7.9}$ /g tissue (Greenough et al. 2005).

15
16 In BALB/c mice, intranasal inoculation, virus titers ranged from $10^{6.0}$ CCID₅₀/g turbinate tissue
17 to $10^{7.0}$ CCID₅₀/g lung tissue at 1–5 days post-infection (Subbarao et al. 2004). In BALB/c mice,
18 intranasal inoculation, $10^{2.8-3.0}$ CCID₅₀/g turbinate, $10^{6.0-6.3}$ CCID₅₀/g lung (Stadler et al. 2005).

19 In infected humans, using quantitative PCR, at median 3.9 days after onset of symptoms, 10^0 to
20 $10^{8.8}$ RNA copies/mL of nasopharyngeal specimens (Chu et al. 2004). With RT-PCR, presence
21 of the RNA of SARS-CoV in nasopharyngeal aspirate (NPA) in 31 percent of infected humans
22 on day 2, 43 percent on days 3–5, and 60 percent of patients from 6 to 8 days to 2 weeks after
23 onset of the illness; in stool samples in almost 100 percent of patients at the end of 2 weeks;
24 32/316 (10 percent) exposed asymptomatic subjects had positive RT-PCR in their NPA (Chan-
25 Yeung and Xu 2003). Virus detectable in the blood, feces, urine and respiratory secretions of
26 SARS patients (Chen et al. 2004).

27
28 RT-PCR and ELISA tests performed in infected humans to evaluate viral RNA load (as an
29 indicator of viremia) and immune responses: both IgG and IgM antibodies present 1 week after
30 diagnosis in > 50 percent of patients, positivity rate for IgM increased for a month and remained
31 constant at approx 70 percent, positivity rate for IgG reached and remained at 100 percent; RT-

1 PCR was more sensitive in detecting blood-borne viral RNA in the early phase of the disease
2 than the ELISA method, but positivity rate was lower than that of antibody assays; viral RNA
3 was detectable in the blood samples 1 week after diagnosis and peaked at around 2 weeks,
4 reaching 75 percent (Chen et al. 2004).

5
6 Median nasopharyngeal viral load of patients living near the index case in a Hong Kong
7 community ($10^{5.09}$ RNA copies/mL) was much higher than in patients (10^0 copies/mL) not living
8 near the index case (Chen et al. 2004).

9
10 Amoy Gardens, at 5, 10, 15 days after first symptoms in patients, RT-PCR titers of NPAs were
11 10^3 to 10^7 RNA copies/mL, $10^{5.5}$ to $10^{8.5}$ RNA copies/mL, 10^3 to $10^{6.5}$ RNA copies/mL,
12 respectively, with mean geometric virus loads of 2.3×10^5 RNA copies/mL, 1.9×10^7 RNA
13 copies/mL, 9.8×10^4 RNA copies/mL, respectively (Peiris, Chu, Cheng, Chan, Hung, Poon, Law,
14 Tang, Hon, Chan, Chan, Ng, Zheng, Ng, Lai, Guan, and Yuen 2003).

15
16 From chicken, turkey, geese, ducks, quail in Vero cells, detected virus to titers of 10^7
17 CCID₅₀/mL; with real-time RT-PCR test detected SARS-CoV to 10^{5-6} copies RNA; with RT-
18 PCR, detected virus in OP swab specimens from two chickens on day 1 PI; no infectious virus
19 was isolated from any of the birds at any time from OP or cloacal swab specimens, plasma, or
20 tissues (Swayne et al. 2004).

21
22 Viral loads in humans: serum, $10^{2.7}$ RNA copies/mL; urine, $10^{4.4}$ RNA copies/mL; feces, $10^{7.0}$
23 RNA copies/mL (Hung et al. 2004).

24
25 In Vero cells, titers of $10^{5.8}$ to $10^{6.0}$ CCID₅₀/mL (Darnell et al. 2004).

26
27 Infectious dose used in *M. mulatta* monkeys was 10^3 , 10^5 , and 10^7 CCID₅₀ ; optimal dose was
28 10^5 CCID₅₀ which produced serologic conversion in 5 of 8 animals (HID63).(Qin et al. 2005).

29
30 Infectious dose studies in NHPs have used between $10^{3.0}$ and $10^{7.0}$ CCID₅₀/mL to infect (Cheng
31 et al. 2007).

Pathogen stability

At Amoy Gardens, virus is believed to have spread between apartment block buildings via aerosols from sewage system carried by ambient wind (Yip et al. 2007).

Virus was inactivated by UV light at 254 nm (UVC wavelength). UV-A had no significant effect. Details as follows: virus suspension 1 cm deep in 24-well plates, UV source at height of 3 cm from the bottom of the wells. UVC (254 nm) at 4016 $\mu\text{W}/\text{cm}^2$ (where $\mu\text{W} = 10^{-6} \text{ J/s}$) and UV-A (365 nm) at 2133 $\mu\text{W}/\text{cm}^2$. UV-A had no significant effect. UVC resulted in a 1 log reduction at 1 minute, a 2 log reduction at 2 minutes, a 3 log reduction at 3 minutes, a 3.5 log reduction at 4 minutes, a 4 log reduction at 6 minutes, complete inactivation at 15 minutes (Darnell et al. 2004) Note that UVC radiation is absorbed by the ozone layer; a negligible amount reaches earth's surface (World Health Organization 2002).

Titer decreased from $10^{7.5}$ CCID₅₀ to $10^{3.2}$ CCID₅₀ within 5 days @ room temperature (details not available) (from Bao, et al, 2003 [Chinese]) (Wang et al. 2005).

Viral shedding studies that are available to date suggest that transmission could occur via close contact involving respiratory tract excretions, and via fecal or urine contamination of surfaces (Anderson et al. 2004; Lim, Ng, and Tsang 2006).

Virus can survive in respiratory samples for 5 days at room temperature and 3 weeks at 4 °C (Lim, Ng, and Tsang 2006).

In diarrheal feces, can survive for a few days at room temperature; fecal droplets with a high titer of virus, 10^6 CCID₅₀/mL, can remain infectious for 4–5 days (Lim, Ng, and Tsang 2006).

Airborne infections from virus aerosols (Lim, Ng, and Tsang 2006).

Virus will survive on paper and absorbent paper gowns for about 5 minutes and on non-absorbent paper gowns and on non-absorbent gloves for more than 5 minutes (Lim, Ng, and Tsang 2006).

1 Virus persists in the environment—1+ day on surfaces and 4 days in feces (McKinney, Gong,
2 and Lewis 2006).

3
4 On dry surfaces at room temperature, virus survives for 2–3 days; in fecal samples, survival for
5 2–4 days; resistance to heat and chemical disinfectants similar to other enveloped viruses [heat,
6 organic solvent, and detergent sensitive](Wong and Yuen 2005).

7
8 Coronaviruses are resistant to trypsin [addition appears to facilitate isolation in cell cultures];
9 rather acid labile; sensitive to lipid solvents, detergents, UV radiation, disinfectants, and heat
10 (Murphy et al. 1994; Anonymous 2007).

11
12 Virus was inactivated by UV light at 254 nm, heat treatment of $\geq 65^{\circ}\text{C}$, alkaline ($\text{pH} > 12$) or
13 acidic ($\text{pH} < 3$) conditions, formalin and glutaraldehyde treatments (Darnell et al. 2004).

14 SARS-CoV detected in the blood of infected individuals might have potential to contaminate
15 donated blood and plasma-derived products; viral inactivation by heat treatment at 60°C
16 required 15'–30', UV light-C inactivated virus in 40', UV-A required addition of psoralen to
17 enhance inactivation of the virus; presence of bovine serum albumin limited the ability of UV-C
18 and UV-A to inactivate virus; octanoic acid treatment does not reduce the infectivity of virus in
19 protein solutions; solvent/detergent treatment required 2, 4, and up to 24 hours for Triton X-100,
20 between 80, and sodium cholate inactivation, respectively (Darnell and Taylor 2006).

21
22 In vitro, virus persists for 2 days in hospital wastewater, domestic sewage and dechlorinated tap
23 water; 3 days in feces, 14 days in PBS, 17 days in urine at 20°C ; at 4°C , virus persists for 14
24 days in wastewater and more than 17 days in feces or urine: free chlorine inactivates virus better
25 than chlorine dioxide; free residue chlorine over 0.5 mg/L for chlorine or 2.19 mg/L for chlorine
26 dioxide in wastewater ensures complete inactivation (Wang et al. 2005).

27
28 At Amoy Gardens, optimum environmental temperature range associated with SARS cases was
29 $16\text{--}28^{\circ}\text{C}$ (Yip et al. 2007).

30
31 Indication that viruses with structural lipids survive best in aerosols at low RH (Benbough 1971).

1 MHV coronavirus [surrogate for SARS-CoV] highly susceptible to inactivation by aerosolization
2 and sampling; an enveloped virus is more likely to be inactivated by mechanical stress; MHV
3 coronavirus easily inactivated in PBS with 0.01 percent betadine but relatively stable when
4 suspended in MEM with 10 percent FBS, a protein concentration similar to that of saliva;
5 inactivated by a relatively low dose of 254 nm UV- high UV susceptibility of coronavirus
6 aerosols suggests that UV air disinfection might be an effective tool for preventing important
7 respiratory viral diseases such as SARS (Walker and Ko 2007).

8
9 Infectivity maintained at least 10 days at 4 °C; titer decreased from $10^{7.5}$ CCID₅₀ to $10^{3.2}$ CCID₅₀
10 within 5 days at room temperature; virus inactivated by heat at 56 °C for 30' or at 70 °C for 5'
11 (from Bao, et al, 2003 [Chinese]) (Wang et al. 2005).

12
13 The virus survived at RT for 9 days in cell culture suspension and 6 days in dried state on plastic
14 (Rabenau et al. 2005). Common laboratory and hospital disinfectants will inactivate the virus,
15 e.g., detergents, hypochlorite solution, and peroxygen compounds (Lim, Ng, and Tsang 2006).

16
17 In a Pennsylvania patient, serial stool specimens collected on days 14, 18, 21, and 26 after the
18 onset of illness were positive by RT-PCR [cannot necessarily correlate with isolation of virus]
19 (Peck et al. 2004).

20
21 In United States, using RT-PCR, virus detected in a day-14 sputum specimen from one case-
22 patient and in five stool specimens from two case-patients; in one case-patient, SARS-CoV
23 persisted in stool for at least 26 days after symptom onset (Isakbaeva et al. 2004).

24
25 Virus loses its infectivity after exposure to several commonly used disinfectants such as Clorox
26 (sodium hypochlorite), 75 percent ethanol, and fixatives such as formaldehyde and
27 paraformaldehyde (Chan-Yeung and Xu 2003).

28
29 At 6–8 weeks of illness all specimens from throat, conjunctiva, and urine were negative for
30 SARS-CoV by RT-PCR; stool specimens from five patients were positive by three RT-PCR
31 assays (Leong et al. 2004).

1 The D_{37} value for BEV (Berne) was calculated to be 3.1 [HL=7 min at maximum solar radiation]
2 (Lytle and Sagripanti 2005). BEV was used a surrogate for SARS-CoV; both are classified in the
3 family *Coronaviridae*.

4
5 Human coronavirus 229E (not SARS-associated) at 20°C survived best at 50 percent RH, having
6 a half-life of 67.33 ± 8.24 hrs (Ijaz et al. 1985).

8 **Vectors**

9 No arthropod vectors.

11 **Other epidemiological/ecological data**

12 Control through the use of quarantine (Cinatl et al. 2005; Low and Wilder-Smith 2005).

13
14 Made public spotlight in 2/2003, businessman traveling from China became afflicted with
15 pneumonia-like symptoms while on a flight to Singapore, which stopped in Vietnam, where the
16 victim died; several medical staff members who treated him soon developed the same disease
17 despite basic hospital procedures; an Italian doctor identified the threat and communicated it to
18 WHO and the Vietnamese government and later succumbed to the disease (Anderson et al. 2004;
19 Feng and Gao 2007).

20
21 Hong Kong, a mainland doctor who arrived in 2/2003 stayed on the 9th floor of a hotel and
22 infected 16 other hotel visitors who spread SARS-CoV to others in Canada, Singapore, Taiwan,
23 and Vietnam (Chan, Tang, and Hui 2006) (Low and Wilder-Smith 2005).

24
25 On a flight from Hong Kong to Beijing, 2003, symptomatic passenger infected no less than nine
26 tourists from Hong Kong, three Taiwanese businessmen, one Singaporean, and four Chinese
27 (Low and Wilder-Smith 2005).

28
29 Another larger cluster of cases in Hong Kong centered on Amoy Gardens and spread is
30 suspected to have been facilitated by defects in the sewage system (Chan, Tang, and Hui 2006).

1 Relatively rare disease with 8,096 cases as of 2003 with at least 774 deaths (Cinatl et al. 2005).

2
3 Netherlands, 2003, scientists demonstrated that SARS-CoV fulfilled Koch's postulates thereby
4 confirming it as the causative agent; macaques, *M. fascicularis*, infected with the virus developed
5 the same signs as human SARS victims (Kuiken et al. 2003).

6
7 Improper handling of SARS-CoV in laboratories caused the infection of two researchers in
8 Singapore and one in Taiwan (Barkham 2004).

9
10 20 percent of patients can progress to acute respiratory distress syndrome, requiring mechanical
11 ventilatory support (Cinatl et al. 2005).

12
13 Rapid spread of the infection to involve clusters of health care workers attending patients was
14 noted (Lam, Zhong, and Tan 2003).

15
16 Temporal-spatial spread of SARS-CoV among patients in a hospital medical ward consistent
17 with airborne transmission; easily spread between healthcare workers and patients via direct or
18 short-range transmission and existence of *superspreaders* who generate a far greater than
19 average number of secondary cases (Chan, Tang, and Hui 2006; Verreault, Moineau, and
20 Duchaine 2008).

21
22 Modeling of transmission dynamics for this virus has been addressed (Lipsitch et al. 2003; Riley
23 et al. 2003; Hsieh, Chen, and Hsu 2004; Meltzer 2004).

24
25 In contrast to Canada, China, and Taiwan, the United States and other countries did not
26 experience any superspreaders or superspreading events, and the reason is unknown (McDonald
27 et al. 2004).

28
29 Coronaviruses cause acute and chronic respiratory, enteric, and central nervous system diseases
30 in humans and animals (Weiss and Navas-Martin 2005).

1 Since the large global outbreak of 2003, a limited number of cases of SARS have occurred that
2 included four community-acquired infections associated with mild disease the following winter,
3 and at least four laboratory-acquired infections, one of which resulted in secondary spread and
4 severe illness and mortality in contacts (Subbarao and Roberts 2006).

5
6 In Toronto, transmission from the index case resulted in at least six generations of transmission,
7 four of which were a result of nosocomial spread (Varia et al. 2003).

8
9 Superspreading events pivotal in the global spread of SARS-CoV; investigated superspreading in
10 one transmission chain early in Beijing's epidemic; *superspreading* is defined as transmission of
11 SARS-CoV to at least eight contacts; an index patient with onset of SARS 2 months after
12 hospital admission was the source of four generations of transmission to 76 case-patients,
13 including 12 healthcare workers and several hospital visitors; 4 (5 percent) case circumstances
14 met the superspreading definition; appeared to be associated with older age (mean 56 versus 44
15 years), case fatality (75 percent vs. 16 percent, $p = 0.02$, Fisher exact test), number of close
16 contacts (36 versus 0.37) and attack rate among close contacts (43 percent versus 18.5 percent, p
17 < 0.025) (Shen et al. 2004).

18
19 Largest community SARS outbreak at Amoy Gardens, Hong Kong, 2003 affected 329 residents,
20 1.7 percent of population, 42 deaths; airborne pathway hypothesized with possible meteorologic
21 factors contributing: virus-laden aerosols transported between apartment blocks via ambient
22 wind, low mixing might have prevented efficient dispersal of aerosols, and drop in temperature
23 might have fostered survival of virus or increased susceptibility of the exposed population (Yip
24 et al. 2007).

25
26 Nucleocapsid protein (NP) is the most predominant virus-derived structural protein shed in high
27 amounts in serum and NPA during the first week of infection; using immunoswab method with a
28 panel of monoclonal antibodies (MAbs) against the NP, detected an NP concentration of 20
29 pg/mL in saline, 20–200 pg/mL in pig NPA, and 500 pg/mL in rabbit serum (Kammila et al.
30 2008).

1 **Therapeutics/vaccines**

2 About 10–20 percent of cases require mechanical ventilation (Cinatl et al. 2005; Low and
3 Wilder-Smith 2005).

4
5 Treatment largely supportive with antipyretics, supplemental oxygen, and ventilatory support as
6 needed (Lam, Zhong, and Tan 2003).

7
8 Suspected cases must be isolated preferably in negative pressure rooms with full barrier nursing
9 precautions taken for contact with these patients (Cinatl et al. 2005; Low and Wilder-Smith
10 2005).

11
12 Initial anecdotal support for steroids and ribavirin but no published evidence; many clinicians
13 suspect that ribavirin is detrimental (Lam, Zhong, and Tan 2003).

14
15 Indomethacin, a cyclopentanone cyclooxygenase metabolite shown to be a potent antiviral
16 against canine and human SARS-CoV, *in vitro* and *in vivo* (Amici et al. 2006).

17 Ribavirin (1- β -d-ribofuranosyl-1,2,4-triazole-3-carboxamide) is a purine nucleoside analogue
18 and has limited clinical efficacy (Cinatl et al. 2005).

19
20 Intranasal recombinant interferon might be an effective prophylactic treatment; limits duration
21 and severity of clinical disease in humans; effective in cynomolgus macaques (Cinatl et al.
22 2005).

23
24 HIV-1 protease inhibitors [lopinavir and ritonavir] show lower mortality rates (2.3 percent) in
25 treated humans (Cinatl et al. 2005).

26
27 Human convalescent plasma apparently had a beneficial effect if used relatively early in the
28 course of illness (Cinatl et al. 2005).

29
30 No antiviral is proven to be of beneficial value (Cinatl et al. 2005).

12/2004, report that Chinese researchers had produced vaccine; tested on a group of 36 volunteers, 24 developed antibodies against the virus (Anderson et al. 2004).

Inactivated vaccine elicits potent spike protein-specific neutralizing antibodies that block receptor binding and virus entry (Feng and Gao 2007).

DNA vaccine encoding virus S GP can induce T cell and neutralizing antibody responses and protective immunity in a mouse model (Feng and Gao 2007).

Vaccines targeting several animal CoVs have been developed and are efficacious, but a phenomenon of enhanced disease following vaccination has been observed in cats when infected with feline infectious peritonitis virus (a related coronavirus) [could be indicative of a potential problem with vaccines] (Gillim-Ross and Subbarao 2006).

Extensive ongoing research on vaccines in animals, but no imminent candidates for human use; inactivated, attenuated, subunit/expressed protein, vectored, and DNA vaccines (Gillim-Ross and Subbarao 2006).

Administration of a human monoclonal antibody might offer prophylaxis (ter Meulen et al. 2004).

Other remarks

Viral cell culture is insensitive (Wong and Yuen 2005).

Within a matter of weeks in early 2003, SARS-CoV spread rapidly from the Guangdong province of China (11/2002) to infect individuals in some 37 countries around the world (Feng and Gao 2007; Lam, Zhong, and Tan 2003).

SARS-CoV causes severe disease, is transmissible in the community, and there is no effective prophylaxis or treatment, perhaps fulfilling the criteria for biohazard group 3 or 4 (Barkham 2004).

1 Recommended to use BSL-3 procedures in a BSL-2 diagnostic laboratory environment with
2 strict controls in administration, engineering (especially airflow and air filters), and PPE
3 (especially BSCs and disposable gloves, gowns, and surgical masks/respirators/full face
4 shields/powered air-purifying respirators [PAPRs]) (Barkham 2004; Gillim-Ross and Subbarao
5 2006; Lim, Ng, and Tsang 2006).

6
7 Research with replication or growth of virus and with animals should be done in a BSL-3
8 laboratory (Lim, Ng, and Tsang 2006).

9
10 Virus escapes reported in from BSL-3 and BSL-4 laboratories in China, Singapore, and Taiwan
11 were due to lapses in good microbiologic practices, not equipment or laboratory failures (Lim,
12 Ng, and Tsang 2006).

13
14 Mainland China and Hong Kong, SARS, accounted for 87 percent of all cases and 84 percent of
15 all deaths (Lam, Zhong, and Tan 2003).

16
17 Excellent recommendations for handling, storing, and transporting samples/virus,
18 facilities/equipment, training, health and medical surveillance, test exercises, and emergency
19 responses (Lim, Ng, and Tsang 2006).

20
21 Coronaviruses (general)—tropism for respiratory and intestinal tracts, liver, and brain; frequently
22 seen by electron microscopy in human feces (White 1994).

23
24 Non-SARS human coronaviruses—frequent causes of *common cold* (White 1994).

25
26 Coronaviruses have the largest genomes of RNA viruses (White 1994).

27
28 In general, coronaviruses replicate poorly in cell cultures, necessitating use of molecular
29 techniques (White 1994).

WHO recommends that manipulation of active viral cultures of SARS-CoV be performed in containment laboratories at BSL3 (Darnell et al. 2004).

Antigenic relationships/synonyms

Order: *Nidovirales*, Family: *Coronaviridae*, Genus: *Coronavirus* (Weiss and Navas-Martin 2005) (Murphy et al. 1994; Weiss and Navas-Martin 2005).

Also called atypical pneumonia in China (Feng and Gao 2007).

Related animal coronaviruses: porcine transmissible gastroenteritis virus, bovine coronavirus [enteritis, winter dysentery], avian infectious bronchitis viruses, mouse hepatitis virus [lethal intestinal virus disease of infant mice], feline infectious peritonitis virus, feline enteric coronavirus, turkey coronavirus [blue comb], hemagglutinating encephalomyelitis virus of pigs, porcine epidemic diarrhea virus, pheasant coronavirus, canine coronavirus [diarrhea], rabbit coronavirus, sialodacryadenitis coronavirus of rats (Murphy et al. 1994; Weiss and Navas-Martin 2005)

C.1.1.6 Rift Valley fever virus (RVFV)

Host range

a. Field

1912–1913 epizootics of abortion occurred with high mortality in domestic animals during which humans were infected (Meegan and Bailey 1989).

1930–1931, viral transmission to lambs/sheep, lab animals, and humans occurred (Meegan and Bailey 1989).

Severe losses in sheep, cattle, goats, water buffalo, and camel herds have been recorded (Meegan and Bailey 1989).

Severe, usually fatal disease occurs in lamb, kid, mouse, and vole (Meegan and Bailey 1989).

RVF is often a fatal clinical disease in sheep and cattle (Meegan and Bailey 1989).

RVF can be a nonfatal clinical disease in human, goat, buffalo, grey squirrel, and rodent [multiple spp] (Meegan and Bailey 1989).

Subclinical infection can occur in horse, pig, camel, rodent [multiple spp], mongoose, hedgehog, tortoise, frog, most avians, hippopotamus, and monkey [certain spp] (Meegan and Bailey 1989).

Abortions in camel and buffalo were reported (Meegan and Bailey 1989).

From 1950 to 1976, at least 16 major epizootics in sub-Saharan Africa (Murphy et al.). 1951, Johannesburg, 100,000 sheep died and 500,000 ewes aborted (Swanepoel and Coetzer 1994).

1974 to 1976, southwest Africa, losses in Angora goats resulted in a reduction of 230,000 Karakul pelts annually during the 2-year period (Swanepoel and Coetzer 1994).

1978, Zimbabwe, nearly 100 percent of pregnant cows aborted and 3 percent died; serologic evidence showed 30 percent infection rates; estimates of 60,000 abortions and 10,000 deaths (Swanepoel and Coetzer 1994).

Outbreaks characterized by economically disastrous *abortion storms* (newborn fatality rates in excess of 10 percent) and a newborn animal mortality approaching 100 percent is reported among livestock (Bird et al. 2008).

1977 to 1978, Egypt, wild rodents do not serve as RVFV reservoirs; domestic sheep, cattle, buffaloes, camels, goats, donkeys, and dogs act as amplifying hosts; more than 30 percent of camels sampled at the southern border of Egypt were serologically positive for antibodies to RVFV (Hoogstraal et al. 1979).

1 Guinea, bats (*Micropteropus* spp and *Hipposideros* spp), one isolate each (Weinbren
2 2008).

3
4 Disease is most severe in sheep, goats, and cattle, in which it produces abortions in
5 pregnant animals and a high mortality rate in the newborn; older, nonpregnant animals,
6 while susceptible to infection, are more resistant to clinical disease; considerable
7 variation in susceptibility of animals of different genotypes, breeds or strains exotic to
8 Africa or are from areas where RVF is not endemic, tend to be more susceptible; camels
9 suffer an inapparent infection with RVF, but abortion rates can be as high as in cattle
10 (Anonymous 2004; Bird et al. 2009).

11
12 Indigenous African animals might have only inapparent infections (Anonymous 2004;
13 Bird et al. 2009).

14
15 Hippopotamus, donkeys, weaverbirds might be susceptible (Shimshony and Barzilai
16 1983).

17
18 Susceptibility of vertebrates has been reported (Brown and Torres 2008)as follows:
19 extremely susceptible are hamsters, kids, kittens, lambs, mice, puppies; highly
20 susceptible are calves, sheep; moderately susceptible are South American/Asian
21 monkeys, buffalo, cattle, goats, humans; less susceptible are camel, cats, dogs, equines,
22 guinea pigs, pigs, rabbits; refractory are amphibians, birds, reptiles.

23
24 The host range is broad(Shimshony and Barzilai 1983; Brown and Torres 2008).

Table C-8. Host range of Rift Valley fever virus reported by Shimshony and Barzilai

100% Fatal	High mortality	Severe, mostly nonfatal	Subclinical	Refractory to experimental infection
Lamb (1) ^a	Sheep (1)	Human (1)	Monkey (African) (1)	Mongoose (1)
Kid (1)	Calf (1)	Monkey (Indian and South American) (1)	Wild rodents (6)	Hedgehog (1)
White mouse (1)	Rat ^b (1)	Cattle (1)	Rabbit (1)	Spider monkey (1)
Hamster (1)	Gerbil (3)	Goat (1)	Pig (1)	Tortoise (1)
Field mouse (1)	Laucha (3)	Sheep ^b (4)	Dog (2)	Frog (1)
Dormouse (1)	Puppy (2)	Buffalo (African) (1)	Cat (2)	Hedgehog (1)
Field vole (1)	Kitten (2)	Buffalo (Asian) (5)	Horse (7)	Geckos (8)
Rat ^b (3)		Gray squirrel (1)	Rat ^b (3)	Hen (1)(9)
		Wild rodents (6)	Guinea pig (3)	Canary (1)
		Camel (5)		Pigeon (1)
				Parakeet (1)

Source: (Shimshony and Barzilai 1983)

b. Experimental

A severe, usually fatal, disease in mice, hamsters, and rats [certain spp] (Meegan and Bailey 1989).

Often fatal in puppies, kittens, and gerbils (Meegan and Bailey 1989).

Nonfatal clinical disease in monkeys [multiple spp] and rats [certain spp] (Meegan and Bailey 1989).

Subclinical infection in rabbits, guinea pigs, cats, dogs, chickens, rats [certain spp], monkeys [multiple spp] has been reported (Meegan and Bailey 1989).

Pigs resistant, but develop transient viremia with high infecting doses (Swanepoel and Coetzer 1994).

1 4/5 African buffalo were viremic, one-half of the pregnant cows aborted (Swanepoel and
2 Coetzer 1994).

3
4 Rhesus monkeys and *Cercopithecus* monkeys, mild or asymptomatic infection, develop
5 antibodies (Weinbren 2008).

6
7 Death reported in newborn Merino lambs (Weinbren 2008).

8
9 Among pregnant ewes, abortions and occasional deaths reported (Weinbren 2008).

10
11 Field voles, dormice, wood mice are susceptible (Weinbren 2008).

12
13 Death in kittens and puppies reported (Weinbren 2008).

14
15 One-day-old puppies died from a dose of $10^{0.2}$ MICLD₅₀ (Shimshony and Barzilai 1983).
16 In kittens, 81 percent died from doses of $10^{2.2}$ to $10^{8.2}$ MICLD₅₀ (Shimshony and Barzilai
17 1983).

18
19 In a gerbil (*Meriones unguiculatus*) model for the encephalitic form of RVF, resistance to
20 necrotizing encephalitis was age-dependent, 100 percent mortality at 3 weeks, decreasing
21 to approx. 20 percent by 10 weeks, inoculated subcutaneously (SQ) (Anderson, Slone,
22 and Peters 1988).

23
24 In rhesus monkeys, *M. mulatta*, three experiments: SQ inoc with $10^{5.3}$ PFU/mL, no
25 viremia in one, $10^{3.6}$ PFU/mL in second monkey lasting 1 day, $10^{6.8}$ viremia on day 2 and
26 $10^{4.9}$ PFU/mL viremia on day 3 in the third monkey; IV inoculation of $10^{4.7}$ PFU/mL,
27 three developed transient viremia without clinical signs, but the fourth developed
28 hemorrhagic diathesis and was euthanatized; IV inoculation of $10^{4.1}$ PFU/mL had
29 transient viremia and one was ill with hemorrhagic signs, but recovered; inoculation
30 (route not specified; IV is implied) of $10^{4.8}$ PFU/mL, one became ill and was killed in a
31 moribund state; viremias to $10^{5.5-6.5}$ PFU/mL (Peters et al. 1988).

Prevalence/incidence/attack rate

1977, Egypt, 20,000 human clinical cases were reported (Meegan and Bailey 1989).

Kenya, systematic multistage cluster sampling across Garissa District in 1997–1998 indicated a 14 percent prevalence of acute (IgM-positive) cases, with an estimated 20–26 percent of the population having either recent or past infection with RVFV; some populations had RVF IgG seropositivity as high as 32 percent; estimated 27,500 infections occurred in Garissa District, making it the largest recorded outbreak of RVFV in East Africa (LaBeaud et al. 2007).

1977–1978 Egyptian epizootic, acute fever was reported in humans with encephalitic, ocular, or fatal hemorrhagic disease; estimates of human cases ranged from 18,000 to 200,000 (Swanepoel and Coetzer 1994); purportedly millions were infected, more than were 200,000 infected (White 1994).

1987, Senegal and Mauritania, 400 human isolates were reported (Meegan and Bailey 1989; Swanepoel and Coetzer 1994; Flick and Bouloy 2005).

Nigeria, humans, 146/2,223 with CF antibody (Weinbren 2008).

Uganda, humans, seven isolates were reported (Weinbren 2008).

Egypt, 1978, humans, 10 isolates were reported (Weinbren 2008).

Egypt, 1979, humans, 53 isolates were reported (Weinbren 2008).

1997–1998, from Somalia, through Kenya to Tanzania, 90,000 human cases were reported (Murphy et al.).

2000, outbreaks occurred in Saudi Arabia and Yemen (Sidwell and Smee 2003; Flick and Bouloy 2005).

Largest reported human outbreak occurred in Kenya during 1997–1998, in which an estimated 89,000 persons (according to a systematic serosurvey) were infected (CDC 2007).

2000, Arabian Peninsula, simultaneous outbreaks; total number of human cases unknown, but if the hospitalized patients represent a small fraction (usually less than 1 percent) of the total infections, the 884 and 1087 patients hospitalized, respectively, in Yemen and Saudi Arabia, provide a strong indication of the magnitude of this epidemic (Flick and Bouloy 2005).

1977–1978, widespread outbreaks in Nile Valley and Delta region of Egypt occurred with extensive human involvement; morbidity was 200,000 (Meegan, Niklasson, and Bengtsson 1979).

R_0 /incubation period/infectious period/infectious dose

R_0 is predicted by one modeling effort to have a mean of 1.193 (95 percent CI 1.177–1.209), (median 1.113, max. 3.743, min. 0.037) (Gaff, Hartley, and Leahy 2007). Note this is an estimate for R_0 for spread through a mosquito population via mosquito-mosquito and mosquito-livestock-mosquito transmission. It is not a prediction for R_0 for human transmission.

Incubation period in livestock is 1–3 days; in humans, 2–6 days (Bird et al. 2009).

Infectious period in ruminants, including camels, is considered to be 30 days (Anonymous 2007).

Infectious dose in humans is unknown (no reports found).

Aerosol infection in lambs, rhesus monkeys, cynomolgus monkeys, hamsters, puppies, kittens, mice used doses varying from $10^{<1.0 \text{ to } 9.0}$ MIPLD₅₀ or $10^{1.9-2.6}$ PFU (Shimshony and Barzilai 1983).

1 **Morbidity/case fatality ratio**

2 **a. Human**

3 Human infection results in self-limiting febrile disease that in 1 to 2 percent of patients
4 progresses to more serious complications including hepatitis, encephalitis, and retinitis or
5 a hemorrhagic syndrome with high fatality (Bird et al. 2008).

6
7 Disease can be severe, occasionally fatal (Meegan and Bailey 1989).

8
9 Disease can be hemorrhagic (Meegan and Bailey 1989).

10
11 Kenya, 1998, 400 deaths reported (Sidwell and Smee 2003; Flick and Bouloy 2005).

12
13 1977, Egypt, 20,000 human clinical cases with 598 deaths (mortality rate of 3 percent);
14 morbidity of 20,000 to 200,000; military estimated 0.2 percent mortality rate; 14percent
15 hospitalized patients died (Meegan and Bailey 1989).

16
17 1977–1978 Egyptian epizootic, acute fever in humans with encephalitic, ocular, or fatal
18 hemorrhagic disease; estimates of human cases ranged from 18,000 to 200,000, with 598
19 deaths (Swanepoel and Coetzer 1994); purportedly millions infected with thousands of
20 deaths, more than 200,000 were infected, with more than 600 deaths (White 1994).

21
22 1977–1978, Egypt, widespread outbreaks occurred in the Nile Valley and Delta region,
23 with extensive human involvement, morbidity 200,000 with 600 deaths (Meegan,
24 Niklasson, and Bengtsson 1979).

25
26 1987, Senegal AND Mauritania, high human mortality rate with 400 human isolates and
27 224 deaths (Meegan and Bailey 1989; Swanepoel and Coetzer 1994; Flick and Bouloy
28 2005).

1 Largest reported human outbreak occurred in Kenya during 1997–1998, in which an
2 estimated 89,000 persons (from a systematic serosurvey) were infected and 478 died
3 (CDC 2007).

4 1987, Senegal and Mauritania, high human mortality rate with 400 human isolates and
5 224 deaths (Meegan and Bailey 1989; Swanepoel and Coetzer 1994; Flick and Bouloy
6 2005).

7
8 1997–1998, from Somalia, through Kenya to Tanzania, 90,000 human cases and more
9 than 500 deaths (Murphy et al.).

10
11 2006–2007, Kenya, about 75 people died and another 183 were infected (Bird et al. 2009;
12 Gerdes 2002, 2004).

13 2006–2007, Kenya, the human case fatality rate was 29 percent (CDC 2007).

14
15 2007, Somalia reported 14 human deaths (Bird et al. 2009; Gerdes 2002, 2004).

16
17 2007, Sudan reported 125 human cases including 60 deaths (Bird et al. 2009; Gerdes
18 2002, 2004).

19
20 1975 South African epizootic, four human deaths from hemorrhagic syndrome and three
21 deaths from encephalitis were reported (Swanepoel and Coetzer 1994; Meegan and
22 Bailey 1989).

23
24 A mortality ratio of 5–10 percent in humans has been reported (White 1994).

25
26 Human case fatality rate of 1–2 percent, unless hemorrhagic symptoms occur, where it
27 can reach 10 percent (Murphy et al.).

28
29 Approximately 1 percent of infected humans die; in livestock, the fatality level is
30 significantly higher; and in pregnant livestock, abortion of virtually 100 percent of
31 fetuses is reported (Anonymous 2004; Bird et al. 2009; Gerdes 2004, 2002).

1
2 Overall human mortality rate from RVF has been estimated at 0.5–1.0 percent of those
3 infected, but the rate is much higher among those with severe disease (CDC 2007).
4 Human morbidity, 1977, estimated at 20,000–200,000 and higher, with at least 598
5 fatalities (Shimshony and Barzilai 1983).
6

7 **b. Animal**

8 Depending on the species, up to 30 percent of infected adult animals die (Meegan and
9 Bailey 1989).
10

11 80–100 percent pregnant animals abort (Meegan and Bailey 1989).
12

13 90–100 percent of infected 7-day-old or younger lambs die (Meegan and Bailey 1989;
14 Gerdes 2005).
15

16 20–60 percent of older lambs and adult sheep die (Meegan and Bailey 1989; Gerdes
17 2005).
18

19 90–100 percent of pregnant ewes abort (Meegan and Bailey 1989).
20

21 10–70 percent of calves die (Meegan and Bailey 1989; Gerdes 2005).
22

23 10–20 percent of adult cattle die (Meegan and Bailey 1989; Gerdes 2005).
24

25 80–100 percent of pregnant cattle abort (Meegan and Bailey 1989).
26

27 Morbidity and mortality are associated with differences in strain virulence and
28 susceptibility of hosts (Swanepoel and Coetzer 1994).
29

30 Lambs suffer more severe disease than monkeys, yet monkeys can be infected by slightly
31 lower doses (Swanepoel and Coetzer 1994).

Exotic livestock breeds are less resistant than indigenous breeds (Swanepoel and Coetzer 1994).

Sub-Saharan Africa, lambs are extremely susceptible and can be fatally infected with 0.1 MIPLD₅₀ (Swanepoel and Coetzer 1994).

Mortality in kids, abortions in pregnant nannies, adult goats resistant (Swanepoel and Coetzer 1994).

Egypt, horses develop low level viremia; 4 abortions in donkeys; low antibody prevalence in both spp (Swanepoel and Coetzer 1994).

Kenya and Egypt, antibody in camels, abortions, low level viremia; in Egypt, 1 abortion, 56 deaths, but circumstantial evidence only (Swanepoel and Coetzer 1994).

Egypt: high antibody prevalence in Asian water buffalo, 12.1 percent abortion rates; mortality rates of 7.2 percent, but might be circumstantial evidence (Swanepoel and Coetzer 1994).

Mortality rate of 90 percent in lambs, 20-60 percent in adult sheep, and 10-30 percent in calves and adult cattle (Murphy et al.).

Mortality of newborn lambs and kids is reported as 70–100 percent, older lambs, kids and adult sheep, and goats is 10–70 percent; cattle 10 percent; calves 20 percent (Brown and Torres 2008).

Aerosol infection/routes of transmission

Humans infected from mosquito bites and contact with infected tissues and blood probably via abraded skin, mucous membranes, aerosol, and intranasally (Swanepoel 1994; White 1994).

1 Human disease is most frequently seen only during epizootics and can result from either feeding
2 by an infected mosquito vector or aerosol transmission, usually associated with slaughtering sick
3 animals (LeDuc 1989).

4 Humans infected from mosquito bites and contact with infected tissues and blood probably via
5 abraded skin, mucous membranes, aerosol, and intranasally (Swanepoel and Coetzer 1994).
6

7 Humans are susceptible to infection via contact with infected material or mosquito bites. Human
8 infections via vectors is a striking feature in countries with a relatively small population of
9 animal hosts. In such areas, RVF can be recognized first in humans. It causes serious disease in
10 laboratory workers and must be handled with high level biosecurity, laboratory workers should
11 be vaccinated (Anonymous 2004; Bird et al. 2009).
12

13 Human infections typically occur either from infected mosquito bites or as the result of
14 percutaneous/aerosol exposure while slaughtering infected animals or via contact with aborted
15 fetal materials (Bird et al. 2008).
16

17 Several field researchers with no physical contact with an infected sheep slaughtered via
18 traditional Islamic method in Egypt became viremic with RVFV 3 days after aerosol exposure;
19 sheep blood titered 10^{10} MICLD₅₀/mL (Hoogstraal et al. 1979).
20

21 Mechanical and biological transmission via arthropods, fomites, direct contact with animal
22 blood, and maternal and fetal tissues and fluids (White 1994).
23

24 Frequency of airborne transmission under natural conditions is unknown. But it is known that
25 laboratory workers acquired RVFV after inhaling infectious aerosols generated by careless
26 handling of infected tissues (Brown, Dominik, and Morrissey 1981).
27

28 RVFV causes serious human infection in laboratory workers in the absence of appropriate
29 biocontainment precautions; staff should either be vaccinated and work under BSL-3, work
30 under BSL- 4 conditions, or wear respiratory protection. Workers must take care when working
31 with infected animals or when performing necropsy examinations (Anonymous 2004).

RVFV has caused frequent laboratory infections [in the absence of appropriate biocontainment precautions] (Meadors, Gibbs, and Peters 1986).

A 1967 publication reported 29 laboratory infections and 1 death [in the absence of appropriate biocontainment precautions] (Hanson et al. 1967; Pike 1979).

A 1980 publication reported an additional 18 infections [in the absence of appropriate biocontainment precautions] and no deaths; the source of infection in these 47 cases was unknown (Subcommittee on Arbovirus Laboratory Safety of the American Committee on Arthropod-Borne Viruses).

Potential for infection via ingestion of raw milk (Flick and Bouloy 2005).

A nonfatal, dengue-like illness most frequently occurs in lab workers, field investigators, and animal handlers (Meegan and Bailey 1989).

1951, Johannesburg, humans assisting in a necropsy of a bull became ill (Swanepoel and Coetzer 1994).

Aerosol infection in lambs, rhesus monkeys, cynomolgus monkeys, hamsters, puppies, kittens, mice, doses varied from $10^{<1.0 \text{ to } 9.0}$ MIPLD₅₀ or $10^{1.9-2.6}$ PFU (Shimshony and Barzilai 1983).

ICR-strain mice infected by exposure to infectious aerosols ($10^{0.5 \text{ to } 4.5}$ PFU) composed of particles with a mass median diameter of 0.96 μm ; respiratory median lethal doses for different RVFV strains were $10^{2.2}$, $10^{1.9}$, $10^{2.6}$, and $10^{1.9}$ PFU; single group of mice infected with $10^{3.1}$ PFU assayed sequentially through 96 hours post infection—between 6 and 30 hours, demonstration of an increasing virus concentration only in the lungs indicated that initial replication occurred there, without evidence of pneumonia; virus isolated from the liver by 48 hours, with fulminating and fatal hepatic necrosis (Brown, Dominik, and Morrissey 1981).

Puppies infected via aerosol of 17–36 MICLD₅₀ had inapparent infection, viremias to 10^{3.2} MICLD₅₀; the infectious dose is estimated at 25 MICLD₅₀ (Keefer, Zebarth, and Allen 1972).

Kittens infected via aerosol of 5–7 MICLD₅₀ had inapparent infection, viremias 10^{2.2-3.8} MICLD₅₀ (Keefer, Zebarth, and Allen 1972).

Puppies and kittens exposed via ingestion at 10^{5.9-6.4} MICLD₅₀ were not infected [virus probably inactivated by stomach acid] (Keefer, Zebarth, and Allen 1972).

Virus titers/concentrations/pathogenesis

RVFV is one of most prolific viruses known, replicating to extremely high titers after a 30–72 hour incubation period (Murphy et al.).

In humans, maximum titers to 10^{8.6} MICLD₅₀ (Swanepoel and Coetzer 1994).

Virus titers in infected humans were 10^{4.2 to 8.6} (Shimshony and Barzilai 1983).

1977–1978, Egypt, virus titers in infected humans were 10^{4.1-8.6} SMICLD₅₀ (Meegan 1979).

In Vero cells, 10⁷-10⁹ CCID₅₀/mL produced in roller bottles/flasks, concentrated 10–100 times via ultracentrifuging to produce concentrations of 10⁸–10¹¹ CCID₅₀/mL, roller bottles/flasks (Johnson 2008).

In Vero cells, 10⁸ PPU/mL after a 48-hour incubation (Brown, Dominik, and Larson 1982).

Maximal titers in hamster kidney cell line attained 10^{8.2} MIPLD₅₀/mL (Shimshony and Barzilai 1983).

10^{9.0} MIPLD₅₀/mL in suspended L cell (mouse L-cells) cultures (Shimshony and Barzilai 1983).

In diploid rhesus monkey cell line, virus titers attained 4.0–10x10⁶ PFU/mL and 0.19–3.89x10⁶ MIP [mouse, intraperitoneal] LD₅₀/mL (Meadors, Gibbs, and Peters 1986).

1
2 Multiplicities of infecting virus from 1 to 10 SMICLD₅₀ produced 10^{6.0} to 10^{7.99} SMICLD₅₀/mL
3 in L cell monolayers from 0 and 72 hour post-inoculation, respectively, and 10^{7.5} to 10^{5.34} in L
4 cell suspension cultures from 0 through 96 hours post-inoculation, respectively [virus infectious
5 doses very low] (Orlando, Delauter, and Riley 1967).

6
7 In 50 L virus fermentors with L cells, 10^{8.2 to 9.0} MICLD₅₀/mL produced (Klein, Jones Jr, et al.
8 1971).

9
10 Before/after ultrafiltration, cell culture origin virus was 10^{5.52 to 7.19}/10^{6.52 to 8.85} MICLD₅₀/mL
11 with total virus infectivity/final volume = 10^{8.28 to 10.67} MICLD₅₀ (Klein, Mahlandt, et al. 1971).

12
13 Virus titers high in susceptible animals (Meegan and Bailey 1989).

14
15 Maximum lamb viremic load reach 10^{10.1} MIPLD₅₀/mL; 10^{7.6} in adult sheep; 10^{7.5} in calves; 10^{8.2}
16 in kids; 10^{5.6} in goats (Swanepoel and Coetzer 1994).

17
18 Rhesus monkeys, *M. mulatta*, three experiments: SQ were inoculated with 10^{5.3} PFU/mL, no
19 viremia in one, 10^{3.6} PFU/mL in second monkey lasting 1 day, 10^{6.8} viremia on day 2 and 10^{4.9}
20 PFU/mL viremia on day 3 in the third monkey; IV inoculation of 10^{4.7} PFU/mL, three developed
21 transient viremia without clinical signs, but the fourth developed hemorrhagic diathesis and was
22 euthanatized; IV inoculation of 10^{4.1} PFU/mL had transient viremia and one was ill with
23 hemorrhagic signs, but recovered; inoculation (route not specified; IV is implied) of 10^{4.8}
24 PFU/mL, one became ill and was killed in a moribund state; viremias to 10^{5.5-6.5} PFU/mL (Peters
25 et al. 1988).

26
27 In African buffalo, maximum titers to 10^{5.4} TCID₅₀; to 10^{4.9} MICLD₅₀ in dogs; to 10^{2.5} MIPLD₅₀
28 in ponies (Swanepoel and Coetzer 1994).

29
30 In newborn and weanling mice, IP and IC inoculation, causes death, virus titers from 10^{6.6} to
31 10^{9.0} log₁₀/mL [test systems not reported] (Weinbren 2008; Shimshony and Barzilai 1983).

1 Hamsters with viremias $\geq 10^{7.4 \text{ to } 10.6}$ PFU/mL of blood; mosquitoes/biting gnats ingested $10^{4.9 \text{ to } 8.1}$
2 PFU/mosquito/biting gnat for transmission studies (Turell et al. 2008).

3
4 Viremias $> 10^8$ PFU/mL of blood (Bird et al. 2009).

5
6 Cattle and sheep maintain very high level viremias for 3–5 days (White 1994).

7
8 Vaccinated rats challenged, SQ, with 1.0×10^3 PFU of virulent wild-type RVFV, lethal to non-
9 vaccinates; induced challenge virus titers of 3.4×10^7 PFU/mL blood in non-vaccinated rats (Bird
10 et al. 2008).

11
12 Several domestic animal species can act as amplifying hosts with viremias of 10^{10} mouse
13 LD₅₀/mL blood (Hoogstraal et al. 1979).

14
15 Several field researchers with no physical contact with an infected sheep slaughtered via
16 traditional Islamic method in Egypt became viremic with RVFV 3 days after aerosol exposure;
17 sheep blood titered 10^{10} MICLD₅₀/mL (Hoogstraal et al. 1979).

18
19 Susceptible rat spp develop fulminating liver necrosis within 3–5 days when inoculated with less
20 than 5 PFU dose; great variation is reported across strains of virus in virulence (Shimshony and
21 Barzilai 1983).

22
23 Clinical responses of cattle inoculated with doses from $10^{4.3}$ to $10^{7.3}$ MIPLD₅₀ were similar;
24 produced viremias to $10^{7.5}$ MIPLD₅₀ (Shimshony and Barzilai 1983).

25 In pregnant cattle, dose 10^5 PFU, aborted, severe clinical disease, death; virus in tissues to $10^{4.5}$
26 MIPLD₅₀; live borne fetuses were viremic at 10 days post-infection (Shimshony and Barzilai
27 1983).

28
29 Virus titers in sheep, $10^{8.9-10.0}$ (Shimshony and Barzilai 1983).

1 In puppies, virus in saliva; in sheep, $10^{5.3}$ PFU/mL in saliva; isolated from sheep and cow milk
2 (Shimshony and Barzilai 1983).

3
4 High titers in fetuses and fetal membranes; virus in human throat washings (Shimshony and
5 Barzilai 1983).

6
7 Fatal encephalitis in 10-week-old adult gerbils was dose-independent [$10^{1.0-7.0}$ PFU, SQ]; viral
8 replication evident in the brains of young from day 4 ($10^{3.0}$ PFU/g) through day 7 ($10^{6.0}$ PFU/g);
9 virus detected in the brain of a single adult gerbil (at day 7, $10^{4.0}$ PFU/g); in two moribund adult
10 gerbils, $10^{7.0}$ PFU/g of virus in the brain tissue on days 8 and 11; when young and adult gerbils
11 were inoculated with a low dose (50 PFU) of virus, IC, no detectable differences in the course of
12 infection with all animals succumbing to fatal necrotizing encephalitis at approx 7 days post-
13 inoculation (Anderson, Slone, and Peters 1988).

14
15 1977–1978, Egypt, virus titers in aborting sheep, $10^{8.9-10.0}$ SMICLD50 (Meegan 1979).

16
17 The virus can be isolated from blood, preferably collected in an anticoagulant, during the febrile
18 stage of the disease, or from liver, spleen and brain tissues of animals that have died and from the
19 organs of aborted fetuses; primary isolations made on cell cultures of various types, such as
20 African green monkey kidney (Vero) cells, baby hamster kidney cells, chicken embryo
21 reticulum, or primary cells of sheep or cattle origin; hamsters, adult or suckling mice,
22 embryonating chicken eggs or 2-day-old lambs can be used for primary virus isolation
23 (Anonymous 2004).

24 25 **Pathogen stability**

26 RVFV survives in aedine mosquito ova that are subject to an obligatory drying period
27 (Swanepoel and Coetzer 1994).

28
29 During interepidemic periods, the virus is maintained in nature via transovarial transmission in
30 mosquitoes, as was shown in *Aedes lineatopennis* in Kenya and in *Aedes vexans* in Senegal
31 (Flick and Bouloy 2005).

1
2 Virus can be maintained by mosquitoes through transovarial transmission. The mosquito species
3 most frequently associated with virus maintenance often breed in natural depressions (dambos)
4 on the African savanna. Heavy rainfall floods the breeding sites creating conditions resulting in
5 hatching of vertically infected mosquitoes and in subsequent transmission of the virus to
6 vertebrates that use the flooded dambos as watering holes. If sufficient vectors and susceptible
7 vertebrate hosts are available, epizootic transmission can follow (LeDuc 1989).

8
9 Virus persists in sheep liver and spleen for 20–21 days (Meegan and Bailey 1989).

10
11 Virus is very stable in serum; survives for several months at 4 °C and > 3 hours at 56 °C
12 (Swanepoel and Coetzer 1994).

13
14 Virus from blood collected in oxalate-phenol-glycerin solution remains viable for more than 8
15 years after storage under variable refrigeration temperatures (Swanepoel and Coetzer 1994).

16
17 Virus is very stable at less than 60 °C or after lyophilization (Swanepoel and Coetzer 1994).

18
19 Virus is very stable in aerosols at 23 °C and 50–85 percent RH (Swanepoel and Coetzer 1994;
20 Shimshony and Barzilai 1983).

21
22 Half life of the virus is 77, 15.8, and 6.9 minutes for 30, 55, and 80 percent RH, respectively
23 (Brown, Dominik, and Larson 1982).

24
25 Geometric mean of the biological decay rate is 2.3 percent per minute over range of 50 and 80
26 percent RH. Aerosol stability is not influenced by RH (Miller et al. 1963).

27
28 Virus is inactivated by lipid solvents, formalin, and pH less than 6.8 (Swanepoel and Coetzer
29 1994).

Virus is sensitive to heat and acid. It is inactivated readily by detergents, lipid solvents, and common disinfectants (Murphy et al.).

Inactivated rapidly at pH 6.2 (Gerdes 2005).

Virus lyophilizes well; blood preserved in oxalate-phenol-glycerin solution retained virulence for more than 8 months at 4 °C; sheep plasma retained infectivity for more than 8 years under a variety of refrigeration conditions; resistant to temperatures less than 60 °C, recovered from serum after several months storage at 4 °C or after 3 hours at 56 °C; inactivated by acetone at –30 °C overnight; by 0.25 percent solution of 10 percent formalin for 3 days, by methylene blue with light; lipid solvents, i.e., ether and sodium deoxycholate inactivate; susceptible to trypsin digestion; in cell monolayers, incomplete inactivation by acetone at –60 °C for 48 hours; inactivated rapidly at pH of less than 6.8 (Shimshony and Barzilai 1983).

Highly stable in aerosol form at 23 °C and RH of 50–85 percent (Shimshony and Barzilai 1983). Indication that viruses with structural lipids survive best in aerosols at low RH (Benbough 1971).

UV radiation inactivates viruses by chemically changing the RNA and DNA; most effective UV is 250 nm; filoviruses [MARV and EBOV] most sensitive to solar UV₂₅₄, requiring 20–100 minutes at mid-day exposure to inactivate one log₁₀ of virus: bunyaviruses (hantaviruses [AND virus] and RVFV), arenaviruses (Lassa, JUN), and flaviviruses (TBE complex viruses) more resistant (Lytle and Sagripanti 2005).

Vectors

a. Field

Transmission occurs by large number of mosquito spp.—23 spp in 5 genera [table p. 62] (Meegan and Bailey 1989).

More than 30 species of genera (*Aedes*, *Anopheles*, *Culex*, *Coquillettidia*, *Eretmapodites*, *Mansonia*) (Bird et al. 2009).

1 Biologic vectors are *Aedes* spp, *Culex* spp, *Anopheles* spp, *Eretmapodites* spp, *Mansonia*
2 spp; mechanical vectors= *Culicoides* spp, phlebotomids, stomoxids, simuliids (Brown and
3 Torres 2008).

4
5 RVFV has been isolated from *Culicoides* (biting gnats or midges), *Simulium* (black flies),
6 *Rhipicephalus* ticks (Meegan and Bailey 1989).

7
8 Biological transmission occurs via mosquitoes, and mechanical transmission is via biting
9 flies (White 1994).

10
11 During the 1977–1978 epizootic in Egypt, *Culex pipiens* was the most ubiquitous and
12 prevalent mosquito species in the Nile Valley and Delta; isolation of RVFV from
13 engorged and unengorged *C pipiens*, and demonstration of laboratory transmission of the
14 virus by this species, strongly implicate it as the chief vector (Hoogstraal et al. 1979).

15
16 RVFV has been isolated from *Aedes africanus*, *A. caballus*, *A. cinereus*, *A. circumluteolus*,
17 *A. dentatus*, *A. dendrophilus*, *A. coustani*, *A. juppi*, *A. lineatopennis*, *A. tarsalis*, *Anopheles*
18 *cinereus*, *An. coustani*, *Coquillettidia fuscopennata*, *Culex antennatus*, *Cx pipiens*, *Cx*
19 *theileri*, *Eretmapodites* spp, *E. quinquevittatus*, *Mansonia africana*, *Culicoides* spp,
20 *Simulium* spp from varied ecosystems: inland plateaus, coastal lowlands, highlands,
21 bushy grasslands, cities, deltas, forests, and rivers (Shimshony and Barzilai 1983).

22
23 Occasional isolations occur from *Rhipicephalus* spp ticks (Flick and Bouloy 2005).

24
25 During interepidemic periods, the virus is maintained in nature via transovarial
26 transmission in mosquitoes, as was shown in *Aedes lineatopennis* in Kenya and in *Aedes*
27 *vexans* in Senegal (Flick and Bouloy 2005).

28
29 Virus can be maintained by mosquitoes through transovarial transmission. The mosquito
30 species most frequently associated with virus maintenance often breed in natural
31 depressions (dambos) on the African savanna. Heavy rainfall floods the breeding sites

1 creating conditions resulting in hatching of vertically infected mosquitoes and in
2 subsequent transmission of the virus to vertebrates that use the flooded dambos as
3 watering holes. If sufficient vectors and susceptible vertebrate hosts are available,
4 epizootic transmission can follow (LeDuc 1989).

5 RVFV adapted quickly to variety of ecosystems outside traditional areas of Africa. From
6 Egypt's arid to semiarid climate, the virus spread into the Middle East, with transmission
7 via *Culex pipiens* (Meegan, Niklasson, and Bengtsson 1979).

8 9 **b. Experimental**

10 Viral load in viremic domestic ruminants, humans, and rodents is sufficient to infect
11 mosquitoes; viremias of $10^{5.7}$ to $10^{9.7}$ MICLD₅₀/mL will infect 50 percent of mosquitoes
12 (Swanepoel and Coetzer 1994).

13
14 Biologic transmission occurs by 7 spp of *Aedes*, 6 spp of *Culex*, and 2 spp of
15 *Eretmapodites* (Meegan and Bailey 1989).

16
17 Mechanical transmission is by *Culicoides*, *Simulium* and *Lutzomyia* (sand flies) (Meegan
18 and Bailey 1989).

19
20 Transovarial transmission to mosquito ova of *Aedes* floodwater spp with isolates from
21 male and female mosquitoes raised from field collected ova (Meegan and Bailey 1989).

22
23 Virus is transmitted by bites of *Erchrysogaster*, *Ae caballus*, and *Ae aegypti* (Weinbren
24 2008).

25
26 *Culex pipiens* from the Nile Delta transmitted the virus after infection from infected
27 hamsters; infection rates were 87 percent, and transmission rates were 40 percent
28 (Weinbren 2008).

1 Arthropod transmission studies have implicated 18 mosquito species of the genera *Aedes*,
2 *Mansonia*, *Culex*, *Anopheles*, and *Eretmapodites* as possible RVFV vectors (Hoogstraal
3 et al. 1979).

4
5 Most effective vector, *C theileri*, was infected with doses of $5 \times 10^{4.0}$ MICLD₅₀/mL
6 (Shimshony and Barzilai 1983).

7 Experimental transmission, *Aedes aegypti*, *A. caballus*, *A. coustani*, *A. juppi*, *A.*
8 *lineatopennis*, *A. triseriatus*, *Culex neavei*, *Cx pipiens*, *Cx quinquefasciatus*, *Cx theileri*,
9 *Cx univittatus*, *Cx zambaensis*, *Eretmapodites chrysogaster*, *E. quinquevittatus*
10 (Shimshony and Barzilai 1983).

11
12 In one study, *Culicoides variipennis* [a North American spp] was not susceptible
13 (Shimshony and Barzilai 1983).

14
15 Virus isolated from *Culicoides* spp (Shimshony and Barzilai 1983).

16 *Phlebotomus duboscqi*, *Phlebotomus papatasi*, *Phlebotomus sergenti*, and *Sergentomyia*
17 *schwetzi* (Diptera: *Psychodidae*) fed on infected hamsters (10^4 PFU/mL inoculum, at 24
18 hours); with virus titers in hamsters of $10^{8.0-8.6}$ PFU/mL, *P. papatasi* were not infected and
19 did not transmit the virus, 18 percent of *P. sergenti* were infected, but did not transmit the
20 virus, 50 percent of *P. duboscqi* were infected and 6 percent transmitted, 12 percent of *S.*
21 *schwetzi* were infected and 7 percent transmitted; with hamster viremias of $10^{10.6}$
22 PFU/mL, 32–45 percent of *P. papatasi* were infected and 2–6 percent transmitted, 57
23 percent of *P. sergenti* were infected, 14 percent transmitted, 22 percent of *S. schwetzi*
24 were infected and 14 percent transmitted; via intrathoracic inoculation of 10^2 PFU, 100
25 percent of *P. papatasi* were infected and 14 percent transmitted, 100 percent of *P.*
26 *duboscqi* were infected and 50 percent transmitted, 41 percent of *S. schwetzi* were
27 infected and 0 percent transmitted (Dohm et al. 2000).

28
29 In North America, potential vector species from Colorado and the Midwest, *Culex*
30 *tarsalis* transmitted efficiently (infection rate = 93 percent, dissemination rate = 56
31 percent, and estimated transmission rate = 56 percent), but using the same virus dose,

1 none of other species tested transmitted under laboratory conditions; *Aedes dorsalis* was
2 susceptible to infection (78 percent) and had a moderate dissemination rate (33 percent),
3 but had a salivary gland barrier and rarely transmitted RVFV by bite; only 30 percent of
4 *Aedes vexans* became infected and 3 percent developed a disseminated infection, but 32
5 percent of those with disseminated infection transmitted virus by bite, so about 1 percent
6 of orally exposed *Ae vexans* would be expected to transmit RVFV by bite; none of the
7 *Culicoides sonorensis* became infected, even after intrathoracic inoculation; none of the
8 *Anopheles quadrimaculatus* tested transmitted RVFV by bite, even after intrathoracic
9 inoculation, indicating that *C. sonorensis* and *An quadrimaculatus* would not be
10 competent vectors of RVFV [terminology: infection rate = percentage of orally exposed
11 mosquitoes/biting gnats that contain virus: dissemination rate = percentage of orally
12 exposed mosquitoes/biting gnats that contained virus in legs; transmission rate =
13 percentage of orally exposed mosquitoes/biting gnats that re-fed on an uninfected host
14 and transmitted virus] (Turell 2008).

15
16 **Other epidemiological/ecological data**

17 1987–1988, Egypt, the virus was recognized in more than 18 African countries; spread over
18 4,200 miles (north to south), circulating in a number of different geographic and climatic
19 settings, with penetration into Egypt showing amplification in a totally new ecosystem
20 (Shimshony and Barzilai 1983).

21
22 Before Egypt, the virus was in 20 countries: Angola, Botswana, Cameroun, Chad, Egypt,
23 Ethiopia, Gabon, Kenya, Lesotho, Malawi, Mali, Mozambique, Namibia, Nigeria, Somalia, S
24 Africa, Sudan, Tanzania, Uganda, Zaire, Zambia, Zimbabwe (Shimshony and Barzilai 1983).

25
26 Recent outbreaks in Kenya, Madagascar, Mauritania, Somalia, Tanzania, and Yemen indicate the
27 potential for RVFV to cause severe disease in both humans and domestic animals and its
28 potential to be introduced into new areas, including North America (Turell et al. 2008).

29
30 RVFV is found in a wide range of ecological zones (Meegan and Bailey 1989).

1 Outbreaks historically are associated with indigenous forests and coastal bush areas (Swanepoel
2 and Coetzer 1994).

3
4 Outbreaks occur in central and eastern Africa when particularly heavy rains favor mosquito
5 breeding by flooding breeding habitats, *dambos* (small to large shallow depressions in the earth
6 that are normally dry, but which flood during rainy seasons/years) [*oshanas* in southwestern
7 Africa] (Meegan and Bailey 1989; Bird et al. 2009).

8
9 Outbreaks in South Africa during the 1950s centered on the *panveld* where surface waters gather
10 in undrained shallow depressions (pans) after heavy rains or in ponds formed by farm dams that
11 are subjected to periodic drying (Swanepoel and Coetzer 1994).

12
13 A correlation in Zimbabwe between endemic cycle and broad vleis (low-lying grassy area
14 serving as a water seepage channel for rain water from higher ground) (Swanepoel and Coetzer
15 1994).

16
17 In eastern Africa, epidemics are associated with above average rainfall at irregular intervals of 5–
18 15 years (Swanepoel and Coetzer 1994).

19
20 In many areas of Africa, the climatic cycle lasts 18 years with 9 years of rainfall followed by 9
21 years of drought; interepizootic periods can last 8–24 years (Swanepoel and Coetzer 1994).

22
23 Outbreaks in northeastern Africa (Egypt, Sudan) associated with movement of infected
24 mosquitoes and transportation of infected sheep and cattle. Virus activity is associated with
25 *Culex pipiens* rather than aedine species (Swanepoel and Coetzer 1994).

26
27 Historic distribution of RVF is the sub-Saharan African continent [including Egypt and Sudan],
28 Madagascar, and the Arabian Peninsula (Anonymous 2007).

1 Epidemics occur in infected areas after flooding; separated by inter-epidemic periods that can
2 last for several decades in arid areas. During those periods, the prevalence of infection in
3 humans, animals, and mosquitoes can be difficult to detect (Anonymous 2004).

4
5 Disease occurs in climatic conditions favoring breeding of mosquito vectors and is characterized
6 by liver damage (Anonymous 2004).

7 Excessively heavy rainfall in semiarid regions often precedes large, periodic outbreaks of RVFV
8 activity, allowing for the abundant emergence of transovarially infected *Aedes* spp. mosquitoes
9 and the subsequent initiation of an outbreak by transmission of virus to livestock and humans via
10 infected mosquito feeding (Bird et al. 2008).

11
12 The most important epidemics/epizootics occur after periods of unusually heavy rains or in
13 association with construction of dams (Flick and Bouloy 2005).

14
15 The virus is found in many areas in sub-Saharan Africa, although it reached beyond the normal
16 distribution in 1978 when a major epidemic occurred in Egypt. In Africa, it is normally
17 associated with excessively heavy rainfall (LeDuc 1989).

18
19 Epidemics in Kenya are associated with the El Niño phase of the Southern Oscillation (ENSO)
20 (Hay et al. 2000; Davies, Linthicum, and James 1985; Bird et al. 2009).

21
22 As a group, the other viral hemorrhagic fever (VHF) agents are linked to the ecology of their
23 vectors or reservoirs, whether rodents or arthropods (Geisbert and Jahrling 2004).

24
25 Epizootic RVF occurred 4 times over a 30-year period in Kenya and was associated with
26 widespread, frequent, persistent rainfall; raises water levels in grassland depressions (dambos),
27 habitats of immature forms of ground-pool-breeding aedine mosquitoes in which RVFV is
28 probably transmitted transovarially; outbreaks last 1–3 years and recur at 5–15 year intervals
29 (Davies, Linthicum, and James 1985).

1 In humans, most infections result in undifferentiated febrile disease, but about 1 percent of
2 infections result in hemorrhagic complications, which are often fatal and ocular sequellae occur,
3 which can cause retinal damage, including blindness (Turell et al. 2008).

4
5 All known RVF outbreaks in East Africa from 1950 to 1998, and probably earlier, followed
6 periods of abnormally high rainfall. An analysis of the record and Pacific and Indian Ocean sea
7 surface temperature anomalies, coupled with satellite normalized difference vegetation index
8 data, shows that prediction of outbreaks can be made up to 5 months in advance of outbreaks in
9 East Africa. Concurrent, near-real-time monitoring with satellite normalized difference
10 vegetation data could identify actual affected areas (Linthicum et al. 1999).

11 12 **Therapeutics/vaccines**

13 Formalinized vaccine is used in cattle and sheep (Meegan and Bailey 1989).

14
15 Attenuated vaccine is used in sheep and cattle, but is abortigenic in pregnant ewes (Meegan and
16 Bailey 1989).

17
18 Smithburn vaccine strain was derived by serial intracerebral passage of wild-type Uganda virus
19 until it lost its liver tropism and became neuro-adapted. After that, it is passed in mice and
20 embryonating hen's eggs, grown in cell culture, and lyophilized (Weinbren 2008).

21
22 Since 1967, a formalin-inactivated vaccine produced in infected primary monkey kidney cells
23 has been used to protect laboratory workers (Meadors, Gibbs, and Peters 1986).

24
25 Formalin-inactivated product that uses a more acceptable seed virus was cloned and propagated
26 in cell culture and a well-characterized diploid fetal rhesus monkey cell substrate. It causes mild
27 vaccine reactions in humans with neutralizing antibody, but no viremia, are produced (Meadors,
28 Gibbs, and Peters 1986).

29
30 Formalinized cell culture origin human vaccine (USAMRIID) exists (Pittman et al. 1999;
31 Meegan and Bailey 1989).

1
2 Attenuated human vaccine exists (Meegan and Bailey 1989).

3
4 Vaccine attenuation has been approached by selection of small [minute] plaque variant (Meegan
5 and Bailey 1989; Swanepoel and Coetzer 1994); chemical mutagenesis with 5-fluorouracil
6 (Swanepoel and Coetzer 1994; Meegan and Bailey 1989); and serial passage in permissive
7 systems, e.g., cell culture, suckling mice (Swanepoel and Coetzer 1994).

8 Treatment of exposed humans with immune plasma and ribavirin has been recommended
9 (Swanepoel and Coetzer 1994).

10
11 No preventive RVF medications or licensed vaccines for humans exist (CDC 2007).

12
13 In vivo studies of a reverse genetics-generated recombinant RVFV vaccine candidate containing
14 precise deletions of complete virus genes with known roles in virulence show promise for
15 humans (Bird et al. 2008).

16
17 Inactivated RVFV vaccine TSI-GSD-200 is safe and provides good, long- term immunity in
18 humans when the primary series and one boost are administered. It is used for at-risk laboratory
19 personnel and military personnel (LaBeaud et al. 2007).

20
21 Vaccine created from the twelfth mutagenesis passage (RVFV ZH-548-P12) of a virus originally
22 isolated from a human with a nonfatal case of RVF. The final vaccine product markedly
23 attenuated for rhesus macaques inoculated intravenously. The vaccine produced transient, low-
24 titer viremias and minimal serum enzyme elevations; potential for use in humans (Morrill and
25 Peters 2003).

26
27 DNA vaccines expressing Gn and Gc genes were tested in mice alone or in various
28 combinations. The DNA vaccine elicited antibodies and protected mice from challenge with 100
29 LD50 when delivered alone or in combination with other DNA (Spik et al. 2006).

30
31 No approved vaccine is available for livestock or humans (Bird et al. 2009).

No specific treatment exists; give supportive care (Bird et al. 2009).

The Working Group for Civilian Biodefense has recommended intravenous ribavirin be administered in the case of a contained casualty situation with RVF infections, and in the case of mass casualties, an oral regimen of ribavirin is recommended (Sidwell and Smee 2003).

A major focus for preventing and controlling RVF outbreaks is reducing numbers of amplifying hosts by immunizing livestock (Morrill, Mebus, and Peters 1997).

In Rhesus macaques, passive administration of 0.025 mL/kg of immune serum (PRN titer of 1:2,560) failed to induce detectable serum-neutralizing antibody in recipients, but it prevented viremia and illness [suggests therapy for humans] (Peters et al. 1988).

Administration of antibodies, interferon, interferon inducer, or the nucleoside analog ribavirin in experimentally RVFV-infected mice, rats, or monkeys was efficient in protecting against the disease; however, those treatments have never been tested in RVFV-infected patients (Flick and Bouloy 2005).

Other remarks

First described in 1912–1913 from an outbreak of abortion in ewes, with accompanying human disease in the Rift Valley of Kenya. The virus was isolated in 1931 (Meegan and Bailey 1989; Swanepoel and Coetzer 1994) and reported in 1930 in another publication (Sidwell and Smee 2003).

Virus isolated from a newborn lamb in 1930 in an area of upland tropical savannah (Weinbren 2008).

Detailed clinical signs and pathologic changes with extensive photos have been published (Swanepoel and Coetzer 1994).

RVFV is assigned to SALS (American Committee on Arthropod-Borne Viruses (ACAV) Subcommittee on Arbovirus Laboratory Safety) level 3 (Weinbren 2008).

RVFV possession in the United States requires a USDA permit, and is a USDA restricted, USDA high consequence agent. A Department of Commerce permit is required, and vaccination is recommended (Weinbren 2008).

Peracute (excessively acute) or acute zoonotic disease occurs among domestic ruminants in Africa (Anonymous 2004).

Considered a BSL-4 pathogen unless humans are immune from prior infection or vaccinated (Murphy et al.).

RVFV is a high-priority concern from a bioterrorism perspective, Category A from NIH, Category B from CDC (Sidwell and Smee 2003).

RVF is a mosquito-transmitted [*Aedes* or *Culex*] zoonotic disease of livestock. (Anonymous 2007; Murphy et al. 1999).

A common pathogenic feature of the hemorrhagic fever viruses is the ability to disable the host immune response by attacking and manipulating the cells that initiate the antiviral response (Geisbert and Jahrling 2004).

Outbreaks occur across sub-Saharan Africa and into Egypt, Sudan, Mauretania, and the Middle East (Meegan, Niklasson, and Bengtsson 1979; Geisbert and Jahrling 2004; Bird et al. 2009).

Taxonomy/antigenic relationships/synonyms

Genus *Phlebovirus*, family *Bunyaviridae* (Meegan and Bailey 1989; Anonymous 2004; White 1994; Murphy et al.; Shimshony and Barzilai 1983; Bird et al. 2009).

Before the 1987 Mauritanian outbreak, RVFV, previously identified as Zinga virus, had been isolated in West Africa from mosquitoes (Saluzzo et al. 1989).

Biological and antigenic traits distinguish the strains isolated during the 1977 Egyptian epidemic from the sub-Saharan strains (Saluzzo et al. 1989).

Twelve distinct viruses associated with hemorrhagic fever in humans are classified among four families: *Bunyaviridae*, which includes Rift Valley fever, Crimean-Congo hemorrhagic fever, and Hantaan viruses (LeDuc 1989).

C.1.2 BSL-4 Pathogens

C.1.2.1 Andes virus (ANDV)

Note: BSL-4 biocontainment precautions are recommended for ANDV when infecting rodent species permissive for (susceptible to) chronic infection. Otherwise, BSL-3 biocontainment precautions are recommended.

Host range

a. Field

Long-tailed pygmy rice rat, *O. longicaudatus*, and other species of genus *Oligoryzomys* are the reservoir (Centers for Disease Control and Prevention 2008; Wells et al. 1997; McCaughey and Hart 2000; Padula et al. 2004).

Rodent reservoirs are in the sub-family *Sigmodontinae* within the family *Muridae*, order Rodentia with which the hantaviruses have evolved for thousands of years (Toro et al. 1998; McCaughey and Hart 2000; Mertz et al. 2006).

Occasional evidence of infection (antibody) is found in numerous other species of rodents and their predators (e.g., dogs, cats, and coyotes), indicating that many (perhaps any) mammal species coming into contact with an infected host might become infected; no evidence supports the transmission of infection to other animals or to humans from those *dead-end* hosts, but domestic cats and dogs might bring infected rodents into contact with humans (Centers for Disease Control and Prevention 2008).

1 In Chile, most frequently captured rodent species in outbreak area, *O. longicaudatus*,
2 12.7 percent hantavirus-antibody–positive; *Akodon olivaceus*, 7.5 percent antibody-
3 positive; *A. longipilis*, 2.7 percent antibody-positive (Toro et al. 1998).

4
5 In areas of Chile and Argentina, natural reservoir of a milder pathogen appears to be
6 *Callomys laucha* (Ferres and Vial 2004).

7 As far as known, all *Hantaviruses* are maintained in nature through chronic infection of
8 rodent and other small mammalian hosts, with transmission between rodents and to
9 humans primarily via aerosolized, infectious excreta (LeDuc 1989).

10
11 Isolates from *O. chacoensis* and *O. flavescens* captured where hantavirus pulmonary
12 syndrome (HPS) patient lived and worked (Gonzalez Della Valle et al. 2002).

13
14 Argentina, serologic evidence of infection in *O. flavescens* (rice rat), *A. azarae* (grass
15 field mouse), *Bolomys obscurus* (dark field mouse) (Levis et al. 1997).

16 17 **b. Experimental**

18 Causes death in Syrian hamster with course of disease that closely models human
19 infection (Wahl-Jensen et al. 2007)(Centers for Disease Control and Prevention 2008).

20
21 *Cynomolgus* macaques, *M. fascicularis*, via IV or aerosol, 4.4×10^5 PFU; no clinical
22 disease, hematologic changes (\downarrow lymphocytes), both IgM and IgG antibodies against the
23 viral nucleocapsid protein, neutralizing antibody response; via plaque assay, serum
24 samples negative for infectious virus, but by non-nested reverse transcriptase–polymerase
25 chain reaction, viral S-segment genomes were detected in whole blood (McElroy et al.
26 2002).

27 28 **Prevalence/incidence/attack rate**

29 Paraguay, hantavirus seroprevalence of 45 percent in Indian populations of Gran Chaco and 35
30 percent seropositives in non-Indian populations (Ferres and Vial 2004).

1 Temuco, Chile, Andes virus (AndesV) seroprevalence in mountainous areas of 2.15 percent and
2 seronegative at lower altitudes (Ferres and Vial 2004).

3
4 Jujuy, northern Argentina, 6.5 percent seropositivity (Ferres and Vial 2004).

5
6 In Jardinopolis, Brazil, seroprevalence 14.3 percent (Ferres and Vial 2004).

7 In Argentina and Chile, 16 percent of cases occurred in children < 16 years old (Ferres and Vial
8 2004).

9
10 In Chile, seroprevalence varies from 1 to 40 percent depending on geographic area and ethnic
11 differences (Pini 2004).

12
13 In Chile from 1995-2006, a total of 492 cases of hantavirus cardiopulmonary syndrome were
14 reported (Torres-Perez et al. 2009).

15
16 Seroprevalence in southern Chile, 2.15 percent (Tager Frey et al. 2003).

17
18 Seroprevalence in northern Argentina study, 1.5 percent of 135 persons (Levis 1995).

19
20 Northern Argentina, prevalence of hantavirus antibodies in the general human population was
21 6.5 percent, one of the highest reported in the literature; high prevalence of hantavirus antibody
22 seemed to be associated with high infestation of rodents detected in domestic and peridomestic
23 habitats (Pini et al. 2003).

24
25 Rodent seroprevalence in northern Chile, *O. longicaudatus*, 5.9 percent, *Abrothrix longipilis*, 1.9
26 percent (Medina et al. 2009).

27
28 Rio Negro Province, Argentina, seroprevalence:

- 29 • In subantarctic forests without presence of HPS cases: *O. longicaudatus* , 4.4 percent; in
30 *A. longipilis*, 0.2 percent; in *Loxodontomus microtus*, 8.3 percent;
31 • in subantarctic forests with related HPS: *O. longicaudatus*, 7.4 percent;

- in steppes without HPS: in *A. olivaceus*, 2.4 percent (Larrieu et al. 2008).

Chile, 10th Region, seropositive rodent species distributed from the Pacific coast to the Andes

mountains, *O. longicaudatus*, 2.7 percent, *A. longipilis*, 0.6 percent; seasonal movement to open
habitats close to human outdoor activity during dry season (Murua et al. 2003).

Diego Gaynor, northwest of Buenos Aires, seroprevalence of 9.3 percent in total sample of 291 *A.
azarae* and 13.5 percent for 37 *O. flavescens* using ELISA; higher rates of seroprevalence in
older males than in females or juveniles (Suarez et al. 2003).

South-central Chile, correlation of seropositive rodent species to confirmed HPS cases; *O.
longicaudatus*, 10.4 percent seropositive using immunoassay (Torres-Perez et al. 2004).

Argentina study, Nt and IFAT antibodies detected in 22.5 percent of laboratory *Rattus
norvegicus* and 23.5 percent of wild-caught *Callomys musculus* (Weissenbacher et al. 1990)
[uncertain significance as study used Old World hantaviruses—Hantaan, Seoul, Puumala,
Prospect Hill viruses—and was done before the identification of Andes virus].

Seroprevalence in small mammals in Patagonian Andes mountain range, Rio Negro province,
Argentina; rodent blood samples collected in natural and peri-urban habitats and at the home of
HPS case patient analyzed by ELISA and organ tissue samples tested by PCR and nucleotide
sequence analysis; AND virus antibody was detected in 5.4 percent of 555 *O. longicaudatus*, 0.7
percent of 411 *A. longipilis*, and 10 percent of 10 *Loxodontomys microtus*; seroprevalence in *O.
longicaudatus* were 13.7 percent in spring 1996, 59.3 percent in summer 1996, 2.1 percent in
autumn 1997, 12.4 percent in winter 1997, and 3.1 percent in spring 1997; much higher
seroprevalence (33 percent) found during trapping around the residence of an HPS case patient;
higher seroprevalence found in older male *O. longicaudatus*; no apparent correlation of
seroprevalence with rodent population density, or of rodent population density or seroprevalence
with numbers of human cases (Cantoni et al. 2001).

Northern Argentina, HPS-endemic area composes Salta and Jujuy provinces; 1997–2000, 30
HPS cases diagnosed in Jujuy province (population 512,329) (Pini et al. 2003).

R₀/incubation period/infectious period/infectious dose

Incubation period estimated at 14–32 (median 18) days from studies of 19 hantavirus cardiopulmonary syndrome (HCPS) patients with history of high risk activities and a biologist with HCPS who was bitten by an infected *O. longicaudatus* (Vial et al. 2006).

Incubation period estimated at 8–43 days (Castillo et al. 2007).

Incubation period 15–24 days (Martinez et al. 2005).

Infectious dose in humans is unknown.

Lethal dose required to kill 50 percent of Syrian hamsters (LD₅₀) calculated to be 8 PFU; virus titers reach 10^{8.0–9.0} PFU/mL in liver (Hooper et al. 2001).

A 50 percent lethal dose (LD₅₀) of 1.54 FFU (focus-forming units) for i.p. injections in hamsters was determined by inoculating a ten-fold serial dilution of 0.8 to 80,000 FFU (Safronetz et al. 2009).

Hantaan virus (“related” to Andes hantavirus) has a reported ID₅₀ = 0.5 PFU (95% C.I. 0.3-1.1) via aerosol in rats (Nuzum et al. 1988).

Morbidity/case fatality ratio

HPS in humans typically presents in a very nonspecific way with a relatively short febrile prodrome lasting 3-5 days. In addition to fever and myalgias, early symptoms include headache, chills, dizziness, non-productive cough, nausea, vomiting, and other gastrointestinal symptoms. Malaise, diarrhea, and lightheadedness are reported by approximately half of all patients, with less frequent reports of arthralgias, back pain, and abdominal pain (Centers for Disease Control and Prevention 2008).

1 Results from serologic studies to determine the prevalence of exposure to the virus among
2 populations in endemic areas suggest that clinically asymptomatic infections occur (Ferres and
3 Vial 2004; Pini et al. 2003).

4
5 Case fatality rate of 25–35 percent in Argentina and 37 percent in Chile (Centers for Disease
6 Control and Prevention 2008).

7 In Chile, 477 cases reported through 4/2006 with CFR of 37 percent; numbers of cases range
8 from 56 in 2004 to 81 cases in 2001 (Mertz et al. 2006).

9
10 Argentina, CFR = 50 percent, 55 percent of patients were male (Lopez et al. 1996).

11
12 Chile, CFR in children 43.8 percent (Toro et al. 1998; Ferres and Vial 2004).

13
14 Chile, 82 cases reported in children as of 2010, CFR 36.6% (Ferres et al.).

15
16 Death rate in northern Argentina 13.3 percent in children with *mild* form of disease (Ferres and
17 Vial 2004).

18
19 46.7 percent lethality rate in children (Ferres and Vial 2004).

20
21 1993–1997, Andean Region, Argentina, 38 cases, 60 percent males, 50 percent fatal (Cantoni et
22 al. 2001).

23
24 Temuco, Chile, 1997–1999, 82 percent male, 88 percent farm workers, mortality rate = 43.8
25 percent of 15 patients with HPS (Castillo et al. 2001).

26
27 Rapidly progressing human disease with 30–50 percent case fatality rate (Custer et al. 2003).
28 1995–1997, 108 cases of HPS with mortality rate of 48 percent reported in Argentina; approx 1/3
29 cases in and about El Bolson, a locality in the province of Rio Negro in southwestern Argentina,
30 with remaining cases in clusters in other parts of the country, including the northern province of
31 Salta, the islands of the Parana River and Patagonia (Ferrer et al. 1998).

Cases of HPS in Salta, Argentina increased annually since 1995 reaching 35 in 1997, 29 in 1998, 22 in 1999, 15 in 2000, with mortality rates of 23, 7, 24, and 27 percent, respectively (Gonzalez Della Valle et al. 2002).

1995–96, Argentina, 77 HPS cases with 48 percent mortality (Enria et al. 1996).
CFR = 55.6 percent in southern Argentina associated with clusters of cases (Lázaro 2007).

Northern Argentina, most patients had a mild clinical course, and the death rate (13.3 percent) was low (Pini et al. 2003).

Aerosol infection/routes of transmission

Hantaviruses are transmitted by persistently infected rodents via aerosolization of feces, saliva, and urine [and contaminated fomites] for many weeks, if not for life (Centers for Disease Control and Prevention 2008).

In rodent reservoirs, causes generalized, chronic, asymptomatic infection with virus shedding in urine, feces, saliva; transmission to humans via inhalation of aerosols of urine or feces, or from rodent bites (Ferrer et al. 1998).

Infections after rodent bites (Centers for Disease Control and Prevention 2008).
Transmission via bite of *O. longicaudatus* in mammalogist; developed HCPS 14 days later (Merino 2002).

1995–1996, Argentina, person-to-person transmission documented from HPS patient to health care professionals 27–28 days after first contact (Enria et al. 1996).

Direct genetic evidence of person-to-person transmission (Padula et al. 1998).

1996, Andean Region, Argentina, 85 percent (16 cases) person-to-person transmission were suspected (Cantoni et al. 2001; Wells et al. 1997). However, in all those cases except one,

1 infection from rodents could not be ruled out; the exception was a physician who had never
2 visited an endemic area but had treated an infected patient (Enria et al. 2001).

3
4 Viral antigen demonstrated in saliva and might be a route of transmission in humans (Gonzalez
5 Della Valle et al. 2002).

6
7 No evidence of nosocomial transmission in southern Chile (Castillo et al. 2004).
8 7 of 64 (11 percent) cases in Chile occurred in family clusters, affecting principally the secular
9 partner (Castillo et al. 2007).

10
11 Person-to-person transmission was described for an outbreak of HPS in southwest Argentina
12 with four clusters in two endemic areas during, or shortly after, the prodromal phase, with an
13 incubation period of 15–24 days (Martinez et al. 2005).

14
15 1993–2005, southern Argentina, retrospective review, six of eight clusters of apparent person-to-
16 person transmission showed no evidence of exposure to rodents (Lázaro et al. 2007).

17
18 Person-to-person transmission rates of 4 percent for surviving patients and 41 percent for those
19 who died (Lázaro et al. 2007).

20
21 It appears that close and prolonged contact is necessary for person-to-person transmission
22 (Lázaro et al. 2007; Castillo et al. 2007).

23
24 HPS in Argentina and Chile, unique predilection for limited person-to-person transmission;
25 prospectively followed 421 household contacts of patients with laboratory-confirmed infection to
26 test the hypothesis that the virus retains the ability to be transmitted from person to person; sex
27 partners of patients with laboratory-confirmed HPS at the greatest risk of infection, with an
28 estimated secondary attack rate of 2.5 percent and detectable viremia 5–15 days before the onset
29 of symptoms (Ferres et al. 2007; Montgomery, Ksiazek, and Khan 2007).

30
31 Occurs in household clusters and transmitted person-to-person (Ferres et al. 2007).

1 Sleeping in the same bed or room; exposure to saliva (deep kissing), urine, and semen; and
2 demolition of a shed were all associated with an increased risk (Ferres et al. 2007).

3
4 Andes virus is only hantavirus with (albeit uncommonly) person-to-person transmission (Centers
5 for Disease Control and Prevention 2008).

6 Evidence for person-to-person transmission, including nosocomial transmission (Lopez et al.
7 1996; Wells et al. 1997; Toro et al. 1998; Mertz et al. 2006)(Centers for Disease Control and
8 Prevention 2008).

9
10 Using Puumala virus, Old World hantavirus, virus RNA could be detected in human saliva
11 several days after onset of disease symptoms; raises the question whether interhuman
12 transmission of hantavirus can occur through saliva; might apply to virus person-to-person
13 transmission (Pettersson et al. 2008).

14
15 While person-to-person transmission does not appear to be a significant problem with the other
16 viruses related to Andes virus, a unique situation has been identified for some of these viruses in
17 which several laboratory workers and animal handlers were infected after exposure to infected
18 laboratory rat colonies (LeDuc 1989).

19
20 Virus injected intramuscularly causes disease in Syrian hamsters closely resembling HPS in
21 humans; lethal in hamsters when administered by routes that model most common routes of
22 human infection, i.e., the subcutaneous, intranasal, and intragastric routes even at very low doses,
23 i.e., highly pathogenic when introduced by the mucosal routes ($LD_{50} = 100$ PFU) (Hooper, Ferro,
24 and Wahl-Jensen 2008).

25
26 Transmission of virus among *O. longicaudatus* reservoir populations occurs with face-to-face
27 and excrement exposure, from 130 attempts with direct contact, 12.3 percent resulted in virus
28 transmission, and with infectious animals from 93 attempts, 16 animal infections (17.2 percent)
29 occurred; transmission from *O. longicaudatus* to *A. olivaceus*, as well (Padula et al. 2004).

Bats and birds might be involved in transmission cycle of some hantaviruses (Centers for Disease Control and Prevention 2008).

Virus titers/concentrations/pathogenesis

In Vero cells, 10^6 CCID₅₀/mL produced in roller bottles (Johnson 2008).

Lethal dose required to kill 50 percent of Syrian hamsters (LD₅₀) calculated to be 8 PFU; virus titers reach $10^{8.0-9.0}$ PFU/mL in liver (Hooper et al. 2001).

A 50 percent lethal dose (LD₅₀) of 1.54 FFU (focus-forming units) for i.p. injections in hamsters was determined by inoculating a ten-fold serial dilution of 0.8 to 80,000 FFU (Safronetz et al. 2009).

Titers to 10^{6-7} PFU/mL in serum, 10^{7-8} PFU/mL in whole blood of infected hamsters (Wahl-Jensen et al. 2007).

Pathogen stability

The D₃₇ value (the dose of UV₂₅₄ in J/m² that reduces the surviving virus to 37% of its original) for hanta virus (a related virus, but not Andes virus) was calculated to be 12 [HL=28 min at maximum solar radiation] (Lytle and Sagripanti 2005).

Inactivated by heat, detergents, organic solvents, and hypochlorite solutions (Pini 2004).

Indication that viruses with structural lipids survive best in aerosols at low RH (Benbough 1971).

Virus not completely inactivated by secretions in the airways or gut (e.g., saliva, mucus, and gastric juices) possibly because of inherent stability of the virions, rapid adherence and uptake of virions by cells lining the luminal space, or a combination of inherent stability and rapid uptake (Hooper, Ferro, and Wahl-Jensen 2008).

Vectors

ANDV is not known to be vector-borne.

Other epidemiological/ecological data

Spring-summer seasonality of human infections (Centers for Disease Control and Prevention 2008).

In contrast to old world hantaviruses, which cause hemorrhagic fever with renal syndrome (HFRS), new world hantaviruses cause hantavirus cardio-pulmonary [or pulmonary] syndrome; death from cardiogenic shock rather than from respiratory failure (Mertz et al. 2006).

Each hantavirus species associated with a rodent reservoir, which is persistently and asymptotically infected (Mertz et al. 2006).

Field data suggest that transmission in host populations occurs horizontally and more frequently among male than female rodents; transmission from rodent to rodent believed to occur primarily after weaning and through physical contact, perhaps through aggressive behavior, such as fighting (Centers for Disease Control and Prevention 2008; Schonrich et al. 2008).

1995, a novel hantavirus (Andes virus) identified in samples from patients in southern Argentina (Lopez et al. 1996; Wells et al. 1997; Toro et al. 1998).

Most hemorrhagic fever viruses are zoonoses; found in both temperate and tropical habitats; generally infect both genders and all ages, although there might be an influence of occupational exposure; transmission to humans is frequently by bite of an infected tick or mosquito or via aerosol from infected rodent hosts; aerosol and nosocomial transmission are especially important with Junin [and, probably Andes] viruses; seasonality of hemorrhagic fever among humans is influenced by the dynamics of infected arthropod or vertebrate hosts; mammals, especially rodents, appear to be important natural hosts for many hemorrhagic fever viruses; transmission cycle for each hemorrhagic fever virus is distinct and dependent on the characteristics of the primary vector species and the possibility for its contact with humans (LeDuc 1989).

Most viruses in the genus are capable of causing severe human disease and death; most of the hantaviral diseases are highly seasonal, with peak incidence in the late fall and early winter for

1 the Asian and Scandinavian viruses, although a recently recognized member of the group, found
2 in Greece, appears to have a different seasonality, with most human disease seen in the warmer
3 months of the year, probably because of differences in the behavior of the natural rodent host of
4 the virus in that area; populations at greatest risk for infection are those with significant rural
5 exposure, such as farmers, shepherds, and persons involved with harvesting grains (LeDuc
6 1989).

7
8 As a group, the other VHF agents are linked to the ecology of their vectors or reservoirs, whether
9 rodents or arthropods (Geisbert and Jahrling 2004).

10
11 Risk of HCPS was greatest among sex partners; among household contacts who developed
12 HCPS, viremia preceded onset of symptoms, and appearance of anti-hantavirus antibodies by up
13 to 2 weeks (Ferres et al. 2007).

14
15 First isolated from asymptomatic 10-year-old male 6 days before death from HPS; virus isolated
16 in Vero cells and identified via rt-PCR, ELISA, and IFAT (Galeno et al. 2002).
17 Rio Negro Province, Argentina, human cases of HPS in subantarctic forests and virus in *O.*
18 *longicaudatus* (Larrieu et al. 2008).

19
20 Northern Argentina, HPS-endemic area composes Salta and Jujuy provinces; 1997–2000, 30
21 HPS cases diagnosed in Jujuy province (population 512,329) (Pini et al. 2003).

22
23 As documented with other hantaviruses, population booms of *Oryzomys longicaudatus* and *A.*
24 *olivaceus* associated with availability of feed/seeds; flowering and seeding of Chilean shrub
25 provides abundant food for cyclic population expansion of AND virus reservoirs (Murúa 1996).

26 27 **Therapeutics/vaccines**

28 Ribavirin of questionable efficacy (Mertz et al. 2006).

1 DNA vaccine for Hantaan virus (HTNV, an AndesV relative) tested in mice alone or in various
2 combinations; vaccines delivered by gene gun; in general, the HTNV DNA vaccine not very
3 immunogenic in mice (Spik et al. 2006).

4
5 Constructed expression plasmid, pWRG/AND-M, containing full-length M genome segment of
6 Andes virus tested in Rhesus monkeys via gene gun; elicits high-titer NAbs in NHPs that
7 protects hamsters from lethal HPS, even when administered 5 days after challenge (Custer et al.
8 2003).

9
10 In passive transfer experiments, neutralizing antibodies produced in rabbits vaccinated by
11 electroporation with ANDV M gene-based DNA vaccine, pWRG/AND-M protected hamsters
12 against intranasal challenge (21 LD₅₀) (Hooper, Ferro, and Wahl-Jensen 2008).

13
14 DNA vaccine plasmid (pWRG/HA-M) that contains both the HTNV and ANDV M gene
15 segments tested in Rhesus macaques, produced antibodies that bound the M gene products (i.e.,
16 G1 and G2 GPs), and neutralized both HTNV and ANDV; neutralizing antibody titers elicited by
17 the dual-immunogen pWRG/HA-M, or single-immunogen plasmids expressing only the HTNV
18 or ANDV GPs, increased rapidly to high levels after a booster vaccination administered 1–2
19 years after the initial vaccination series (Hooper et al. 2006).

20
21 Replication-deficient adenovirus vectors constructed to deliver either nucleocapsid protein AdN,
22 GP AdG_N, or GP AdG_c were able both alone and in combination to prevent illness in the Syrian
23 hamster model (Safronetz et al. 2009).

24
25 **Other remarks**

26 Hantavirus cardiopulmonary syndrome in humans, or HPS (renal variant) (McCaughey and Hart
27 2000) (Centers for Disease Control and Prevention 2008).

28
29 Zoonotic disease transmitted from rodents (Centers for Disease Control and Prevention 2008).

30 Hantaviruses are not arboviruses (no arthropod vectors) (Centers for Disease Control and
31 Prevention 2008).

Recommend laboratory work at BSL-3 (Mertz et al. 2006) except BSL-4 biocontainment is required when infecting rodent species permissive for chronic infection (CDC and NIH 2007).

Common pathogenic feature of the hemorrhagic fever viruses is ability to disable the host immune response by attacking and manipulating the cells that initiate the antiviral response (Geisbert and Jahrling 2004).

Taxonomy/antigenic relationships/synonyms

Genus *Hantavirus*, family Bunyaviridae (Centers for Disease Control and Prevention 2008). More than 20 recognized sero/genotypes of hantaviruses; each type appears to be specific to a different rodent host (McCaughey and Hart 2000).

12 distinct viruses associated with hemorrhagic fever in humans are classified among four families: family Bunyaviridae, which includes Rift Valley fever, Crimean-Congo hemorrhagic fever, and the genus *Hantavirus* (Hantaan viruses) (LeDuc 1989).

Known that at least four (and possibly several more) distinct viruses make up the genus *Hantavirus* (LeDuc 1989).

Almost 30 different hantaviruses have been identified, more than half of which are known to cause disease (McElroy et al. 2002; Schonrich et al. 2008).

C.1.2.2 Ebola virus (EBOV)

Host range

a. Field

Virus first isolated from an adult female human with a severe, prostrating, febrile illness with hemorrhagic signs and rash, located in undulating tropical rain forest at 400 m altitude in Zaire (Pattyn, Bowen, and Webb 2008).

Isolated in intraperitoneally inoculated guinea pigs and in cell cultures (Pattyn, Bowen, and Webb 2008).

1
2 Hemorrhagic fever with rash, death in humans; 651 cases with 452 deaths reported in
3 Sudan and Zaire [Democratic Republic of Congo], 1976 (Pattyn, Bowen, and Webb
4 2008). Cases listed above include several nosocomial hospital personnel infections in all
5 three outbreaks and, in addition, there were about 90 cases by syringe needle
6 transmission in Zaire; 1976 (Pattyn, Bowen, and Webb 2008). Numerous epidemics in
7 sub-Saharan Africa (Swanepoel 1994; Warfield, Deal, and Bavari 2009).

8
9 Virus believed to be transmitted to humans via contact with infected animal host
10 (Swanepoel et al. 1996; Pourrut et al. 2005).

11
12 Zoonotic virus with devastating effect on western lowland gorillas of Central Africa
13 (Leroy, Rouquet, et al. 2004).

14
15 Fruit bats/Old world fruit bats/flying foxes in three genera of *Pteropus*, family
16 *Pteropodidae* [*Hypsignathus monstrosus*, *Epomops franqueti*, and *Myonycteris torquata*]
17 are considered the reservoir (Leroy et al. 2005; Warfield, Deal, and Bavari 2009).

18
19 No virus isolates from more than 30,000 mammals, birds, reptiles, amphibians, and
20 arthropods captured in epidemic areas (Pourrut et al. 2005; Groseth, Feldmann, and
21 Strong 2007; LeDuc 1989).

22
23 Virus isolated from gorilla, chimpanzee, and duiker carcasses in 2001 and 2003 (Leroy,
24 Rouquet, et al. 2004).

25
26 Natural reservoir remains unknown, but unlikely to be NHPs, because they are especially
27 sensitive to filovirus infection as evidenced by both experimental studies and outbreaks
28 among gorillas and chimpanzees in Africa; surveys of wild populations as well as
29 experimental inoculations of animals, arthropods, and even plants have failed to identify
30 a potential reservoir (Leffel and Reed 2004) 2006, massive gorilla and chimpanzee die-
31 offs in the Democratic Republic of Congo due to an EBOV outbreak serves as an

1 unfortunate testament to the deadly nature of filovirus infections in primates (Swenson et
2 al. 2008).

3
4 Filoviruses circulate widely in the central African rain forests and can infect humans and
5 many NHPs, including previously undocumented members, e.g., mandrills and baboons
6 as well as chimps and gorillas, which has created substantial additional concern for these
7 already endangered species (McCormick 2004).

8
9 In central Africa rain forests where outbreaks occurred during 2001–2005, fruit bats of
10 the suborder *Megachiroptera* were naturally infected with EBOV without clinical signs:
11 *Hypsignathus monstrosus*, hammer-headed fruit bat; *Epomops franqueti*, singing fruit
12 bat; *Myonycteris torquata*, little-collared fruit bat (Gonzalez, Pourrut, and Leroy 2007).

13
14 Test of more than 1,000 small vertebrates during 2001–2003 outbreaks in humans and
15 great apes in Gabon and DRC; evidence of asymptomatic infection in 3 species of fruit
16 bat indicating possible reservoir for EBOV (Leroy et al. 2005).

17
18 IgG for EBOV detected in serum from *Hypsignathus monstrosus*, *Epomops franqueti*,
19 *Myonycteris torquata*; no virus isolated, but nucleotide sequences demonstrated (Leroy et
20 al. 2005).

21
22 EBO-Reston, Philippines, 2007–2008, first known outbreak in pigs; previously found
23 only in sick monkeys and few contacts; no known incidents of serious illness or death in
24 humans; concern “because this is new, because it is unexpected, because virus is slightly
25 different from previous EBO-Reston isolates, and because it is in pigs,” which live in
26 close proximity to humans; farms quarantined and pigs being depopulated (Normile
27 2009).

28 29 **b. Experimental**

30 Causes sickness and death in newborn and suckling mice inoculated IC, SC, and IP
31 (Pattyn, Bowen, and Webb 2008).

1
2 Death in guinea pigs inoculated IP, titers in liver to $10^{6.5}$ CCID₅₀/mL (Pattyn, Bowen, and
3 Webb 2008).

4 Fever and death in IP inoculated vervet, cynomolgous, and rhesus monkeys with virus
5 titers to $10^{6.0}$ to $10^{7.5}$ CCID₅₀/mL in blood, serum, liver, and spleen (Pattyn, Bowen, and
6 Webb 2008).

7
8 Of 24 plant species and 19 vertebrate species experimentally inoculated, only bats
9 became infected (Swanepoel et al. 1996).

10
11 Clinical signs absent in bats.

12
13 Several NHP species have been used to model EBOV (Zaire) HF including African green
14 monkeys (*Chlorocebus aethiops*, formerly *Cercopithecus aethiops*), cynomolgus
15 macaques (*M. fascicularis*), rhesus macaques (*M. mulatta*), and hamadryad baboons
16 (*Papio hamadryas*; similar pathologic features of EBOV infection have been documented
17 among these species; however, African green monkeys do not present with a macular
18 cutaneous rash, which is a characteristic feature of disease in macaques and baboons and
19 a prominent feature of human disease (Geisbert et al. 2003).

20
21 In cynomolgus monkeys inoculated i.m. with 10^3 PFU, onset of plasma viremia was
22 rapid, within 3 days, ranged from $10^{1.4}$ to $10^{4.2}$ PFU/ml (mean, peak viremia of $10^{6.9}$
23 occurred at 6 dpi (Geisbert et al. 2003).

24
25 NHP models for human disease comparative; rodent (mouse, guinea pigs) models have
26 significant gaps and used for evaluating antivirals (Paragas and Geisbert 2006).

27
28 Laboratory studies show that fruit and insectivorous bats support replication and
29 circulation of high titers of EBOV without showing overt illness (Hensley et al. 2005).

Several primate species used to model human filoviral HF, including African green monkeys, cynomolgus macaques, rhesus macaques (*M. mulatta*), and hamadryad baboons (*Papio hamadryas*) (Hensley et al. 2005).

Hypsignathus monstrosus, hammer-headed fruit bat; *Epomops franqueti*, singing fruit bat; *Myonycteris torquata*, little-collared fruit bat confirmed as reservoirs (Gonzalez, Pourrut, and Leroy 2007).

33 varieties of 24 species of plants and 19 species of vertebrates and invertebrates were inoculated with Zaire EBOV; fruit and insectivorous bats supported replication and circulation of high titers of virus without necessarily becoming ill; deaths occurred only among bats that had not adapted to the diet fed in the laboratory (i.e., death might not have been due to EBOV infection) (Swanepoel et al. 1996).

Rhesus monkeys exposed to $1 \times 10^{5.2}$, by i.m., oral, or conjunctival routes experienced lethal infection (Jaax et al. 1996).

Prevalence/incidence/attack rate

There have been more outbreaks of *Zaire ebolavirus* than any other strain (Mahanty and Bray 2004).

Using EBOV-Zaire as antigen in an ELISA test, an overall seroprevalence of 5.3 percent was found among populations in the rain forest of the Central African Republic (Gonzalez et al. 2000).

Using ELISA for Zaire subtype, 1985–2000, Cameroun, Central African Republic, Gabon—in 638 primates seroprevalence of wild-born chimpanzees (*Pan troglodytes*), 12.9 percent; antibodies in *Papio annulus* [baboon (4.0 percent)], *Gorilla gorilla* (6.75 percent), *Mandrillus* spp (2.8 percent), *Cercopithecus neglectus* (0.9 percent) (Leroy, Telfer, et al. 2004).

Dogs in Ebola outbreak areas had Ebola-specific IgG rates ranging from 8.9 percent to 25.2 percent; in areas with active cases, seroprevalence was 31.8 percent; infections subclinical (Allela et al. 2005).

Sudan, 1976, secondary attack rate of 12 percent (Feldmann, Slenczka, and Klenk 1996).
Zaire, 1976, 5 percent secondary attack rate, 20 percent in close relatives of patients (Feldmann, Slenczka, and Klenk 1996).

EBO-Reston, isolated in 1989 from cynomolgus macaques imported from the Philippines for medical research in the United States; unusual numbers of the monkeys started dying in quarantine, about 1000 monkeys died or were euthanized; subsequently, 21 animal handlers at the Philippine exporter and four employees of the quarantine facility were found to have antibodies to the virus, indicating that they had been infected, but just one reported flulike symptoms (Normile 2009).

R_0 /incubation period/infectious period/infectious dose

R_0 is estimated to be 1.83 (SD 0.06) and 1.34 (SD 0.03) for the 1995 Congo and 2000 Uganda outbreaks, respectively (Chowell, Hengartner, et al. 2004). Alternate analysis gives median 1.89 (Interquartile range 1.66-2.28) based on empirical data from Zaire 1976 outbreak (Chowell, Hengartner, et al. 2004).

R_0 of 1.36 (SD 0.13) estimated from 1995 Congo outbreak (Lekone and Finkenstadt 2006).
1.50 (90% confidence interval: (0.85-2.08)) estimated from 2000 Uganda outbreak (Lloyd-Smith et al. 2005).

Secondary transmission of EBOV in humans caused by close contact with infected patients, direct contact with infected blood, tissue, or body fluids, or improper needle hygiene (Jaax et al. 1995).

Human-to-human transmission is possible for all VHF viruses; majority of the person-to-person transmission for the arenaviruses and filoviruses attributed to direct contact with infected blood

1 and body fluids; potential for airborne transmission of the VHF agents appears to be an
2 infrequent event but cannot be categorically excluded as a mode of transmission (Geisbert and
3 Jahrling 2004).

4
5 Infectious doses are unknown (Said et al. 2007; Johnson 2008).

6 "Incubation period for African-derived strains 3–8 days in primary cases, slightly longer in
7 secondary cases; however cases with incubation periods of 19 and 21 days have occurred (King
8 2008).

9
10 High mortality rate, low infective dose indicated de facto of Category A agent (Leffel and Reed
11 2004).

12
13 **Morbidity/case fatality ratio**

14 Results from serologic studies to determine the prevalence of exposure to the virus among
15 populations in endemic areas suggest that clinically asymptomatic, or minimally symptomatic,
16 infections occur (Gonzalez et al. 2000).

17
18 Mortality of 23 to 90 percent, depending on the virus strain (Leffel and Reed 2004).

19 CFR = 20–90 percent (Said et al. 2007).

20
21 CFR ranges from 41 to 90 percent (Warfield et al. 2004).

22
23 Mortality ranges from 22 to 88 percent (Feldmann, Slenczka, and Klenk 1996).

24
25 Zaire and Sudan strains appear to be the most virulent, with the mortality rate approaching 90
26 percent for the Zaire strain and 50 to 60 percent for the Sudan strain (Leffel and Reed 2004;
27 Groseth, Feldmann, and Strong 2007).

28
29 Reston and Ivory Coast strains virulent for NHPs, but the few reported cases in humans have not
30 resulted in any fatalities, although the Ivory Coast strain appears to be highly pathogenic in
31 humans (Leffel and Reed 2004).

1
2 Case fatality rate is 85–90 percent for the Zaire strains and 25 percent for Uganda strains
3 (Warfield, Deal, and Bavari 2009; King 2008).

4
5 The strain of Ebola in Zaire has one of the highest case fatality rate of any human pathogenic
6 virus, roughly 90 percent (Warfield, Deal, and Bavari 2009; King 2008).

7
8 Zaire ebolavirus has the highest case fatality rate, up to 90 percent in some epidemics, with an
9 average case fatality rate of approximately 83 percent in patients over 27 years; case fatality rates
10 were 88 percent in 1976, 100 percent in 1977, 59 percent in 1994, 81 percent in 1995, 73 percent
11 in 1996, 80 percent in 2001–2002, and 90 percent in 2003 (King 2008).

12
13 Sudan EBOV isolated in 1976; average fatality rates were 54 percent in 1976, 68 percent in
14 1979, and 53 percent in 2000/2001; average case-fatality rate is 54 percent (McCormick and
15 Fisher-Hoch 1999; King 2008).

16
17 Strain isolated later in Sudan has a case fatality rate of around 50 percent (King 2008).

18
19 Reston ebolavirus is suspected as either another subtype or a new filovirus or Asian origin
20 discovered in crab-eating macaques in 1989; despite its status as a BSL-4 pathogen, it is non-
21 pathogenic to humans and mildly fatal to monkeys (McCormick and Fisher-Hoch 1999; King
22 2008).

23
24 During the incident in which *Reston ebolavirus* was discovered, six animal handlers
25 seroconverted [one of whom had cut himself while performing a necropsy on an infected
26 monkey; and failed to become ill]; concluded that the virus had a very low pathogenicity for
27 humans (McCormick and Fisher-Hoch 1999; King 2008).

28
29 Tai ebolavirus isolated in 1994, Côte d’Ivoire from chimpanzees, possibly infected from eating
30 Western Red *Colobus* monkeys; one scientist performing necropsies was infected with febrile
31 illness, but recovered 6 weeks after infection (McCormick and Fisher-Hoch 1999; King 2008).

1 Bundybugyo ebolavirus isolated in Uganda in 2007; total of 149 cases with 37 deaths and a case
2 fatality rate of 24.83 percent(King 2008).

3
4 DRC, 11 deaths/35 infected humans in 2008; in 2007, 217 illnesses; in 1995, 245 deaths (King
5 2008).

6
7 Uganda, 2007, 37 dead of 149 cases (King 2008).

8
9 Emerging pathogens, Marburg and EBOV cause very severe hemorrhagic fevers and mortality as
10 high as 90 percent (Huggins, Zhang, and Bray 1999).

11
12 High rates of morbidity and mortality (Huggins, Zhang, and Bray 1999).

13
14 Acute mortality caused by Zaire species of EBOV is approximately 80 percent in human
15 outbreaks and > 90 percent in monkey models of the genus *Macaca* (Geisbert et al. 2003).

16 Sudan, 1976, 1/3 hospital staff infected with 41 dead; approx 15 generations of person-to-person
17 transmission due to close contact; total of 284 probable/confirmed cases with 151 (53 percent)
18 dead (Feldmann, Slenczka, and Klenk 1996).

19
20 Sudan, 1979, 33 cases with 22 dead (65 percent mortality); 7 generations of transmission, with
21 89 percent mortality in first 4 generations and 38 percent in last 3 generations (Feldmann,
22 Slenczka, and Klenk 1996).

23
24 2001–2003, central African Republic, Gabon: 5 outbreaks, 313 cases, 264 dead; 78 percent
25 patients died within 5–7 days; coincided with outbreaks in gorillas, chimpanzees, and duikers
26 (Leroy, Telfer, et al. 2004).

27
28 1976, Ebola Zaire and Ebola Sudan outbreaks associated with high mortality, especially among
29 healthcare providers; secondary transmission propagated by reuse of needles and syringes;
30 outbreak in the DRC involved 318 cases with 88 percent mortality; in Sudan, mortality was 53
31 percent among 284 total cases (Salvaggio and Baddley 2004).

Mortality 100 percent when infection source was contaminated syringes and needles (Salvaggio and Baddley 2004).

* Outbreaks of filovirus infection in human beings or captive NHPs (Mahanty and Bray 2004).

Table C-9. EBOV infections

Date	Location	Source of infection	Number of cases	Case-fatality rate (%)
<i>Zaire ebolavirus</i>				
1976	Zaire (now DRC)	Unknown	318	88
1977	Zaire (now DRC)	Unknown	1	100
1994	Gabon	Unknown	49	65
1995	DRC	Unknown	317	77
1996	Gabon	Dead chimp	37	57
1996	Gabon	Unknown	60	75
2001	Gabon	Contact with NHP	123	79
2003	Republic of Congo	Contact with NHP	143	90
<i>Sudan ebolavirus</i>				
1976	Sudan	Unknown	284	53
1979	Sudan	Unknown	34	65
2000	Uganda	Unknown	425	53
<i>Ivory Coast ebolavirus</i>				
1994	Cote d'Ivoire	Dead chimp	10	21
<i>Reston ebolavirus</i>				
1989	Virginia, USA	Imported macaques	--	--

Date	Location	Source of infection	Number of cases	Case-fatality rate (%)
1990	Pennsylvania, USA Imported macaques	--		--
1992	Italy		Imported macaques	--
1996	Texas, USA	Imported macaques	--	

DRC = Democratic Republic of Congo; NHP = nonhuman primate.

* In 1976 more than 550 cases of severe hemorrhagic fever with more than 430 fatalities occurred simultaneously in [DRC] and Sudan (Beer, Kurth, and Bukreyev 1999).

Aerosol infection/routes of transmission

Not naturally transmitted by aerosol, but highly infectious as respirable particles under laboratory conditions (Leffel and Reed 2004).

“Epidemiological data from natural outbreaks would suggest ... that the survivability of filoviruses as a respirable particle is very short outside of controlled laboratory conditions, or that infected patients do not expire infectious virus particles” (Leffel and Reed 2004).

Large outbreaks usually driven by person-to-person transmission, with caregivers both at home and in hospitals at particular risk (Bausch et al. 2007).

LAI can occur by needle stick (Emond et al. 1977).

Human-to-human transmission via contact with blood and body fluids and via contaminated medical equipment; might infect via skin and mucous membranes (Leffel and Reed 2004).

1 Transmission primarily associated with close contact with infected persons and perhaps by
2 contaminated needles (LeDuc 1989).

3 Communicable primarily through direct contact with infected blood or tissues or both; some
4 evidence of infectivity via the respiratory, oral, and conjunctival routes (Leffel and Reed 2004).

5
6 Most documented cases have been either secondary or nosocomial infections; institution of basic
7 isolation procedures generally sufficient to stop outbreaks (Leffel and Reed 2004).

8
9 During the 2000 EBOV outbreak in Uganda, however, 14 healthcare workers were exposed after
10 isolation procedures were instituted; while possibility of aerosol exposure cannot be ruled out in
11 some cases, it is clear that direct contact is the primary means of transmission (Leffel and Reed
12 2004).

13 Although transmission during naturally occurring outbreaks is believed to occur from close
14 personal contact with blood or other body fluids, or the failure to practice proper medical
15 hygiene as relates to blood-borne pathogens, in the past 10 years several publications have
16 indicated that filoviruses possess a number of properties that would make them suitable as
17 biological weapons (Leffel and Reed 2004).

18
19 Airborne transmission between monkeys demonstrated by an accidental outbreak in a laboratory,
20 but very limited evidence for human-to-human airborne transmission in any reported epidemics
21 (Peterson, Bauer, and Mills 2004).

22
23 After the original outbreak of MARV in 1967, concern increased about transmission of
24 filoviruses, especially aerosol transmission, even with few secondary cases; epidemiological
25 analysis of the outbreak suggested aerosol transmission between shipments of primates had
26 occurred (Leffel and Reed 2004).

27
28 1995, lethal experimental infection of rhesus monkeys by aerosol exposure to Ebola Zaire;
29 exposed to doses of 400 pfu or 50,000 pfu; all monkeys died or were euthanized after becoming
30 moribund between days 7 and 9 postexposure; within the same time frame that rhesus monkeys
31 die from parenteral exposure to Ebola Zaire (Leffel and Reed 2004).

1
2 Filoviruses can infect via aerosol, and extraordinarily low doses are lethal for both guinea pigs
3 and NHPs; epidemiological data from natural outbreaks suggests that the aerosol infectious dose
4 for humans is considerably higher, that survivability of filoviruses as a respirable particle is very
5 short outside controlled laboratory conditions or that infected patients do not expire infectious
6 virus particles (Leffel and Reed 2004).

7
8 Reported transmission of Zaire strain to Rhesus monkey (*M. mulatta*) controls under BSL-4
9 biocontainment without direct contact with infected monkeys in same room; most likely route of
10 infection by aerosol, oral, or conjunctival exposure to virus-laden droplets secreted or excreted
11 from infected monkeys (Jaax et al. 1995). The study did not exclude the possibility that exposure
12 had occurred from excreted virus that was aerosolized during routine cleaning of the cages rather
13 than primate-to-primate transmission (Leffel and Reed 2004).

14
15 Might not be highly contagious early in infection and contact with a patient might not transmit
16 the virus; as the illness progresses, bodily fluids from diarrhea, vomiting, and bleeding represent
17 an extreme biohazard (Bausch et al. 2007; Leffel and Reed 2004).

18
19 Secondary transmission of EBOV in humans caused by close contact with infected patients,
20 direct contact with infected blood, tissue, or body fluids, or improper needle hygiene (Jaax et al.
21 1995).

22
23 Secondary cases from direct physical contact with ill persons, with additional risk from exposure
24 to body fluids (Dowell et al. 1999).

25
26 Transmitted from infected patients via blood, secretions (saliva, respiratory, urine, feces,
27 vomitus), organs, semen; via handling and eating ill or dead animals; via contaminated syringes
28 and needles; associated with customary burial practices (Curtis 2006).

29
30 Transmission via breaks in skin or contact with mucous membranes (Jaax et al. 1996).

1 EBOV transmitted via unprotected physical contact with bodily fluids from infected persons,
2 Uganda studies with clinical specimens from 26 laboratory-confirmed cases and from
3 environmental specimens collected from an isolation ward using culture or rtPCR; positives in
4 16 of 54 clinical specimens (including saliva, stool, semen, breast milk, tears, nasal blood, and a
5 skin swab) and in 2 of 33 environmental specimens; concluded that EBOV is shed in a wide
6 variety of bodily fluids during the acute period of illness, but risk of transmission from fomites in
7 an isolation ward and from convalescent patients is low when recommended infection control
8 guidelines for the viral hemorrhagic fevers are followed (Bausch et al. 2007).

9
10 Kikwit, 1995, person-to-person transmission by intimate contact, possible droplet and small
11 aerosol transmission; reservoir unknown (Feldmann, Slenczka, and Klenk 1996).

12
13 Transmission via inhalation, inoculation, ingestion, person-to-person, direct contact, and by
14 doing autopsies (Said et al. 2007).

15
16 Transmission via respiratory droplets less than 2 m, but aerosolized virions have greater range
17 (Said et al. 2007).

18
19 Little data from animal studies with aerosolized filoviruses; animal models of filovirus exposure
20 are not well characterized, and there are discrepancies between these models and what has been
21 observed in human outbreaks (Leffel and Reed 2004).

22 Some recent outbreaks attributed to the consumption or handling of bush meat (Leffel and Reed
23 2004).

24
25 Human infections documented via handling of infected dead and living chimpanzees, gorillas,
26 and forest antelopes (Peterson, Bauer, and Mills 2004).

27
28 No documented sexual transmission, but PCR signal documented in semen of partner of woman
29 who seroconverted (Salvaggio and Baddley 2004).

30
31 Possible infections from breast milk (Salvaggio and Baddley 2004).

1 Risk of transmission to infants from breast milk and of sexual transmission from contaminated
2 semen (Bausch et al. 2007).

3
4 Isolation of EBOV from only one saliva specimen, in contrast to the 8 that were RT-PCR
5 positive, suggests that virus is rapidly inactivated by salivary enzymes or other factors in the oral
6 cavity that are unfavorable to virus persistence and replication (Bausch et al. 2007).

7
8 Fruit bats eaten by local populations in outbreak areas and could be the source of human
9 infections (Leroy et al. 2005) (Leroy et al. 2005).

10
11 While feeding, chronically, asymptomatic infected bats shed the virus in saliva; drop partially
12 eaten fruit and masticated fruit pulp to the ground where ground-dwelling mammals [great apes
13 and forest duikers (*Cephalophus* spp) particularly sensitive to the virus] eat the fruit/pulp and are
14 infected; during reproductive periods, high titers of virus are found in birthing fluids, blood, and
15 placental tissues (Gonzalez, Pourrut, and Leroy 2007).

16
17 Experimental transmission in monkeys via aerosols and direct inoculation (Jaax et al. 1996).

18
19 Rhesus monkeys infected via aerosol (droplet size 0.8–1.2 μm) with doses as low as 400 PFU
20 caused rapidly fatal disease in 4–5 days (Johnson et al. 1995).

21
22 **Virus titers/concentrations/pathogenesis**

23 Vero cells, 2.5×10^7 – 10^8 CCID₅₀/mL; max 3 L quantities produced in roller bottles (Johnson
24 2008).

25
26 Vero cells, titer $10^{7.3}$ (Halfmann et al. 2008).

27
28 Vero cells, titer $10^{5.5}$ CCID₅₀/mL from human serum (Pattyn, Bowen, and Webb 2008).

29
30 Vero cells, titer $10^{6.4}$ PFU/mL (Pattyn, Bowen, and Webb 2008).

Virus titer tissue burdens via plaque formation in VERO cells = 2.5×10^6 pfu; via IFA = 3.0×10^7 TCID₅₀; Intracerebral suckling mouse inoculation = 9.0×10^6 MICLD₅₀ (Moe, Lambert, and Lupton 1981).

Rhesus monkeys: in interferon-treated; $10^{5.7}$ PFU/g lung, $10^{5.2}$ PFU/g lymph node, $10^{4.2}$ /g heart, $10^{4.1}$ /g gonad; in untreated, $10^{4.5}$ PFU/g lung, $10^{4.0}$ PFU/g lymph node, $10^{3.9}$ PFU/g heart, $10^{3.5}$ PFU/g gonad (Jaax et al. 1995).

Cynomolgus monkeys infected with EBOZ virus- viremias more than $10^{7.0}$ PFU/mL (Jahrling et al. 1996).

Viremia titers in Rhesus macaques attain 10^{7-8} PFU/mL (Jahrling et al. 2007; Martin et al. 2006).

Mice inoculated with lethal dose: on day 2, liver had an average virus titer of 3×10^5 PFU/g liver and spleen had 2×10^6 PFU/g; on day 3, liver had an average virus titer of 2×10^7 PFU/g and spleen had 2×10^8 PFU/g (Huggins, Zhang, and Bray 1999).

EBOV replicated in bats (*Tadarida condylura*, Angola free-tailed bat; *T. pumila*, little free-tailed bat; *Epomophorus wahlbergi*, Wahlberg's epauletted fruit bat): titers of $10^{4.6}$ – $10^{7.0}$ fluorescent focus-forming units (FFU)/mL recorded in sera and titers of $10^{2.0}$ – $10^{6.5}$ FFU/g in pooled viscera of fruit bats; virus recovered from feces of a fruit bat on day 21 postinoculation (Swanepoel et al. 1996).

Pathogen stability

Based on experimental data, aerosol decay rates for EBOV were calculated to be 15 and 24 minute half-lives for the Zaire and Reston strains, respectively (Piercy et al. 2010).

Filoviruses are relatively stable in aerosols, retain virulence after lyophilization, and can persist for long periods on contaminated surfaces (Leffel and Reed 2004).

1 Predicted inactivation of a filovirus was calculated for six geographic points for as many as five
2 times of year. The time for a 1 log decrease varied from 20 to 100 minutes[HL range of 6 to 30
3 min] (Lytle and Sagripanti 2005). The D_{37} value (the dose of UV_{254} in J/m^2 that reduces the
4 surviving virus to 37% of its original) for filovirus was calculated to be 7.3 [HL=17 min at
5 maximum solar radiation] (Lytle and Sagripanti 2005).

6
7 Indication that viruses with structural lipids survive best in aerosols at low RH (Benbough 1971).
8 UV radiation inactivates viruses by chemically changing the RNA and DNA; most effective UV
9 is 250 nm; filoviruses [MARV and EBOV] most sensitive to solar UV_{254} , requiring 20'–100' at
10 mid-day exposure to inactivate 1 \log_{10} of virus: bunyaviruses (hantaviruses [AND virus] and
11 RVFV), arenaviruses (Lassa, Junin), and flaviviruses (TBE complex viruses) more resistant
12 (Lytle and Sagripanti 2005).

13
14 Filoviruses retain infectivity at room temperature on environmental surfaces; thus, fomites could
15 be sources of transmission, e.g., blankets and sleeping mats identified (Salvaggio and Baddley
16 2004).

17
18 Animal carcasses (NHP) left in the forest are not infectious after 3–4 days (Leroy, Rouquet, et al.
19 2004).

20
21 EBOV and MARV survive for weeks; rapidly inactivated in environment, being sensitive to
22 heat, sunlight, or drying [Note: Some data reported in this section by others might challenge that
23 position]; susceptible to chlorine disinfectants, heating to 60 °C for 1 hour, UV light; survives in
24 carcasses/body fluids and on fomites (Said et al. 2007).

25
26 Sensitive to lipid solvent (50 percent ether) at 4 °C, 1 hour, titer $10^{6.3}CCID_{50}/mL$ reduced to less
27 than $10^{1.7}CCID_{50}/mL$ (Pattyn, Bowen, and Webb 2008).

28
29 Negative-stranded RNA virus with lipid envelope; stable at a neutral pH, as a result of which the
30 virus can survive for long periods in blood, and viral isolation is possible weeks after exposure,
31 even during convalescence (Leffel and Reed 2004).

1 **Vectors**

2 No known vectors.

3
4 Maintenance and transmission unknown; recent evidence suggests that fruit bats might have a
5 reservoir role; it is unclear as to whether other species are involved or how transmission to
6 humans or apes occurs (Groseth, Feldmann, and Strong 2007).

7
8 EBO Reston virus does not replicate in *Culex* or *Aedes* mosquitoes or *Ornithodoros* ticks
9 (Monath 1999).

10
11 **Other epidemiological/ecological data**

12 Most hemorrhagic fever viruses are zoonoses; found in both temperate and tropical habitats;
13 generally infect both sexes and all ages, although there might be an influence of occupational
14 exposure; transmission to humans is frequently by bite of an infected tick or mosquito or via
15 aerosol from infected rodent hosts; aerosol and nosocomial transmission are especially important
16 with EBOV; seasonality of hemorrhagic fever among humans is influenced by the dynamics of
17 infected arthropod or vertebrate hosts; mammals, especially rodents, appear to be important
18 natural hosts for many hemorrhagic fever viruses; transmission cycle for each hemorrhagic fever
19 virus is distinct and dependent on the characteristics of the primary vector species and the
20 possibility for its contact with humans (LeDuc 1989).

21
22 EBOV first recognized during an outbreak of human disease, 1976; two major epidemics of what
23 in retrospect appears to have been sustained nosocomial transmission started within a few weeks
24 of one another, one in DRC and the other a few hundred miles away in southern Sudan;
25 subsequent to these outbreaks, isolated cases have occurred, and serologic surveys have found an
26 antibody to EBOV in other African countries, but, as yet, little is known as to how the viruses are
27 maintained in nature (LeDuc 1989; Feldmann, Slenczka, and Klenk 1996).

28
29 Near-simultaneous outbreaks of the Ebola Zaire and Sudan occurred in 1976; Reston and Ivory
30 Coast are virulent for NHPs, but the few reported cases in humans have not resulted in any
31 fatalities (Feldmann, Slenczka, and Klenk 1996; Leffel and Reed 2004).

1 Although a lot of epidemiological evidence of human transmission of disease is not available,
2 what is known suggests that transmission of EBOV does not occur before the appearance of
3 symptoms; experiments in NHPs support this assumption (Leffel and Reed 2004).

4
5 Reemergence in Kikwit, 1995 (Feldmann, Slenczka, and Klenk 1996).

6
7 For surveillance, failed to detect antibodies against EBOV in oral fluid specimens obtained from
8 patients with seropositive serum samples; patients with positive serum RT-PCR results had
9 positive results for their oral fluid specimens; oral fluid samples useful for investigation of Ebola
10 outbreaks (Formenty et al. 2006).

11
12 Ecological niche modeling of potential habitats (Peterson et al. 2006; Peterson, Bauer, and Mills
13 2004).

14
15 Persistence in body fluids from 12 convalescent patients studied via virus isolation and RT-PCR
16 during 1995 Ebola hemorrhagic fever outbreak in Kikwit, DRC; RNA detected for up to 33 days
17 in vaginal, rectal, and conjunctival swabs of one patient and up to 101 days in the seminal fluid
18 of four patients; infectious virus detected in one seminal fluid sample obtained 82 days after
19 disease onset; patient samples selected to include some from a suspected line of transmission
20 with at least three human-to-human passages, some from 5 survivors and 4 deceased patients,
21 and 2 from patients who provided multiple samples through convalescence (Rodriguez et al.
22 1999).

23
24 Geographic range of fruit bats (*Epomops franqueti*, *Hypsignathus monstrosus*, *Myonycteris*
25 *torquata*) overlaps the distribution of cases (Warfield, Deal, and Bavari 2009).

26
27 Late 1980s, an outbreak of EBOV occurred in an NHP-holding facility in Reston, Virginia;
28 appeared to jump from animal to animal and room to room in a manner that suggested aerosol
29 transmission; animal handlers in the facility seroconverted, indicating they had been infected;
30 identified as new subtype originating in the Philippines; suggestion that primates were infected
31 with Ebola Reston by aerosol exposure; no evidence to indicate that primate-to-primate

transmission by aerosol actually occurred; in an outbreak of Ebola Reston in the Philippines it was concluded that transmission between cages and buildings was due to poor sanitation and hygiene (Warfield, Deal, and Bavari 2009; Leffel and Reed 2004).

Therapeutics/vaccines

No approved vaccine or treatment is available (Feldmann, Slenczka, and Klenk 1996; Groseth, Feldmann, and Strong 2007; Warfield, Deal, and Bavari 2009).

No vaccine or therapy for EBOV or MBGV hemorrhagic fever is approved for human use (Geisbert et al. 2003).

Experimental vaccines have been produced for both Ebola and Marburg with 99 percent efficacy to protect monkeys from the disease; vaccine is based on either a recombinant vesicular stomatitis virus or adenovirus carrying the Ebola spike protein on its surface; vaccine trial demonstrated an immune response in humans, but the vaccine must be given within 1–4 days after the symptoms begin (Paragas and Geisbert 2006; Geisbert et al. 2008).

No standard treatment, but primarily supportive, including minimizing invasive procedures, balancing electrolytes, replacing coagulation factors lost due to dehydration to help stop bleeding, maintaining oxygen and blood levels, and treating any complicating infections; convalescent plasma shows promise, Ribavirin and interferon are ineffective, and administration of an inhibitor of coagulation (rNAPc2) has shown some benefit in monkeys [protecting 33 percent of infected monkeys from a usually 100 percent lethal infection- does not work on humans] (Swenson et al. 2008).

LAI (needle stick) treated with interferon and convalescent serum resulted in complete recovery (Emond et al. 1977).

No treatments for Marburg and EBO viral hemorrhagic fevers; ribavirin, an antiviral drug used to treat several other hemorrhagic fevers, has no *in vitro* effect on Marburg and EBOV, failed to

1 protect in multiple primate studies, and is unlikely to have any clinical value to human patients
2 (Huggins, Zhang, and Bray 1999).

3
4 Human convalescent plasma containing antibodies has been used for treatment in the past,
5 despite the lack of coherent clinical or experimental data regarding its use. Equine IgG with high
6 titer neutralizing antibodies to EBOV protected guinea pigs and baboons but failed to protect
7 rhesus monkeys (Huggins, Zhang, and Bray 1999).

8
9 In 2006, USAMRIID scientists announced a 75 percent recovery rate after infecting four Rhesus
10 monkeys and administering antisense drugs (Martin et al. 2006).

11
12 α -interferon ineffective to treat Rhesus monkeys infected with Zaire strain (Jaax et al. 1995).

13
14 S-Adenosylhomocysteine hydrolase inhibitors show promise as antivirals; significant protection
15 (90 percent) when treatment began on day 2, at which time, the liver had an average virus titer of
16 3×10^5 pfu/g and the spleen had 2×10^6 pfu/g; treatment on day 3, when the liver had an average
17 virus titer of 2×10^7 pfu/g and the spleen had 2×10^8 pfu/g, resulted in 40 percent survival
18 (Huggins, Zhang, and Bray 1999).

19
20 Blended vesicular stomatitis virus vector expressing glycoprotein from multiple EBOV strains
21 and 1 MARV strain protected *Macaca fascicularis* primates from lethal challenges of MARV
22 and EBOV virus strains (Geisbert et al. 2009).

23
24 A multivalent adenovirus-based vector vaccine candidate (EBO7) expressing glycoproteins of
25 *Zaire ebolavirus* and *Sudan ebolavirus* protected nonhuman primates against the parenteral and
26 aerosol routes of lethal challenge (Pratt et al.).

27
28 Tested panfilovirus vaccine based on a complex adenovirus (CAVax) technology that expresses
29 multiple antigens from five different filoviruses *de novo*; vaccination of NHPs [IM with 10^{10}
30 PFU, challenged with 10^3 PFU] demonstrated 100 percent protection against infection by two

1 species of EBOV and three MARV subtypes, each administered at 1,000 times the lethal dose
2 (Swenson et al. 2008).

3
4 Candidate vaccine based on recombinant replication-defective adenovirus protects NHP from
5 EBOV infection (Paragas and Geisbert 2006).

6
7 Candidate vaccine based on recombinant replication-competent vesicular stomatitis virus
8 protected monkeys against EBOV (Paragas and Geisbert 2006).

9
10 Immunization with DNA or replication-defective adenoviral vectors (rAd) encoding the Ebola
11 glycoprotein (GP) and nucleoprotein (NP) shown to confer specific protective immunity in
12 NHPs, cynomolgus macaques (*M. fascicularis*); might work as human vaccine (Sullivan et al.
13 2006).

14
15 Vaccine candidate using human parainfluenza virus type 3 (HPIV3) as vector with HPIV3
16 recombinants expressing the EBOV (*Zaire* species) surface GP alone or in combination with the
17 nucleocapsid protein NP or with the cytokine adjuvant granulocyte-macrophage colony
18 stimulating factor; administered by the respiratory route to rhesus monkeys; single immunization
19 with any construct expressing GP moderately immunogenic against EBOV and protected 88
20 percent of the monkeys against severe hemorrhagic fever and death caused by EBOV; two doses
21 highly immunogenic, and all the animals survived the virus challenge without clinical signs or
22 viremia (Bukreyev et al. 2007).

23
24 Single injection of attenuated recombinant vesicular stomatitis virus vector expressing the EBOV
25 GP completely protected rodents and NHPs from lethal EBOV challenge; in guinea pig and
26 mouse models possible to protect 50 percent and 100 percent of the animals, respectively,
27 following treatment as late as 24 h after lethal challenge; in rhesus macaques protection if treated
28 20'–30' after an otherwise uniformly lethal infection (Feldmann et al. 2007).

29
30 Recombinant VSV-based *Zaire ebolavirus* (ZEBOV) and *Marburg virus* (MARV) vaccines used
31 against aerosol challenge in cynomolgus macaques; all monkeys vaccinated with a VSV vector

1 expressing the GP of ZEBOV protected against an aerosol exposure of ZEBOV; all monkeys
2 vaccinated with a VSV vector expressing GP of MARV protected against an aerosol exposure of
3 MARV (Geisbert et al. 2008).

4
5 Cynomolgus monkeys immunized with hyperimmune IgG horse serum somewhat protected from
6 EBOV challenge, viremias reduced, clinical signs delayed, but death still occurred (Jahrling et al.
7 1996).

8
9 Expression of viral structural proteins in cells leads to assembly and release of particles that
10 resemble virions in size and morphology: virus-like particle vaccines highly effective to protect
11 small lab animals and NHP against lethal doses of virus (Yang et al. 2008).

12
13 Passive immunotherapy of monkeys with convalescent-phase blood from immune monkeys not
14 protective (Jahrling et al. 2007).

15
16 Candidate EBOV DNA vaccine; plasmids expressing EBOV GP (Zaire), GP (Sudan/Gulu), and
17 NP (Zaire) are safe and well-tolerated and induce EBOV-specific antibody and T-cell responses
18 in healthy adults (Martin et al. 2006).

19
20 Neutralizing human monoclonal antibody, KZ52, fails to protect against EBOV in rhesus
21 macaques (Oswald et al. 2007).

22
23 Despite restriction of replication of human paramyxovirus-vectored vaccine by preexisting
24 HPIV3-specific immunity, the expressed EBOV GP was highly immunogenic in guinea pigs
25 (Yang et al. 2008).

26
27 DNA vaccines offered protective immunity via gene gun to NHP and laboratory animals
28 (Riemenschneider et al. 2003).

29
30 **Other remarks**

31 SALS BSL-4 virus (Pattyn, Bowen, and Webb 2008).

1 Department of Commerce permit required (Pattyn, Bowen, and Webb 2008).

3 Zaire is now known as Democratic Republic of Congo.

5 Considerable media attention and fear generated by outbreaks of filoviruses because they can
6 cause a severe VHF syndrome that has a rapid onset and high mortality (Leffel and Reed 2004).

8 Great bioterrorism concern because of their high mortality rate; low infective dose; ease of
9 dissemination; potential for major public health impact, public panic, or social disruption; and
10 requirement for major public health preparedness measures , i.e., a Category A pathogen (Leffel
11 and Reed 2004).

13 Progress in understanding origins of pathophysiologic changes that make EBOV infections of
14 humans so devastating have been slow; a primary reason is the status of filoviruses as BSL-4
15 pathogens necessitating study in high biocontainment settings (Geisbert et al. 2003).

17 Common pathogenic feature of the hemorrhagic fever viruses is the ability to disable the host
18 immune response by attacking and manipulating the cells that initiate the antiviral response
19 (Geisbert and Jahrling 2004).

21 Natural reservoir for *Filoviridae* remains unknown (Geisbert and Jahrling 2004).

23 **Taxonomy/antigenic relationships/synonyms**

24 EBOV and MARV are the sole members of the genus *Filovirus* in the family *Filoviridae* (Leffel
25 and Reed 2004; Feldmann, Slenczka, and Klenk 1996).

27 Family *Flaviviridae* is divided into two genera: *Ebolavirus* and *Marburgvirus*; genus *Ebolavirus*
28 further divided into four species, *Zaire ebolavirus* (ZEBOV), *Ivory Coast ebolavirus*, *Sudan*
29 *ebolavirus* (SEBOV), and *Reston ebolavirus*); 2007 Uganda outbreak virus might be a 5th
30 species; *Marburgvirus* genus, is represented by a single species (*Lake Victoria marburgvirus*)
31 (Swenson et al. 2008).

Order Mononegavirales, family Filoviridae, divided into two genera: *Marburgvirus* and *Ebolavirus*. *Lake Victoria marburgvirus* is the lone species in the genus *Marburgvirus* while the genus *Ebolavirus* contains four distinct species: *Ivory Coast ebolavirus* (ICEBOV), *Sudan ebolavirus* (SEBOV), *Zaire ebolavirus* (ZEBOV) and *Reston ebolavirus* (REBOV) (Hensley et al. 2005).

MARV group [weak cross reaction via indirect immunofluorescence] (Pattyn, Bowen, and Webb 2008).

12 distinct viruses associated with hemorrhagic fever in humans are classified among four families: *Filoviridae*, which includes Marburg and EBOV (LeDuc 1989).

4 known subtypes of EBOV: Zaire, Sudan, Reston, Ivory Coast (Leffel and Reed 2004).

4 subtypes of ebolavirus (McCormick and Fisher-Hoch 1999; King 2008).

C.1.2.3 Marburg virus (MARV)

Host range

a. Field

First isolated from human blood in 1967 via IP inoculation of guinea pigs with blood, salivary gland, nasopharyngeal swabs, liver, spleen, and CNS tissue in newborn mice, suckling hamsters, and WI-26 human diploid embryo fibroblasts (Siegert and Simpson 2008; Warfield, Deal, and Bavari 2009).

First isolated and Marburg hemorrhagic fever first described in 1967 during outbreaks in Germany and Yugoslavia; outbreaks linked to infected monkeys imported from Uganda (Warfield, Deal, and Bavari 2009; Bausch et al. 2006).

First filovirus described, identified after cluster of hemorrhagic fever cases occurred in laboratory workers, Marburg, Germany, 1967; all infected workers handled blood and tissue or cell cultures from African green monkeys originating from Uganda; 32 cases, 26 primary and 6

1 secondary (contacts of primary patients) documented, with overall mortality 23 percent
2 (Salvaggio and Baddley 2004).

3
4 Disease, isolates from humans in West Germany, Yugoslavia laboratories, Southern Africa
5 (Siegert and Simpson 2008).

6
7 No specific CF antibodies or virus isolations from *Cercopithecus aethiops* monkeys ; positive CF
8 tests reported with sera from primate species is possible evidence of natural infection of primates
9 in Uganda, but specificity of CF antibodies employing infected guinea pig crude liver antigens
10 still questionable (Siegert and Simpson 2008).

11
12 No firm evidence of infection of monkeys in Uganda (Swanepoel 1994).

13
14 Two vervet monkeys and three baboons IFA positive in Kenya (Siegert and Simpson 2008).

15
16 Studies for reservoir hosts, examined the fauna of a mine in northeastern DRC associated with
17 protracted outbreak of hemorrhagic fever, 1998–2000; MARV nucleic acid detected in 12 bats,
18 composing 3.0 percent–3.6 percent of two species of insectivorous bat, *Miniopterus inflatus*
19 (1/33, 3.0 percent), *Rhinolophus eloquens* (7/197, 3.6 percent) and one species of fruit bat, *R.*
20 *aegyptiacus* (4/127, 3.1 percent); antibody to the virus in the serum of 9.7 percent of one of the
21 insectivorous species (*Rh eloquens*) and in 20.5 percent of the fruit bat species, but attempts to
22 isolate virus were unsuccessful (Swanepoel et al. 2007).

23
24 Fruit bat (*R. aegyptiacus*), Gabon, virus detected via virus-specific RNA; IgG antibody detected
25 in individual bats, captured in area outside of known range of MAR virus indicating potential for
26 expanding infected areas (Towner et al. 2007).

27
28 MARV RNA detected in tissue of *Rousettus aegyptiacus* bat in Kenya (Kuzmin et al.).
29 Investigation of July and September, 2007, infections among miners in Kitaka Cave, Uganda,
30 found the likely source of infection to be Egyptian fruit bats (*Rousettus aegyptiacus*) based on

1 detection of Marburg virus RNA in 31/611 (5.1%) bats, and virus-specific antibody in bat sera
2 (Towner et al. 2009).

4 **Experimental**

5 Several primate species used to model human filoviral hemorrhagic fevers, including African
6 green monkeys, cynomolgus macaques, rhesus macaques (*M. mulatta*), and hamadryad baboons
7 (*Papio hamadryas*) (Hensley et al. 2005).

8
9 One study failed to demonstrate transmission of MARV from infected rhesus macaques to
10 uninfected macaques (Leffel and Reed 2004).

11
12 Aerosol exposure of African green monkeys with lyophilized virus; 60 percent monkeys died
13 within 13–22 days; lyophilization reduced virulence by nearly $10^3 \log_{10}$; time to death appeared
14 extended as compared to parenteral exposure of cynomolgus macaques to 1,000 pfu of MARV;
15 however, the doses mentioned were extremely low (0.1 to 0.003 guinea pig LD₅₀ (Leffel and
16 Reed 2004).

17
18 NHP models for human disease comparative; rodent (mouse, guinea pigs) models have
19 significant gaps; used for evaluating antivirals (Paragas and Geisbert 2006).

20
21 Inapparent infections in IC, IP, SC inoculated newborn and weanling mice (Siegert and Simpson
22 2008).

23
24 Only the guinea pig has been successfully adapted as a rodent model of the human disease; time
25 course and pathogenesis via parenteral exposure are similar to reports for NHPs and humans
26 (Leffel and Reed 2004).

27
28 From original human tissue, febrile illness in IC, IP, SC inoculated guinea pigs (Siegert and
29 Simpson 2008).

1 First guinea pig passage material produced sickness and death in IC, IP, SC inoculated guinea
2 pigs (Siegert and Simpson 2008).

4 Original and first guinea pig-passaged materials produced sickness and death in IC, IP, SC
5 inoculated vervet, squirrel, and rhesus monkeys (Siegert and Simpson 2008).

7 Death in newborn hamsters from IP, IC inoculated 9th gp and 9th hamster passage material
8 (Siegert and Simpson 2008).

10 Laboratory studies show that fruit and insectivorous bats support replication and circulation of
11 high titers of EBOV without showing overt illness (Hensley et al. 2005).

13 **Prevalence/incidence/attack rate**

14 1 percent of more than 400 human serums IFA positive in Liberia (Siegert and Simpson 2008).
15 Serosurveys in general population of eastern and southern Africa showed prevalence rates of <2
16 percent (Bausch et al. 2003).

18 Using MARV (Musoke strain) as antigen in an ELISA test, an overall seroprevalence of 2.4
19 percent was found among populations in the rain forest of the Central African Republic
20 (Gonzalez et al. 2000).

22 Serologic studies using ELISA for risk factors in area with confirmed MAR virus transmission in
23 DRC; 2 percent of 912 in general village cross-sectional survey positive for IgG, 87 percent of
24 15 seropositives were males who worked in local gold mines; work in mines and receiving
25 injections associated with seropositivity; all of 103 health care workers were seronegative in
26 study; primary transmission from unknown reservoir in mines, secondary transmission less
27 common than with EBOV (Bausch et al. 2003).

29 31, 3, 4 isolates from humans in W Germany, South Africa, Yugoslavia, respectively (Siegert
30 and Simpson 2008).

Virus prevalence in presumed reservoir, fruit bat, might be as low as 1 percent (Fisher-Hoch 2005).

First documented in 1967, when 31 people became ill in the Germany and Yugoslavia; 25 primary infections, with 7 deaths in laboratory staff working with *Cercopithecus aethiops* from Uganda, and 6 secondary cases in medical staff, with no deaths from blood exposure to primary cases or needle sticks (CDC 2009).

R₀/incubation period/infectious period/infectious dose

“Epidemiological data from natural outbreaks would suggest ... that the survivability of filoviruses as a respirable particle is very short outside of controlled laboratory conditions, or that infected patients do not expire infectious virus particles” (Leffel and Reed 2004).

Morbidity/case fatality ratio

Results from serologic studies to determine the prevalence of exposure to the virus among populations in endemic areas suggest that clinically asymptomatic, or minimally symptomatic, infections occur (Siegert and Simpson 2008; Bausch et al. 2003; Gonzalez et al. 2000).

2004–2005, Angola, more than 328 deaths in children; 80 percent of the deaths in the early stages of the outbreak were children under the age of 15, but that dropped to 30–40 percent in later stages, 14 nurses and 2 doctors infected (Fisher-Hoch 2005; CDC 2009).

Recent outbreaks of MARV in DRC and Angola, where mortality of over 80 percent has been reported, comparable with that in outbreaks of Zaire EBOV in Yambuku (88 percent) and Kikwit (81 percent), higher than that reported in outbreaks of Zaire EBOV (59–78 percent) in Gabon and DRC, and more than 3 times that (23 percent) in the European MARV outbreak in Europe (Ascenzi et al. 2008).

Mortality rate in Angola very high, 88 percent (329 of 374), compared with only 23 percent in the original 1967 outbreak in Germany; in the outbreak in Durba, DRC, in 1998–2000, mortality was also high (83 percent) (Fisher-Hoch 2005).

1 2007–2008, Uganda, 2/3 cases dead (Warfield, Deal, and Bavari 2009; CDC 2009).

3 Seven human deaths from 31 cases (Siegert and Simpson 2008).

5 Case fatality rate is from 23 percent to over 90 percent (Leffel and Reed 2004; Siegert and
6 Simpson 2008).

8 Mortality of 23 to 90 percent, depending on the virus (Leffel and Reed 2004).

10 First outbreak, 1967, 32 cases with 23 percent mortality rate (Leffel and Reed 2004).

12 1998–2000, Durba, DRC, 103 cases and a fatality rate of 67 percent (Leffel and Reed 2004).

14 In 1975, three people in South Africa infected from a human from Zimbabwe, resulting in one
15 death (Warfield, Deal, and Bavari 2009; CDC 2009).

17 1980, 1987, 2 similar cases with 2 deaths in Kenyan European visitors to a cave (Warfield, Deal,
18 and Bavari 2009; CDC 2009).

Table C-10. Outbreaks of filovirus infection in human beings or captive NHPs

Date	Location	Source of infection	Number of cases	Case-fatality rate (%)
<i>Marburgvirus</i>				
1967	Europe	Imported monkeys	31	23
1975	South Africa	Unknown	3	33
1980	Kenya	Unknown	2	50
1987	Kenya	Unknown	1	100
1998	DRC	Unknown	141	82

Source: (Mahanty and Bray 2004)

DRC = Democratic Republic of Congo; NHP = non-human primate.

Emerging pathogens, MARV and EBOV cause very severe hemorrhagic fevers and mortality as high as 90 percent (Swenson et al. 2008).

High rates of morbidity and mortality (Swenson et al. 2008).

1998–1999, DRC, total of 154 cases (48 laboratory-confirmed and 106 suspected) identified (case fatality rate, 83 percent); 52 percent of cases in young male miners; only 27 percent men reported contact with other affected persons, whereas 67 percent of patients who were not miners reported such contact ($P < 0.001$); most affected miners (94 percent) worked in an underground mine (Bausch et al. 2003; Bausch et al. 2006) (Fisher-Hoch 2005; Warfield, Deal, and Bavari 2009; CDC 2009).

Mortality ranges from 22 to 88 percent (Feldmann, Slenczka, and Klenk 1996).

Mortality 30–35 percent (Kiley 1988).

Aerosol infection/routes of transmission

Seven lab deaths in Europe (Pike 1979).

Spread through bodily fluids, including blood, excrement, saliva, and vomit (CDC 2005).

Nosocomial transmission occurs, especially after close or intimate contact (LeDuc 1989).

Two major MAR outbreaks, in eastern DRC and in 2004–2005) in Angola; most, but not all, were single-point source epidemics, with index cases often unidentified and with subsequent spread in hospitals and in rural villages because of inadequate facilities and poor practices in caring for the sick (Fisher-Hoch 2005).

Although transmission during naturally occurring outbreaks is believed to occur from close personal contact with blood or other body fluids, or the failure to practice proper medical hygiene as relates to blood-borne pathogens, in the past 10 years several publications have indicated that filoviruses possess a number of properties that would make them suitable as biological weapons (Leffel and Reed 2004).

1967 outbreak, majority of cases were primary infections as a result of handling tissues from infected African green monkeys; 9 cases considered secondary cases, attributed to inadvertent needle sticks and unprotected contact ; in one case MARV was transmitted via semen 3 months after the patient had recovered from the disease (Leffel and Reed 2004; Martini and Schmidt 1968).

Communicable primarily through direct contact with infected blood and/or tissues; some evidence of infectivity via the respiratory, oral, and conjunctival routes (Leffel and Reed 2004).

Suggestion that human-to-human transmission needs relatively close contact although aerosol transmission might be increased in cases of hemorrhagic syndrome with high level viremia (Belanov et al. 1996).

1 Sexual transmission documented (Salvaggio and Baddley 2004).

3 Possible infection from breast milk (Salvaggio and Baddley 2004).

5 Not naturally transmitted by aerosol, but highly infectious as respirable particles under
6 laboratory conditions (Leffel and Reed 2004).

8 1998-99, Democratic Republic of Congo, multiple short, apparently independent chains of
9 transmission noted, with 7 being the largest number of cases noted in any single chain;
10 incidences of secondary spread from at least 20 patients, tertiary spread from at least 3 patients,
11 and quaternary spread from at least 2 patients documented, most often related to exposure of
12 family members caring for a sick miner; nosocomial infection did not play an important role in
13 virus transmission (Bausch et al. 2006).

15 Human-to-human transmission possible for all VHF viruses; majority of the person-to-person
16 transmission for the arenaviruses and filoviruses attributed to direct contact with infected blood
17 and body fluids; potential for airborne transmission of the VHF agents appears to be an
18 infrequent event, but cannot be categorically excluded as a mode of transmission (Geisbert and
19 Jahrling 2004).

21 Virus has been isolated from semen (Ascenzi et al. 2008).

23 Transmitted from infected patients via blood, secretions(saliva, respiratory, urine, feces,
24 vomitus), organs, semen; via handling and eating ill or dead animals; via contaminated syringes
25 and needles; associated with customary burial practices (Curtis 2006).

27 Transmission via inhalation, inoculation, ingestion, person-to-person, direct contact, and by
28 doing autopsies (Said et al. 2007).

30 Some recent outbreaks attributed to the consumption or handling of bush meat (Huggins, Zhang,
31 and Bray 1999).

1 Little data from animal studies with aerosolized filoviruses; animal models of filovirus exposure
2 are not well characterized, and there are discrepancies between these models and what has been
3 observed in human outbreaks (Leffel and Reed 2004).

4
5 1995, guinea pigs exposed via aerosol; homogenates of guinea pig liver containing 3×10^7 LD₅₀
6 were aerosolized with 10 percent glycerol in a biological aerosol generator; dose was reported in
7 the range of 2 to 6 aerosol LD₅₀ (Leffel and Reed 2004).

8
9 Filoviruses can infect via aerosol and extraordinarily low doses are lethal for both guinea pigs
10 and NHPs (0.1 to 0.003 guinea pig LD₅₀); epidemiological data from natural outbreaks suggests
11 that the aerosol infectious dose for humans is considerably higher, that survivability of
12 filoviruses as a respirable particle is very short outside of controlled laboratory conditions, or
13 that infected patients do not expire infectious virus particles (Leffel and Reed 2004).

14
15 In guinea pigs and Rhesus monkeys (*M. mulatta*), contact and aerosol infection demonstrated
16 (Pokhodiaev, Gonchar, and Pshenichnov 1991).

17
18 Aerosolized infectious doses ranging from 0.1 - 5 conditional units were uniformly fatal for 17
19 green monkeys (a conditional unit was defined as the amount of virus equivalent to guinea pig
20 intraperitoneal LD₅₀). Lower concentrations of virus (0.003-0.1 CU per animal delivered by
21 aerosol) caused lethal infection of 6 of 10 animals (Bazhutin et al. 1992).

22
23 Transmission via respiratory droplets is less than 2 meters, but aerosolized virions have a greater
24 range (Said et al. 2007).

25
26 **Virus titers/concentrations/pathogenesis**

27 In Vero cells, 2.5×10^6 - 5×10^7 CCID₅₀/mL produced in flasks and roller bottles (Johnson 2008).
28 Infects and replicates in a variety of mammalian cell cultures, including primary and continuous
29 cell cultures, primary and continuous primate cell cultures, primary and continuous guinea pig
30 cell cultures and BHK-21 cell cultures with variable or absent CPE; one primary and one
31 continuous primate cell culture, a continuous human cell culture, and BHK-21 exhibited distinct

CPE after infection; variable CPE was produced in Vero cell cultures, and CPE endpoints generally were 10-100 times lower than infectious virus titrations (Siegert and Simpson 2008).

High mortality rate; low infective dose (0.1 to 0.003 guinea pig LD₅₀ in African green monkeys) (Leffel and Reed 2004).

Rhesus monkey (*M. mulatta*) studies, virus titers to 10^{8.3} LD₅₀/mL or /g tissue at 9-10 post infection (Lub et al. 1995).

Pathogen stability

Based on experimental data, the aerosol decay rate for MARV was calculated to be 14 minutes (half-life) (Piercy et al. 2010).

Filoviruses are relatively stable in aerosols, retain virulence after lyophilization, and can persist for long periods on contaminated surfaces (Leffel and Reed 2004).

Survives up to 5 days on contaminated surfaces; unstable in aerosols with specific rate of inactivation= 0.05/min (Belanov et al. 1996).

Filoviruses retain infectivity at room temperature on environmental surfaces; thus, fomites might be sources of transmission, e.g., blankets and sleeping mats identified (Salvaggio and Baddley 2004).

Predicted inactivation of a filovirus was calculated for six geographic points for as many as five times of year. The time for a 1 log decrease varied from 20 to 100 minutes [HL range of 6 to 30 min] (Lytle and Sagripanti 2005). The D₃₇ value (the dose of UV₂₅₄ in J/m² that reduces the surviving virus to 37% of its original) for filovirus was calculated to be 7.3 [HL=17 min at maximum solar radiation] (Lytle and Sagripanti 2005).

EBO and MAR viruses survive for weeks; rapidly inactivated in environment, being sensitive to heat, sunlight, or drying [NOTE-- some data reported in this section by others might challenge

that position]; susceptible to chlorine disinfectants, heating to 60 °C for 1 hour, UV light;
survives in carcasses/body fluids and on fomites (Said et al. 2007).

Negative-stranded RNA virus with lipid envelope; stable at a neutral pH, as a result of which the
virus can survive for long periods in blood, and viral isolation is possible weeks after exposure,
even during convalescence (Leffel and Reed 2004).

Indication that viruses with structural lipids survive best in aerosols at low RH (Benbough 1971).

UV radiation inactivates viruses by chemically changing the RNA and DNA; most effective UV
is 250 nm; filoviruses [MAR and EBOV] most sensitive to solar UV₂₅₄, requiring 20'-100' at
mid-day exposure to inactivate 1 log₁₀ of virus: bunyaviruses (hantaviruses [AND virus] and
RVFV), arenaviruses (Lassa, JUN), and flaviviruses (TBE complex viruses) more resistant
(Lytle and Sagripanti 2005).

Lipid solvent (ether, chloroform) & deoxycholate (detergent) sensitive; titer reduced from
10^{6.0}CCID₅₀/mL to <10^{1.7}CCID₅₀/mL (Siegert and Simpson 2008).

Vectors

a. Field

1978, Rhodesia (Zimbabwe), possible infection via spider or horsefly bite (Conrad et al.
1978; Feldmann, Slenczka, and Klenk 1996).

b. Experimental

Replicates in *Aedes aegypti* but not in *Anopheles maculipennis* mosquitoes or *Ixodes*
ricinus ticks after intrathoracic inoculation (Siegert and Simpson 2008).

Virus persists in *Aedes* mosquitoes for 3+ weeks (Monath 1999).

1 **Other epidemiological/ecological data**

2 22/22 infected humans were CF antibody positive in Germany (Siegert and Simpson 2008; CDC
3 2009).

4
5 Epidemiology of this virus sketchy, with the exception of two major outbreaks that led to
6 discovery; MARV first recognized during an outbreak of a severe hemorrhagic disease
7 associated with importation of African green monkeys (*Cercopithecus aethiops*) from East Africa
8 to Germany; subsequent, isolated human cases have been reported, primarily from sub-Saharan
9 Africa (LeDuc 1989).

10
11 Natural reservoir for *Filoviridae* remains unknown (Geisbert and Jahrling 2004).

12
13 Ecological niche modeling of potential MAR virus habitats (Towner et al. 2007).

14 Sporadic cases occurred from 1975 to 1987, with total of 6 cases and 3 deaths; from 1998 to
15 2000, series of cases occurred near Durba in the Democratic Republic of Congo; all the cases
16 have been associated with miners working in gold mines, with 103 cases and a fatality rate of 67
17 percent (Leffel and Reed 2004).

18
19 1998–1999, Democratic Republic of Congo, evidence of multiple introductions of infection into
20 the population substantiated by detection of at least nine genetically distinct lineages of virus in
21 circulation during the outbreak; implication that reservoir hosts of MARV inhabit caves, mines,
22 or similar habitats (Bausch et al. 2006).

23
24 1975, Rhodesia (Zimbabwe), index case and 2 secondary cases, probably via fomites, aerosol, or
25 close contact; possible insect/arachnid transmission (Conrad et al. 1978; Feldmann, Slenczka,
26 and Klenk 1996).

27
28 Northeastern Democratic Republic of Congo, October 1998, in gold-mining village; sporadic
29 cases and short chains of human-to-human transmission continued until September 2000;
30 suspected cases identified on the basis of a case definition and confirmed by the detection of
31 virus antigen and nucleic acid in blood, cell culture, antibody responses, and

1 immunohistochemical analysis; outbreak ceased with flooding of the mine (CDC 2009; Bausch
2 et al. 2006).

3
4 Most hemorrhagic fever viruses are zoonoses; found in both temperate and tropical habitats;
5 generally infect both genders and all ages, although there might be an influence of occupational
6 exposure; transmission to humans is frequently by bite of an infected tick or mosquito or via
7 aerosol from infected rodent hosts; aerosol and nosocomial transmission are especially important
8 with MARV; seasonality of hemorrhagic fever among humans is influenced by the dynamics of
9 infected arthropod or vertebrate hosts; mammals, especially rodents, appear to be important
10 natural hosts for many hemorrhagic fever viruses; transmission cycle for each hemorrhagic fever
11 virus is distinct and dependent on the characteristics of the primary vector species and the
12 possibility for its contact with humans (LeDuc 1989).

13
14 First filovirus identified was MARV, 1967, after a severe outbreak of VHF that began in
15 Marburg, Germany, with subsequent cases appearing in Frankfurt and Belgrade; 32 cases with
16 23 percent mortality rate; majority of cases were primary infections as a result of handling
17 tissues from infected African green monkeys, *Cercopithecus aethiops*; 9 cases considered
18 secondary cases, attributed to inadvertent needle sticks and unprotected contact ; in one case
19 MARV was transmitted via semen 3 months after the patient had recovered from the disease
20 (Feldmann, Slenczka, and Klenk 1996; Leffel and Reed 2004).

21
22 Angola, 2004–2005 outbreak shows again devastating and rapid spread of viral hemorrhagic
23 fevers in medical settings where hygiene practices are poorly applied or ignored; legacy of years
24 of war and poverty in Angola resulted in very poor medical education and services; initial high
25 rate of infection among infants in Angola might be related to poor hospital practices, possibly
26 administration of vaccines; though the outbreak in Angola was in a part of Africa not previously
27 known to have filovirus infection, prior ecological modeling predicted this location (Fisher-Hoch
28 2005).

29
30 Greater than 75 percent of the Marburg cases in Angola were in children, mostly infants (Fisher-
31 Hoch 2005).

Geographical distribution of fruit bats, *R. aegyptiacus*, overlaps distribution of cases (Warfield, Deal, and Bavari 2009).

Therapeutics/vaccines

No treatments for Marburg and Ebola viral hemorrhagic fevers; ribavirin, an antiviral drug used to treat several other hemorrhagic fevers, has no in vitro effect on MARV and EBOV, failed to protect in multiple primate studies, and is unlikely to have any clinical value to human patients (Huggins, Zhang, and Bray 1999).

No specific antiviral therapy; hospital care is supportive in nature, e.g., early administration of vasopressors and hemodynamic monitoring with attention to fluid and electrolyte balance, circulatory volume, and blood pressure, but fluid infusions might cause pulmonary edema (Swenson et al. 2008).

Blended vesicular stomatitis virus vector expressing glycoprotein from multiple EBOV strains and 1 MARV strain protected *Macaca fascicularis* primates from lethal challenges of MARV and EBOV virus strains (Geisbert et al. 2009).

First experimental vaccine from USAMRIID completely protects animals from lethal infection; now being tested in NHP (Swenson et al. 2008).

MARV surface protein inserted on vesicular stomatitis vector developed in Canada shows promise in mice and NHP; effective in rhesus monkey even after infection (Geisbert et al. 2008). Tested panfilovirus vaccine based on a complex adenovirus (CAVax) technology that expresses multiple antigens from five different filoviruses *de novo*; vaccination of NHPs [IM with 10^{10} PFU, challenged with 10^3 PFU] demonstrated 100 percent protection against infection by two species of EBOV and three MARV subtypes, each administered at 1,000 times the lethal dose (Swenson et al. 2008).

Candidate vaccine based on recombinant replication-competent vesicular stomatitis virus completely protected monkeys against MARV (Paragas and Geisbert 2006).

1 Recombinant VSV-based *Zaire ebolavirus* (ZEBOV) and *Marburg virus* (MARV) vaccines used
2 against aerosol challenge in cynomolgus macaques; all monkeys vaccinated with a VSV vector
3 expressing the GP of ZEBOV protected against an aerosol exposure of ZEBOV; all monkeys
4 vaccinated with a VSV vector expressing GP of MARV protected against an aerosol exposure of
5 MARV (Geisbert et al. 2008).

6
7 Expression of viral structural proteins in cells leads to assembly and release of particles that
8 resemble virions in size and morphology: virus-like particle vaccines highly effective to protect
9 Small lab animals and NHP against lethal doses of virus (Yang, Ye, and Compans 2008;
10 Warfield et al. 2004).

11
12 Attenuated recombinant vesicular stomatitis virus vaccine shown to have preventive and post-
13 exposure efficacy in NHP (Bausch and Geisbert 2007).

14
15 DNA vaccines offered protective immunity via gene gun to NHP and laboratory animals
16 (Riemenschneider et al. 2003).

17
18 No medical interventions or vaccines are approved for humans (Warfield, Deal, and Bavari
19 2009).

20
21 **Other remarks**

22 BSL-4 pathogen as determined by SALS (Siegert and Simpson 2008).

23
24 Department of Commerce permit required (Siegert and Simpson 2008).

25
26 Green monkey disease or Marburg hemorrhagic fever (Swanepoel 1994).

27
28 Zoonotic pathogen related to Ebola -virus genes isolated from Egyptian fruit bats, *R.*
29 *aegyptiacus*; Uganda, Angola, Congo and African fruit bats in Gabon; antibodies found in
30 healthy bats (Warfield, Deal, and Bavari 2009; Peterson et al. 2006; Peterson, Bauer, and Mills
31 2004; Towner et al. 2007; Mackenzie 2007).

1 Considerable media attention and fear generated by outbreaks of filoviruses because they can
2 cause a severe VHF syndrome that has a rapid onset and high mortality (Leffel and Reed 2004).

3
4 Great bioterrorism concern because of their high mortality rate; low infective dose; ease of
5 dissemination; potential for major public health impact, public panic, or social disruption; and
6 requirement for major public health preparedness measures (Leffel and Reed 2004).

7
8 Common pathogenic feature of the hemorrhagic fever viruses is ability to disable the host
9 immune response by attacking and manipulating the cells that initiate the antiviral response
10 (Geisbert and Jahrling 2004).

11 12 **Taxonomy/antigenic relationships/synonyms**

13 Distantly related via indirect immunofluorescence to Ebola (Siegert and Simpson 2008).

14
15 Twelve distinct viruses associated with hemorrhagic fever in humans are classified among four
16 families: Filoviridae, which includes Marburg and EBOV is 1 of the 4 families (LeDuc 1989).

17
18 MARV poorly understood virus; family Filoviridae (Kiley 1988; LeDuc 1989).

19
20 EBOV and MARV are the sole members of the genus *Filovirus* in the family Filoviridae
21 (Feldmann, Slenczka, and Klenk 1996; Leffel and Reed 2004).

22
23 Family Flaviviridae is divided into two genera: *Ebolavirus* and *Marburgvirus*; genus *Ebolavirus*
24 further divided into four species, *Zaire ebolavirus* (ZEBOV), *Ivory Coast ebolavirus*, *Sudan*
25 *ebolavirus* (SEBOV), and *Reston ebolavirus*; *Marburgvirus* genus, is represented by a single
26 species (*Lake Victoria marburgvirus*) (Swenson et al. 2008).

27
28 Order Mononegavirales, family Filoviridae, divided into two genera: *Marburgvirus* and
29 *Ebolavirus*. *Lake Victoria marburgvirus* is the lone species in the genus *Marburgvirus* while the
30 genus *Ebolavirus* contains four distinct species: *Ivory Coast ebolavirus* (ICEBOV), *Sudan*

ebolavirus (SEBOV), *Zaire ebolavirus* (ZEBOV) and *Reston ebolavirus* (REBOV) (Mahanty and Bray 2004).

C.1.2.4 Lassa virus (LASV)

Host range

a. Field

Reservoir host: *Mastomys natalensis* where infection is life-long (Fisher-Hoch 2005).

Zoonotic in rodents particularly the *Mastomys* species complex (Curtis 2006).

M. natalensis is very likely the only reservoir host of LASV in Guinea and Sierra Leone

Evidence of vertical as well as horizontal transmission of the virus in *M. natalensis*

(Lecompte et al. 2006).

“Rodents are infected *in utero*” (McCormick and Fisher-Hoch 2002).

Infection in the rodent is “life-long, persistent, and mostly silent” (Fisher-Hoch 2005).

Ag or Ab were found in very few *Mus musculus* and *Rattus rattus* and none were culture positive; multiple explanations given including non-specificity of the reagents. Cites a sole prior study claiming positive culture outside *Mastomys* but the possibility of misidentification was raised (Demby et al. 2001).

b. Experimental

Marmoset *C. jacchus* model due to macaques shortage; infected SQ with 10^3 and 10^6 PFU (Carrion, Brasky, et al. 2007).

An interference phenomenon in which lower doses (11 PFU) were more infective than higher doses (PFU $10^{6.1}$) has been reported for rhesus monkeys (Peters et al. 1987).

Strain 13 guinea pigs (Carrion, Patterson, et al. 2007), uniform lethal infection by 2 or more PFU (Jahrling et al. 1982).

Mice, guinea pigs, Rhesus, African green, and capuchin monkeys (Peters et al. 1987).

Pathogenicity of LASV for guinea pigs depends both on the virus and the host strain. For example, the Josiah strain of LASV has an LD₅₀ of 0.3 PFU for strain 13 guinea pigs, but

1 kills only about 30 percent of outbred Hartley animals receiving between 2 and 200,000
2 PFU (Peters et al. 1987).

3
4 Outbred Hartley strain guinea pigs and cynomolgus monkeys: monkeys exposed to inhaled
5 doses greater than or equal to 465 PFU were infected and died. The median infectious dose
6 (ID₅₀) for guinea pigs was 15 PFU (Stephenson, Larson, and Dominik 1984).

7
8 **Prevalence/incidence/attack rates**

9 Prevalence of antibodies to LASV in the general population varies greatly (from 1.9 percent to
10 55 percent) among different regions or even villages within the endemic countries (authors cite
11 internal references 139,141–143,145,152,161,171). Longitudinal studies in selected villages in
12 Sierra Leone revealed a high incidence of LASV-specific seroconversion (5–20 percent per year)
13 in susceptible (i.e., antibody negative) individuals (authors cite internal reference 139). However,
14 the majority of these subjects did not report a febrile illness temporally associated with
15 seroconversion. This is in agreement with the high seroprevalence of LASV specific antibodies
16 in the general population, and indicates that most LASV infections are mild or even
17 asymptomatic (Gunther and Lenz 2004).

18
19 Endemic in Guinea, Sierra Leone, Liberia, Nigeria, and also in Ghana, Ivory Coast or Burkina
20 Faso (Drosten et al. 2003).

21
22 Mano River basin is considered epicenter of Lassa fever (Fisher-Hoch 2005).

23
24 Incidence of Lassa fever is highest in Sierra Leone (Khan et al. 2008).

25
26 As high as 52 percent seroconversion in Sierra Leone (Jeffs 2006).

27
28 Antibody prevalence in Sierra Leone ranges from 5 percent in coastal villages to 40 percent in
29 forests and savannahs (average prevalence is 18 percent) (McCormick and Fisher-Hoch 2002).

1 Serostudies in Liberia and Sierra Leone—up to 50 percent seropositivity w/ 6 percent of
2 seronegative converting per year (ter Meulen 2000).

3
4 In Sierra Leone infection rates of up to 20 percent of the population each year have been
5 documented (Curtis 2006).

6
7 Guinea seroprevalence found by cross-sectional study to be 12.9% (10.8-15%) and 10.0% (8.1-
8 11.9%) in rural and urban areas, respectively (Kerneis et al. 2009).

9
10 Estimated antibody prevalence: 4–6 percent Guinea, 15–20 percent Nigeria; in some villages in
11 Sierra Leone as many as 60 percent “have evidence of exposure” (presumably antibodies, but
12 this is not stated) (Fisher-Hoch and McCormick 2004).

13
14 In endemic areas accounts for 10–16 percent of adult medical admissions and 30 percent of adult
15 deaths (Fisher-Hoch and McCormick 2004).

16
17 Prevalence of antibody is 1–6 percent in Liberia & Guinea, and 5–25 percent (average 21
18 percent) in Nigeria (McCormick and Fisher-Hoch 2002).

19
20 Some studies indicate that 300,000 to 500,000 infections and 5,000 deaths occur annually across
21 West Africa (Ogbu, Ajuluchukwu, and Uneke 2007; Gunther and Lenz 2004).
22 100,000 to 300,000 infections annually in endemic areas are estimated (McCormick et al. 1987;
23 Gunther and Lenz 2004).

24
25 The at risk seronegative population (in Sierra Leone, Guinea, and Nigeria) estimated to be as
26 high as 59 million, with an annual incidence of illness of three million, fatalities up to 67 000,
27 and up to three million reinfections (Richmond and Baglolle 2003).

28
29 Seropositivity has also been found in the Central African Republic, DRC, Mali, and Senegal
30 (Richmond and Baglolle 2003).

1 Highest case rates occur in the dry season from February through May (McCormick and Fisher-
2 Hoch 2002).

3
4 5–20 percent of susceptible persons are infected each year (McCormick and Fisher-Hoch 2002).

5
6 “About 25 cases of imported Lassa fever have been reported worldwide (cites 243–249). Four
7 cases of Lassa fever have been imported into Europe in the year 2000 (cites 178,180,186,204)
8 and a further case was imported in 2003 (cites 179). At least two of these patients died from
9 typical Lassa fever (cites 204, 234)...” So far, no clinically apparent secondary cases were
10 reported after import of Lassa fever, despite high and medium risk contacts” (Gunther and Lenz
11 2004).

12
13 A survey was conducted of small mammals in selected regions of Guinea to assess the degree to
14 which LV poses a public health risk in that country; the proportion of LV-infected *Mastomys* per
15 region ranged from 0 to 9 percent and was highest in the savannah and forest zones. The
16 proportion of infected animals per village varied considerably, even between villages in close
17 proximity. Infected animals tended to cluster in relatively few houses, suggesting the existence
18 of focal *hot spots* of LV-infected *Mastomys* that might account for the observed heterogeneous
19 distribution of Lassa fever (Demby et al. 2001).

20
21 **R₀/incubation period/infectious period/infectious dose**

22 R₀ N/A. Person-to-person transmission is associated with direct contact with the blood or other
23 excretions, containing virus particles, of infected individuals (CDC 2008; Gunther and Lenz
24 2004).

25
26 Incubation period reported to range from 1–24 days (Mertens et al. 1973) and 7–18 days
27 (McCormick and Fisher-Hoch 2002).

28
29 Incubation up to 3 weeks, flu-like, gastrointestinal symptoms—subset with hemorrhage & organ
30 failure associated with high mortality, neurological complication of tremor, convulsions and
31 coma, sensorineural deafness complication of convalescence phase (Drosten et al. 2003).

1 7–18 day incubation period (Carrion, Brasky, et al. 2007; Fisher-Hoch 2005).

3 3–21 day incubation (Ogbu, Ajuluchukwu, and Uneke 2007).

5 Interference phenomenon in which lower doses are more infective than higher doses might have
6 implications for modeling in the Risk Analysis (Peters et al. 1987).

8 **Morbidity/case fatality ratio**

9 Results from serologic studies to determine the prevalence of exposure to the virus among
10 populations in endemic areas suggest that clinically asymptomatic, or minimally symptomatic,
11 infections occur, and that that most LASV infections are mild or even asymptomatic (Gunther
12 and Lenz 2004).

14 The onset of illness is typically indolent, might result in a spectrum of clinical effects ranging
15 from asymptomatic to multi-organ system failure and death (Khan et al. 2008).

17 Lassa fever is mild in about 80 percent of people infected with the virus—20 percent have a
18 severe multisystem disease. Lassa fever is also associated with occasional epidemics, during
19 which the case-fatality rate can reach 50 percent (CDC 2008).

21 Symptoms include progressive fever, malaise, myalgia, abdominal pain, vomiting, diarrhea,
22 chest pain, headache, cough, sore throat, weakness, dizziness, tinnitus, deafness, hypotension,
23 shock, facial or cervical swelling, bleeding, conjunctivitis, petechiae, rales, and wheezing. Case
24 fatality ratios have been reported from 9–52 percent. Reports of ribavirin use relate a 2–3 fold
25 decrease in mortality (Peters 1991) but must be used within the first week for optimal efficacy
26 (Fisher-Hoch and McCormick 2004).

28 Symptoms also include pulmonary edema (Fisher-Hoch and McCormick 2004).

30 Fever, weakness, malaise, severe headache. Up to one-third of hospitalized patients progress to
31 prostrating illness with persistent vomiting and diarrhea. Bleeding in 15–20 percent of patients.

1 Severe pulmonary edema and adult respiratory distress is common in fatal cases (Fisher-Hoch
2 2005).

3
4 Sensorineural deafness is the major chronic sequelae of Lassa fever (Khan et al. 2008).

5
6 Inflammation of the throat with white tonsillar patches helps in differentiating Lassa Fever from
7 other tropical diseases (Roberts and Kemp 2002).

8
9 Data from human observation shows that a single infection with LASV provides long term
10 protection (Fisher-Hoch and McCormick 2004).

11
12 “Pathology triggered by arenaviruses has a more insidious onset. For Lassa fever patients,
13 hemorrhagic manifestations are not pronounced; and neurological complications are infrequent,
14 develop late and manifest only in the most severely ill group. Deafness is a frequent long-term
15 consequence of severe Lassa fever” (Geisbert and Jahrling 2004).

16
17 Viremia $\geq 10^3$ is associated with increased fatality; high titer viremia and elevated AST levels
18 together indicate a risk of death of 80 percent (McCormick and Fisher-Hoch 2002).

19
20 4 concurrent symptoms- fever, pharyngitis, retrosternal pain, & proteinuria- correctly predicated
21 70 percent of laboratory confirmed Lassa cases (Roberts and Kemp 2002).

22
23 Overall fatality rate estimated at 1–2 percent (McCormick and Fisher-Hoch 2002).

24 Estimated overall fatality rate of 1–2 percent among the estimated 100,000–300,000 annual cases
25 (much lower than the rate among hospital admissions (Gunther and Lenz 2004).

26
27 “Mortality is about 16 percent in untreated hospitalized cases, perhaps only about 2 percent in
28 the community, but the number of people exposed in West Africa is very large; therefore, the
29 actual number of cases is considerable” (Fisher-Hoch 2005).

1 Mortality is reported as 16 percent in hospitalized untreated points. In Nigeria some outbreaks
2 with 50 percent mortality in community and as high as 70 percent in hospitalized patients
3 (McCormick and Fisher-Hoch 2002).

4
5 Hospitalized fatality rate is 16 percent in Nigeria, and in 3rd trimester pregnant women as high as
6 30–70 percent (Fisher-Hoch 2005).

7
8 Case fatality ratio of 28% (18/64) was found from a retrospective review of medical records at
9 one teaching hospital in Nigeria (Inegbenebor, Okosun, and Inegbenebor).

10
11 Mortality 17 percent among hospitalized patients if untreated (Fisher-Hoch 2005).

12
13 Some studies indicate that 300,000 to 500,000 infections and 5,000 deaths occur annually across
14 West Africa (Ogbu, Ajuluchukwu, and Uneke 2007; Gunther and Lenz 2004).

15
16 Lower case mortality than other VHF, but more common, therefore ↑morbidity and mortality
17 overall. Nosocomial infection mortality reported as high as 65 percent (Jeffs 2006).

18
19 Approximately 15–20 percent of patients hospitalized for Lassa fever die from the illness.
20 However, overall only about 1 percent of infections with LASV result in death. The death rates
21 are particularly high for women in the third trimester of pregnancy, and for fetuses, about 95
22 percent of which die in the uterus of infected pregnant mothers (CDC 2008).

23 24 **Aerosol infection/routes of transmission**

25 Aerosol infections in laboratory animals—anecdotal and experimental infections by aerosols.
26 Monkeys housed in room that had been previously used to infect guinea pigs with the LASV
27 (Josiah strain) contracted the virus and died. Macaques exposed to inhaled doses ranging from
28 2.7–4.5 log₁₀ PFU all died, mean time to death 14 days (Peters et al. 1987).

1 Probability of aerosol dissemination function of 3 variables (1) aerosols occur primarily from
2 infected host or secondarily from animal bedding or other source (2) stability of the virus once
3 aerosolized (3) infectivity of small particle aerosol for animal at risk (Peters et al. 1987).

4
5 “Data from this study, combined with epidemiological evidence and the occurrence of
6 nosocomial hospital infections, strongly suggested that airborne droplet nuclei represent an
7 additional means of indirect virus dissemination. The biological half-lives at both 24 and 32 °C
8 were sufficient for aerosol transmission of LASV to considerable distances in natural situations”
9 (Stephenson, Larson, and Dominik 1984).

10
11 Primary infection from aerosolized rodent sources and ingestion of food contaminated by rodent
12 feces, and by consumption of the rodent host. “Secondary human to human transmission” by
13 blood and body fluids (Curtis 2006).

14
15 Presence of virus in pharyngeal secretions and urine for 3 to 4 weeks after onset of clinical signs
16 provides an excellent source of airborne, infectious virions (Stephenson, Larson, and Dominik
17 1984).

18
19 Primary route is via cuts and abrasions of the skin, or by mucosal contact; does not mention
20 pulmonary route ; “stirring of dust contaminated with urine might cause some cases but
21 epidemiological data (secondary attack rates in households) do not support respiratory infection
22 as a frequent event;” rodents roaming in the houses deposit urine on utensils, etc., and virus gets
23 in through skin breaks and perhaps by ingestion in some cases (McCormick and Fisher-Hoch
24 2002).

25
26 “Needle stick injuries estimated to deliver approximately 10^2 to 10^4 infectious particles from
27 patient blood that contains 10^5 to 10^7 infectious particles per milliliter have been described
28 previously (author cites internal reference 62)” (Djavani et al. 2007).

29
30 Human infection with arenaviruses is incidental to the natural cycle of the viruses and occurs
31 when an individual comes into contact with the excretions or materials contaminated with the

1 excretions of an infected rodent, such as ingestion of contaminated food, or by direct contact of
2 abraded or broken skin with rodent excrement [and urine]. Infection can also occur by inhalation
3 of tiny particles soiled with rodent urine or saliva (aerosol transmission). The types of incidental
4 contact depend on the habits of both humans and rodents. For example, where the infected rodent
5 species prefers a field habitat, human infection is associated with agricultural work. In areas
6 where the rodent species' habitat includes human homes or other buildings, infection occurs in
7 domestic settings (CDC 2008).

8
9 LASV and Machupo virus are transmissible from human to human. For those reasons, the highly
10 pathogenic arenaviruses must be handled in laboratories of BSL-4 (Gunther and Lenz 2004).
11 Some arenaviruses, such as Lassa and Machupo viruses, are associated with secondary person-
12 to-person and nosocomial (healthcare setting) transmission. That occurs when a person infected
13 by exposure to the virus from the rodent host spreads the virus to other humans. That could occur
14 in a variety of ways. Person-to-person transmission is associated with direct contact with the
15 blood or other excretions, containing virus particles, of infected individuals. Airborne
16 transmission has also been reported in connection with certain viruses. Contact with objects
17 contaminated with these materials, such as medical equipment, is also associated with
18 transmission (CDC 2008).

19
20 By *M. natalensis* feces or by close personal contact (Carrion, Brasky, et al. 2007).
21 Nosocomial human to human transmission in Africa because of poor medical practices (Drosten
22 et al. 2003).

23
24 Humans presumably become infected through contact with infected rodent excreta, urine, tissues,
25 or blood (3,27). Transmission to man is through fecal-oral route, or respiratory tract by inhaling
26 contaminated air containing the virus, or when infected blood touches bruised skin or by sexual
27 intercourse (Ogbu, Ajuluchukwu, and Uneke 2007).

28
29 Person-to-person transmission of Lassa fever can also occur through contaminated medical
30 equipment, such as reused needles or when a person comes into contact with virus in blood,
31 tissue, secretions, or excretions of an infected individual, the but virus cannot be spread through

casual contact (including skin-to-skin contact without exchange of body fluids) (Ogbu, Ajuluchukwu, and Uneke 2007).

Virus titers/concentrations/pathogenesis

“Nearly all patients with fatal Lassa fever remain viremic until death, with terminal viremia ranging from 10^3 – 10^8 50 percent -tissue culture infectious doses (TCID₅₀/mL.)” (Gunther and Lenz 2004).

In humans, a viremia level of $\times 10^{3.6}$ TCID₅₀/mL in Lassa fever patient admission was associated with case fatality rate of 76 percent (Carrion, Brasky, et al. 2007).

Samples of human serum were adjusted to contain 10^6 – 10^7 TCID₅₀/mL of Lassa fever virus (Lloyd, Bowen, and Slade 1982).

2×10^7 FFU in vitro (in supernatant) (Cosset et al. 2009).

Infectious titers of 5×10^6 PFU/mL. grown in Vero E6 cells (Carrion, Brasky, et al. 2007).

Chronic viruria in infected *Mastomys* ranges from 10^4 – 10^6 PFU/ml urine (Stephenson, Larson, and Dominik 1984).

In lab-infected marmosets viremia levels of 5 to 7 log₁₀ on day 14 and day of necropsy (Carrion, Brasky, et al. 2007).

“Needle stick injuries estimated to deliver approximately 10^2 to 10^4 infectious particles from patient blood that contains 10^5 to 10^7 infectious particles per milliliter have been described previously (author cites reference 62)” (Djavani et al. 2007).

Pathogenesis is poorly understood. The virus can be isolated from almost every organ, but histopathology reveals lesions not sufficient to cause organ failure and death (Drosten et al. 2003).

1 “...the currently available data are not sufficient to reconstruct the chain of pathophysiological
2 events in Lassa fever. Some mechanisms are likely to play a role: i) early during infection LASV
3 may target immune cells and interfere with their activation; ii) the high affinity of LASV for the
4 receptor cy-DG may allow virus replication in several organs; iii) the relatively low
5 susceptibility of the virus to IFN may facilitate virus spread; iv) a continuous and uncontrolled
6 rise in virus load in several organs may eventually trigger a fatal inflammatory syndrome in the
7 terminal stage of the disease” (Gunther and Lenz 2004).

8
9 “Pathogenesis of LF appears to be related to unchecked viremia ... Cell mediated immunity
10 appears to be the most important arm in recovery... LASV infection probably results in lifelong
11 immunity, at least against severe disease” (Khan et al. 2008).

12
13 Microvascular instability and impaired hemostasis are the pathophysiologic hallmarks (Khan et
14 al. 2008).

15
16 “Severe disease appears to result from the interaction of LASV with macrophages and dendritic
17 cells, either directly or indirectly via soluble mediators, resulting in a process akin to septic
18 shock, with activation of a host of inflammatory and vasoactive mediators leading to cellular
19 dysfunction, insufficient effective circulating intravascular volume, and multi-organ system
20 failure” (Khan et al. 2008).

21
22 Hemorrhage appears to be primarily attributable to LASV-induced release of a soluble mediator
23 impairing platelet aggregation (Khan et al. 2008).

24 25 **Pathogen stability**

26 Biological half-lives of the virus in aerosols at both 24 °C and 32 °C ranged from 10.1 to 54.6
27 minutes and were sufficient for aerosol dispersion of virus to considerable distances in natural
28 situations; ability of the virus to readily infect two mammalian hosts via the respiratory route—
29 monkeys exposed to inhaled doses 5,465 PFU were infected and died. The median infectious
30 dose (ID₅₀) for guinea pigs was 15 PFU (Stephenson, Larson, and Dominik 1984).

1 The D_{37} value (the dose of UV_{254} in J/m^2 that reduces the surviving virus to 37% of its original)
2 for Lassa was calculated to be 13 [HL = 30 min at maximum solar radiation] (Lytle and
3 Sagripanti 2005).

4
5 Stability of LASV at 32 °C indicates that airborne transmission of the virus in the natural
6 environment most likely could occur during the dry season when the RH is minimal (Lloyd,
7 Bowen, and Slade 1982).

8
9 In acute-phase serum containing 10^5 TCID₅₀/mL of LASV, 0.2 percent beta-propiolactone (BPL)
10 reduced infectivity to undetectable levels within 30 min at 37 °C (Lloyd, Bowen, and Slade
11 1982).

12
13 Complete inactivation of Lassa fever virus in human sera containing 10^6 TCID₅₀/mL of the virus
14 occurs in 60 min at 60 °C (Lloyd, Bowen, and Slade 1982).

15
16 Virus is inactivated by heating to 56 °C, pH less than 5.5 or more than 8.5, UV or gamma
17 radiation, or detergents (Curtis 2006).

18
19 “...prolonged presence of high virus titers in the lungs and upper respiratory tract tissues,
20 pharyngeal secretions, and urine of infected humans or rodents would provide exemplary seed
21 sources for infectious aerosols” (Stephenson, Larson, and Dominik 1984).

22
23 Virus is excreted in urine 3 to 9 weeks, semen 3 months from infection (McCormick and Fisher-
24 Hoch 2002).

25 26 **Vectors**

27 LASV is not known to be vector-borne (CDC 2008).

28 29 **Other epidemiological/ecological data**

30 In 2000, at least four cases were imported to Europe (Fisher-Hoch 2005).

1 Human contact with rodent excreta, tissues, urine or blood (Ogbu, Ajuluchukwu, and Uneke
2 2007).

3
4 Endemic in parts of West Africa with outbreaks of the disease occurring typically in the dry
5 season between January and April. Potential for large nosocomial outbreaks due to secondary
6 human to human transmission (Curtis 2006).

7
8 Nosocomial transmission can be avoided by taking preventive precautions against contact with
9 patient secretions by instituting strict barrier nursing—using PPE, complete sterilization of
10 medical equipment, patient isolation and properly disposing of all contaminated supplies (Ogbu,
11 Ajuluchukwu, and Uneke 2007).

12
13 Four strains of virus: *Josiah*—Sierra Leone, *Nigeria* and *LP-Nigeria*, and *AV* imported to
14 Germany by a traveler who had visited Ghana, Côte D'Ivoire, and Burkina Faso (Ogbu,
15 Ajuluchukwu, and Uneke 2007).

16
17 The main feature of fatal illness is impaired or delayed cellular immunity leading to fulminant
18 viremia (Richmond and Baglole 2003).

19
20 **Therapeutics/vaccines**

21 Ribavirin effective (Drosten et al. 2003).

22
23 Rx with Ribavirin reduces case fatality of pts with ↑ AST from 55 to 5 percent if given within
24 the first 6 days (Jeffs 2006).

25
26 Because of its expense, need for intravenous administration, potential toxicity, and
27 teratogenicity, empiric therapy with ribavirin is undesirable (Ogbu, Ajuluchukwu, and Uneke
28 2007).

Supportive treatment is often necessary and includes fluid replacement, blood transfusion, administration of paracetamol, phylometadione, ringer lactate, hemocele quinine and broad spectrum antibiotics (Ogbu, Ajuluchukwu, and Uneke 2007).

No vaccine success as of 2004 (Fisher-Hoch and McCormick 2004).

“Guinea pigs vaccinated with a ML29 reassortant vaccine experienced sterilizing immunity and complete protection when challenged on day 30 either with homologous virus or with the distantly related Nigerian isolate. Simultaneous vaccination–challenge or challenge on day 2 after vaccination also protected 60–100 percent of the animals against both strains, but without sterilizing immunity. These results indicate that simultaneous replication of ML29 and LASV attenuates the virulence of LASV infection” (Carrion, Patterson, et al. 2007).

“A killed vaccine tested in NHPs elicited antibodies to major structural proteins of LASV but did not protect animals against challenge [authors cite reference 5]. Controlled clinical trials failed to show protective efficacy of human convalescent plasma [authors cite reference 6]. In addition, there is a solid body of evidence that the clearance of LASV and recovery of Lassa fever patients is not dependent on antibody responses but is associated with cell-mediated immunity” (Carrion, Patterson, et al. 2007).

Other remarks

Increased prevalence of LASV in rainy season in Guinea (Fichet-Calvet et al. 2008).

Taxonomy/antigenic relationships/synonyms

Taxonomically, LASV is classified in the genus *Arenavirus*, family *Arenaviridae* and is an enveloped RNA virus (ICTVdB - The Universal Virus Database 2006; Ogbu, Ajuluchukwu, and Uneke 2007).

“Arenaviruses are classified as segmented negative-strand RNA viruses. The genes are oriented in both negative and positive senses on the two RNA segments, a coding strategy which is called

ambisense.” LASV is serologically, phylogenetically, and geographically part of the Old World complex of Arenaviruses (Africa, Europe, and Asia) (Gunther and Lenz 2004).

C.1.2.5 Junín virus (JUNV)

Host range

a. Field

The disease was first reported in 1950s with virus isolation in 1958.

Junín, Argentina, 1958; virus isolated from humans in IP-inoculated guinea pigs, then passed in suckling mice (Parodi 1958).

Mus musculus, 10/33 pools (411 rodents) were virus positive according the Arbovirus Catalogue (Parodi 2008). Examination of the papers cited in the catalog document culture of 40 *M. musculus* mice. The 40 mice were divided into three pools and two of the three were positive by culture in guinea pig followed by culture in suckling mice (Parodi et al. 1959; Parodi et al. 1961).

C. laucha, 1/28 pools (229 rodents) and 4/36 were virus positive (Parodi 2008).

A. arenicola, 1/13 pools (78 rodents) were virus positive (Parodi 2008).

Primary hosts are the rodents *C. laucha* and *C. musculus* (LeDuc 1989; Carballal, Videla, and Merani 1988).

Based on combined tests for antibody and antigen detection, the most recent field data showed a prevalence of JUNV in *C. musculus* of 11% (Mills et al. 1994).

Field mouse *C. musculus* is the main natural reservoir; other rodent species like *C. laucha*, *Mus musculus*, and *A. azarae* reported as less important natural hosts (Carballal, Videla, and Merani 1988; Ambrosio et al. 2006). However, examination of Carballal et al (Carballal, Videla, and Merani 1988) shows no mention of *Mus musculus*, and attribution by Ambrosio et al (Ambrosio et al. 2006) is not entirely clear. Translation of the original Parodi articles (Parodi, A.S., et al. 1959. Prensa Medica 46:554; and Parodi, A.S., et al. 1961. Prensa Medica 48:2321) clarifies that viral antigen was detected via a complement-

1 fixation test, and that each of the papers reports one *Mus musculus* pool positive for
2 JUNV antigen [this is at odds with the information listed in the Arbovirus Catalogue that
3 10 of 33 pools, consisting of 411 rodents, were antigen positive].

4
5 One of 217 *Mus musculus* was antigen-positive (Mills, Ellis, et al. 1991).

6
7 One of 286 *Mus musculus* was antigen-positive (Mills, Calderon, et al. 1991).

8
9 Virus isolations from *C. musculus* (family *Muridae*, subfamily *Sigmodontinae*), *C.*
10 *laucha*, *A. azarae*, *Bolomys obscurus*, *Oxymycterus rufus*, *O. flavescens*, *Necomys*
11 *benefactus*; viral antigen positive via ELISA, *Mus musculus* (Mills, Ellis, et al. 1991;
12 Enria and Barrera Oro 2002).

13
14 Argentina, strains of Junin virus isolated from *C. musculus* captured at same sites as
15 *Mus musculus* from which LCM virus was isolated (Sabbatini 1974).

16
17 *Echinolaelaps* spp (mites), > 40 isolates (Parodi 2008).

18
19 Other isolates from *C. laucha*, *A. azarae*, *A. obscurus*, *C. musculus*, *Oryzomys*
20 *flavescens*, *Cavia pamparum* (wild cavy), and *Lepus europaeus* (hare) (Parodi 2008).
21 First isolated by IP-inoculated guinea pig, 1958, Argentina, infected human with
22 hemorrhagic syndrome (Parodi 2008).

23
24 Argentina, > 60 isolates from human blood; 20–60 percent of collected human paired
25 serum samples had CF antibody (Parodi 2008).

26
27 Córdoba Province, Argentina, field and experimental studies indicate predominant role of
28 cricetid rodents in JUNV maintenance over an 11 year period (Sabbatini 1977).

1 **b. Experimental**

2 Rhesus macaques (*M. mulatta*), disease most closely simulates human disease with
3 clinical course/symptoms reflecting disease caused by respective strains isolated from
4 infected humans, i.e., strains causing serious disease in humans caused serious disease in
5 macaques, while less virulent human pathogens produced less severe disease in macaques
6 (Peters et al. 1987).

7
8 Infection of rhesus monkeys and marmosets produced lesions similar to those reported in
9 human cases; include hemorrhage, bone marrow necrosis, mild hepatocellular necrosis,
10 poliencephalomyelitis and autonomic ganglioneuritis; *C. jacchus* infected with Junin
11 virus developed acute hematologic and neurologic manifestations with anemia,
12 leucopenia and thrombocytopenia and death within 17–24 days (Enria, Briggiler, and
13 Sanchez 2008).

14
15 Rhesus monkeys were killed by 1MICLD₅₀ (mouse intracranial LD), whereas
16 cynomolgus monkeys were more resistant (Peters et al. 1987).

17
18 Aerosol infection of Rhesus macaques (*M. mullata*) with $10^{1.6-1.9}$ or $10^{3.9-4.3}$ PFU
19 produced illness after 3 weeks' incubation, and death similar to effects of parenteral
20 inoculation and mimicking human disease; virus isolated from blood (10^{1-3} PFU/mL), OP
21 swabs ($10^{3->6}$ PFU/mL), and visceral organs and central nervous system (up to $10^{7.3}$
22 PFU/g) (Kenyon, McKee, et al. 1992).

23
24 NHPs in *M. mulatta* model mimics the human clinical syndrome via parenteral infection
25 of adults with low-passage isolates; distinct hemorrhagic or neurologic disease that
26 correlated with clinical illness patterns present in the humans from whom the viral strains
27 were obtained; however, patterns of viremia, OP viral shedding, and antibody response
28 were different; with postmortem virologic and histopathologic findings, suggests that
29 viral-strain-specific factors are important determinants of clinical disease patterns (Peters
30 et al. 1987).

1 Intramuscular inoculation of *Aotus trivirgatus* with 3×10^1 or 3×10^5 TCID₅₀; subclinical
2 infection, no clinical response, minimal viremia (10^{1-2} SMICLD₅₀/mL) detectable at 2
3 and 3 weeks post-infection, and NT antibodies produced (Samoilovich et al. 1983).

4 Inoculation: *Alouatta caraya*, *Saimiri sciureus* responded like *A trivirgatus* (subclinical
5 infection); *Callithrix jacchus* (Samoilovich et al. 1983).
6

7 Virus non virulent for *Alouatta caraya* ; no signs, viremia, or lesions, NT antibody
8 produced to high titers (Weissenbacher et al. 1978; Weissenbacher et al. 1979).
9

10 *Cebus apella* inoculated IM develop inapparent infection with transient viremia, virus in
11 saliva, and leukothrombocytopenia followed by high antibody titers, similar to the mild
12 AHF forms in humans (Carballal, Videla, and Merani 1988).
13

14 Infection with pathogenic strain of JUNV causes 100 percent mortality in guinea pigs and
15 *Callithrix jacchus* marmoset (Samoilovich et al. 1988).
16

17 Marmoset, *Callithrix jacchus*, develops a fatal disease that mimics the natural infection in
18 humans in clinical course, 100 percent lethal around the third week of infection,
19 characterized by hemorrhagic or neurologic signs, pronounced and long-lasting viremia,
20 wide virus spread, leukopenia, anemia, and thrombocytopenia (Weissenbacher et al.
21 1986).
22

23 Susceptibility of the marmoset, *Callithrix jacchus* to TAC virus infection investigated to
24 perform cross-protection studies between JUN and TAC viruses; no signs of disease or
25 hematologic changes, no viremia, anti-TAC neutralizing antibodies produced 3 weeks
26 post-infection; TAC virus-infected marmosets challenged with JUNV showed no signs of
27 disease, no viremia, and no challenge virus replication, but anti-JUN NT antibodies were
28 produced (Weissenbacher et al. 1982).
29

1 *Callithrix jacchus* is useful model of human disease; *Cebus* spp produced mild or
2 inapparent responses, while *Alouatta caraya*, *Saimiri sciureus*, *Aotus trivirgatus*
3 seroconverted without disease (Peters et al. 1987).

4
5 *Callithrix jacchus* useful model for human disease; clinical syndrome, death, virus in
6 urine, blood, and all tissues (Weissenbacher et al. 1979).

7
8 *Calomys callidus*, *Akodon. molinae* develop persistent infections with virus shedding
9 (Carballal, Videla, and Merani 1988).

10
11 Newborn mice, IC inoculation, death, $10^{5.25}$ ID₅₀/mL [test system not reported](Parodi
12 2008).

13
14 Guinea pig, IC inoculation, death, $10^{6.0}$ ID₅₀/mL [test system not reported](Parodi 2008).

15
16 Depending on strain, lethal to guinea pigs at less than 1 PFU dose (Peters et al. 1987).

17
18 In guinea pig, some JUNV strains required less than 1 PFU to produce an LD₅₀ while
19 other strains killed 20 percent regardless of dose (Peters et al. 1987).

20
21 Median infectious dose (stated by authors to be the same as an LD₅₀) in outbred guinea
22 pigs 15 PFU (Peters et al. 1987).

23
24 ID₆₆ (66 percent infection with no mortality) for a dose of $10^{3.5}$ TCID₅₀ in guinea pigs
25 (Samoilovich et al. 1988; Peters et al. 1987).

26
27 Hamsters, IP; *Saguinus geoffreyi* (marmoset); *Callitrix jacchus* (marmoset)—death
28 (Parodi 2008).

29
30 Establishes persistently infected carrier cultures in a variety of cell lines and produces
31 chronic infection in a natural rodent host (Candurra et al. 1990).

1 7-day-old chick embryo, CAM inoculation, $10^{4.0}$ ID₅₀/mL [test system not
2 reported](Parodi 2008).

3
4 **Prevalence/incidence/attack rate**

5 Affects a 150,000 square mile area in Argentina with an at risk population of approx 5 million
6 (Vainrub and Salas 1994; Jay, Glaser, and Fulhorst 2005).

7
8 Incidence rates 140/100,000 in general population; 335/100,000 in adult males in rural areas
9 (Enria and Barrera Oro 2002).

10
11 Cases reported from 1958–1987, 21,000, annual from 100 to 4,000 cases; initially estimated to
12 affect an area of 16,000 km² with 250,000 persons at risk, now considered 150,000 km² with
13 more than 2 million at risk (Vainrub and Salas 1994).

14
15 Estimated 200 to 2,000 cases of AHF reported annually in the north-central Argentine Pampas;
16 distinct seasonal peak in the fall (February to May) during the agricultural harvest (Jay, Glaser,
17 and Fulhorst 2005).

18
19 Since the 1950s, JUNV is estimated to have caused about 30,000 cases of symptomatic disease
20 (Charrel and de Lamballerie 2003).

21
22 Since 1991 vaccination has reduced disease to 94 suspected and 19 confirmed cases in 2005
23 (Vainrub and Salas 1994).

24
25 Prevalence in rodents assessed by ELISA on samples of body fluids or organs or both, variable
26 (0–3.7 percent); prevalence 1.4 percent in AHF epidemic area, 0.6 percent in the historic low
27 incidence area, 0.4 percent beyond the defined endemic area (Mills, Ellis, et al. 1991).

28
29 Using indirect fluorescence antibody test, the cricetid rodent *C. musculus* had a 30-month
30 prevalence of 7.9 percent; with data on antigen detection, provided an estimated total prevalence
31 of infection of 10.9 percent for this species; other infected species included two cricetids, *C.*

1 *laucha* (seroprevalence 0.2 percent) and *Bolomys obscurus*, and a predatory carnivore, *Galictis*
2 *cuja* (a felid); approximately half of infected animals simultaneously carried serum antibody and
3 antigen in blood and saliva; *C laucha* associated with crop habitats, other seropositive animals
4 strongly associated with the relatively rare roadside and fence-line habitats; seropositive *C.*
5 *musculus* were predominantly males in the oldest age and heaviest body mass classes and
6 seropositive males were twice as likely to have body scars as seronegative males; these
7 observations suggest that most infections were acquired through horizontal transmission and that
8 aggressive encounters among adult, male *C musculus* in relatively densely populated roadside
9 and fence-line habitats are an important mechanism of transmission within reservoir populations.
10 Of the 437 rodents captured only 2% were *Mus musculus* and all were negative for antibodies
11 and antigen (Mills et al. 1994).

12
13 Virus prevalence via ELISA in rodent spp in 3 distinct zones of Argentina, 1990–1991: the
14 central Argentine pampas area, the historic AHF zone in Buenos Aires province, and the current
15 AHF zone in Santa Fe province; in high incidence zone, 1.7 percent ELISA positive; in historic
16 zone, 4 percent positive; in disease-free zone, 0.2 percent positive; *C. musculus* in high
17 incidence zone, 4.0 percent positive; *Bolomys obscuris*, 1.2 percent positive; *C. laucha*, *A.*
18 *azarae*, *Mus musculus*, 0.3–0.5 percent positive; virus isolated from all spp except *M musculus*;
19 although *O. flavescens* were ELISA negative, virus was isolated (Mills, Calderon, et al. 1991).

20
21 **R₀/incubation period/infectious period/infectious dose**

22 R₀ is <1 (Enria and Barrera Oro 2002).

23
24 5 days post-inoculation in guinea pigs (Weissenbacher, de Guerrero, and Boxaca 1975).

25
26 7- to 12-day post-inoculation in mice (Weissenbacher, de Guerrero, and Boxaca 1975).

27
28 **Morbidity/case fatality ratio**

29 80 percent of infections result in clinical disease; viremia occurs throughout the acute febrile
30 period. Subclinical infections occur (Enria, Briggiler, and Sanchez 2008).

1 Severe hemorrhagico-neurologic disease occurs in 20–30 percent of cases in the second week;
2 late neurologic disease occurs later in 10 percent of cases as a truncal cerebellar ataxia with fever
3 in immune serum-treated patients (Enria and Barrera Oro 2002).

4
5 In humans, primates, and rodents, JV disease is characterized by viral replication in lymphoid,
6 hemopoietic, or neural tissue, by a cellular or humoral immune response, or by long-term viral
7 persistence (Samoilovich et al. 1988).

8
9 Chronic infection of the host (accompanied by a chronic viremia or viruria) appears to be crucial
10 for the long-term persistence of arenaviruses in nature (Charrel and de Lamballerie 2003).

11
12 Fatal outcome more frequently occurs in pregnant women in last trimester and with high fetal
13 mortality—associated with both JUN and Machupo virus infections (Charrel and de Lamballerie
14 2003).

15
16 Mortality rate in untreated humans is 15–30 percent (Jay, Glaser, and Fulhorst 2005).

17
18 In early years, about 1,000 cases per year recorded, with a high mortality rate (more than 30
19 percent) in untreated humans (Jay, Glaser, and Fulhorst 2005).

20
21 Mortality 20–30 percent (Bushar and Sagripanti 1990).

22
23 Case fatality rates up to 30 percent without treatment (Enria and Barrera Oro 2002).

24
25 Mortality of 10 percent registered among clinical cases of AHF (Weissenbacher et al. 1980).

26
27 Significant morbidity, case-fatality rate without treatment between 15–30 percent (Enria,
28 Briggiler, and Sanchez 2008).

29
30 Up to 17 percent mortality among hospitalized patients (Mills et al. 1996).

Aerosol infection/routes of transmission

Lab infections from rodents [in the absence of appropriate biocontainment precautions] are documented (Carballal, Videla, and Merani 1988).

In virology labs [in the absence of appropriate biocontainment precautions], arenaviruses have been infectious to humans under circumstances implicating aerosol spread (Charrel and de Lamballerie 2003).

Risk of laboratory infection for those who handle JUNV is high [in the absence of appropriate biocontainment precautions] (Weissenbacher et al. 1980).

1967, laboratory infections [in the absence of appropriate biocontainment precautions] consisted of 5 cases and one death (Hanson et al. 1967; Pike 1979).

Previous report [in the absence of appropriate biocontainment precautions]—5 laboratory infections, 1 death; 11 clinical infections, 5 subclinical infections, 0 deaths; 1 aerosol infection, other 20 infections source unknown or other non-aerosol route (Scherer 1980).

Transmission of JUNV to humans is thought to be by aerosol (LeDuc 1989; Kenyon, McKee, et al. 1992; Enria and Barrera Oro 2002).

Prenatal infection, acquired through placenta (Ambrosio et al. 2006).

Human-to-human transmission is possible for all VHF viruses; majority of the person-to-person transmission for the arenaviruses and filoviruses has been attributed to direct contact with infected blood and body fluids; potential for airborne transmission of the VHF agents appears to be an infrequent event, but cannot be categorically excluded as a mode of transmission (Geisbert and Jahrling 2004).

Human-to-human transmission occurs (Enria and Barrera Oro 2002).

1 In rodents, transmission generally horizontal through close contact with; congenital infection not
2 seen (Mills, Ellis, et al. 1991).

3
4 Mouse suffers chronic subclinical infection and virus is excreted in saliva and urine (Jay, Glaser,
5 and Fulhorst 2005).

6
7 Annual epidemics of AHF occur at the time of the fall harvest, and primarily affect rural males
8 between the ages of 15 and 55; transmission to humans believed to occur by inhaling aerosolized
9 viral particles from contaminated soil and plant litter, which are disturbed during the mechanized
10 harvesting process (Mills et al. 1994).

11
12 In nosocomial arenavirus infections, most dangerous route is parenteral exposure through
13 improperly sterilized needles, autopsy accidents, or other failings in techniques (Charrel and de
14 Lamballerie 2003).

15
16 Fetal infection and death common in pregnant women infected with JUNV, with an associated
17 increase in maternal mortality; virus isolated from breast milk (Khan 1997).

18
19 Aerosol infection of guinea pigs (IN inoculation)- at $10^{4.5}$ TCID₅₀ = 100 percent infection, 100
20 percent mortality; at $10^{3.5}$ TCID₅₀ = 100 percent infection, 83 percent mortality; attenuated strain
21 at $10^{6.5}$ TCID₅₀ = 100 percent infection, 25 percent mortality, at $10^{3.5}$ TCID₅₀ = 66 percent
22 infection, no mortality (Parodi 1958).

23
24 Viremic pregnant *C. musculus* produced negative offspring; became infected within 2 weeks
25 from dam's infected oral secretions and urine; breast milk not tested; horizontal transmission
26 demonstrated between adults and juveniles (Sabbatini 1977).

27
28 **Virus titers/concentrations/pathogenesis**

29 Rhesus macaques, no to low viremias from human low virulence strains; viremias to 10^{5-7}
30 PFU/mL, and persisting at greater than 10^3 PFU/mL until death with highly virulent humans
31 strains (Peters et al. 1987).

1 *Alouatta caraya*, titers in blood and tissues from $10^{1.5}$ to $10^{6.0}$ TCID₅₀ (Weissenbacher et al. 1978;
2 Weissenbacher et al. 1979).

3
4 In 1965–1966, Córdoba Province, Argentina, JUNV first recovered from *C. musculus*, *C*
5 *laucha*, and *A. azarae*; high virus titers in blood, brain, spleen to titers of $10^{6 \text{ to } 7}$ SMICLD₅₀/mL
6 (Sabbatini 1977).

7
8 Rodent body fluids, i.e., urine, blood, and saliva carry substantial amounts of infectious virus
9 (Kenyon, McKee, et al. 1992).

10
11 In suckling mice, 10^6 SMICLD₅₀ produced (Weissenbacher et al. 1986).

12
13 In marmosets, JUNV inoculation replicated to 10^6 SMICLD₅₀/mL (Weissenbacher et al. 1982).

14
15 In guinea pigs, different strains of JUN produced wide variety of clinical syndromes and viremia
16 titers; from viscerotropic to neurologic disease with paralysis; viremias from 10^2 to 10^6 PFU/mL
17 and virus in tissues from 10^3 to $10^{>7}$ PFU/g and death rates from 0 to 100 percent (Kenyon et al.
18 1988).

19
20 In tissues of guinea pigs, titers to 10^{5-6} PFU/g (Peters et al. 1987).

21
22 HeLa cell line, $10^{5.0}$ to $10^{7.0}$ TCID₅₀/mL (Parodi 2008).

23
24 LLC-MK2 cell line, $10^{7.2}$ PFU/mL (Parodi 2008).

25
26 Vero cell line, $10^{7.0}$ PFU/mL (Parodi 2008).

27
28 In Vero cells, 10^6 CCID₅₀/mL produced in roller bottles (Johnson 2008).

29
30 In Vero cells, titers of $10^{6.3}$ to $10^{7.3}$ PFU/mL (Videla et al. 1989).

1 In Vero cells, produces 10^6 to 10^7 PFU/mL (Candurra et al. 1990).

3 **Pathogen stability**

4 Virus in guinea pig plasma, diluted in isotonic phosphate buffer with 2% rabbit plasma was
5 placed into glass tubes and monitored for inactivation of virus at various time points. Inactivation
6 at 37°C was 47% [66 min], 59% [280 min], and 99.9% [157 min] at time points of 1, 6, and 26
7 hours, respectively. At 25°C, inactivation was 75% [780 min] and 99% [650 min] at 26 and 72
8 hours, respectively (Parodi et al. 1966). Bracketed information is half-life as derived by Ken
9 Bulmahn (TetraTech) from the Parodi et al data.

11 The D_{37} value (the dose of UV_{254} in J/m^2 that reduces the surviving virus to 37% of its original)
12 for Junín was calculated to be 13 [HL = 30 min at maximum solar radiation] (Lytle and
13 Sagripanti 2005),

15 Resistant to pH 6.5–9.5 (Parodi 2008).

17 Indication that viruses with structural lipids survive best in aerosols at low RH (Ambrosio et al.
18 2006).

20 UV radiation inactivates viruses by chemically changing the RNA and DNA; most effective UV
21 is 250 nm; filoviruses [MARV and EBOV] most sensitive to solar UV_{254} , requiring 20'–100' at
22 mid-day exposure to inactivate 1 \log_{10} of virus: bunyaviruses (hantaviruses [AND virus] and
23 RVFV), arenaviruses (Lassa, JUNV), and flaviviruses (TBE complex viruses) more resistant
24 (Lytle and Sagripanti 2005).

26 Rapidly inactivated at 56 °C, at pH less than 5.5 or greater than 8.5, or by exposure to UV or
27 gamma irradiation or both (Charrel and de Lamballerie 2003).

29 Inactivated by lipid solvent (ether, chloroform), formalin, trypsin, phenol, and deoxycholate
30 (Parodi 2008; Videla et al. 1989).

1 **Vectors**

2 **a. Field**

3 No evidence of arthropod vectors (Jay, Glaser, and Fulhorst 2005).

5 **b. Experimental**

6 *Mesostigmata* spp mites able to transmit JUNV infection (Parodi 2008).

8 **Other epidemiological/ecological data**

9 80 percent of the affected humans are males 15–60 years of age; reside or work in rural areas
10 (Vainrub and Salas 1994).

11
12 Most hemorrhagic fever viruses are zoonoses; found in both temperate and tropical habitats;
13 generally infect both genders and all ages, although there might be an influence of occupational
14 exposure; transmission to humans is frequently by bite of an infected tick or mosquito or via
15 aerosol from infected rodent hosts; aerosol and nosocomial transmission are especially important
16 with JUN virus; seasonality of hemorrhagic fever among humans is influenced by the dynamics
17 of infected arthropod or vertebrate hosts; mammals, especially rodents, appear to be important
18 natural hosts for many hemorrhagic fever viruses; transmission cycle for each hemorrhagic fever
19 virus is distinct and dependent on the characteristics of the primary vector species and the
20 possibility for its contact with humans (LeDuc 1989).

21
22 Disease localized in a relatively well-defined area of Argentina, where it causes annual
23 epidemics from about January to August of each year; persons most commonly infected are
24 farmers and others with exposure to rural areas (LeDuc 1989).

25
26 Argentina labs, over 20 years, nearly 280 persons worked with JUNV; of 150 people considered
27 as high risk personnel, 35 developed clinical disease with recovery but 3 died; figures indicate
28 that nearly 25 percent of the personnel exposed to virulent virus strains acquired an overt disease
29 while the rest of infected personnel experienced subclinical infections (Weissenbacher et al.
30 1980).

1 As a group, the other VHF agents are linked to the ecology of their vectors or reservoirs, whether
2 rodents or arthropods (Geisbert and Jahrling 2004).

3
4 Ability to establish chronic infections in their respective principal rodent hosts is the hallmark of
5 the arenaviruses (Jay, Glaser, and Fulhorst 2005).

6 7 **Therapeutics/vaccines**

8 Specific treatment hyperimmune human plasma from recovered patients; if started early, is
9 extremely effective and reduces mortality to 1 percent (Bushar and Sagripanti 1990).

10
11 Immunoglobulin is effective if used within first 8 days of clinical illness, but late neurologic
12 symptoms occur in ~10 percent recipients (Peters et al. 1987).

13
14 Attenuated strain of JUNV is the basis of the only arenaviral vaccine (Candid #1) that has been
15 evaluated in humans. Its status is that of an investigational new drug. The vaccine appears to
16 cross-protect against Machupo virus challenge in guinea pigs and NHPs (Jay, Glaser, and
17 Fulhorst 2005).

18
19 Immune therapy effective, though a late neurologic syndrome occasionally associated with
20 treatment; attempted to determine in the infected marmoset *Callithrix jacchus* whether immune
21 therapy leads to protection and/or CNS damage; reduced mortality from 100 percent to 25
22 percent, lowered viremia and viral titers in organs; late neurologic signs in 30 percent of treated
23 marmosets (Avila et al. 1987).

24
25 Immune plasma reduces mortality to less than 3 percent (Bushar and Sagripanti 1990).
26 Treatment with immune plasma during first week; approx 10 percent of patients treated develop
27 a late neurologic disease (Enria and Barrera Oro 2002).

28
29 Ribavirin has shown some promise for treatment (Enria, Briggiler, and Sanchez 2008).

30
31 Ribavirin limited efficacy in Rhesus macaques (Peters et al. 1987).

1 Immune serum treatment of JUN virus-infected marmosets reduced mortality from 100 percent
2 to 25 percent (Enria, Briggiler, and Sanchez 2008).

3
4 Early use of immune plasma in patients with a clinical diagnosis of AHF is standard specific
5 treatment in Argentina (Enria, Briggiler, and Sanchez 2008).

6
7 *Callothrrix jacchus*, immune serum significantly reduces lethality, although late neurologic
8 syndrome observed similar to that in humans; Ribavirin, limited efficacy (Weissenbacher et al.
9 1986).

10
11 Some attenuated strains show neurovirulence on intracerebral inoculation in *Cebus* sp. primates;
12 related Tacaribe (TAC) virus seems nonpathogenic for humans and causes no overt illness in
13 guinea pigs and marmosets (nasal inoculation), which remain protected against later challenge
14 with JUNV–TAC virus conferred protection against AHF and the intrathalamic inoculation
15 showed lack of neurovirulence (Samoilovich et al. 1988).

16
17 NT antibody persists in 86 percent of Candid #1 vaccinates for more than 42 months (Levis
18 1993).

19
20 Marmoset *C. jacchus* can be considered an experimental model for protection studies with
21 arenaviruses; TAC virus could be considered as a potential vaccine against JUNV
22 (Weissenbacher et al. 1982).

23
24 Efficacy trial of Candid 1, attenuated JUNV vaccine; no serious adverse events were attributed to
25 vaccination; Candid 1, the first vaccine for the prevention of illness caused by an arenavirus, is
26 safe and highly efficacious; produced from original isolate made in guinea pigs from a fatal case
27 of AHF; following 44 newborn mouse brain passages, candidate vaccine strain was cloned by
28 single-burst selection and passed in certified fetal rhesus lung cells (Maiztegui et al. 1998).

29
30 Candid #1, attenuated JUNV vaccine, s/q in rhesus macaques; no significant effect on physical,
31 hematologic, or biochemical parameter measured; virus recovered from peripheral blood

mononuclear cells (PBMC); no reversion to virulence detected; all NHP developed a detectable neutralizing antibody response; Candid #1 is safe and immunogenic for NHP (McKee et al. 1993).

Many vaccine initiatives [reviewed] (Enria and Barrera Oro 2002).

Attenuated vaccine markedly reduced incidence of AHF; specific therapy involves transfusion of immune plasma in defined doses of neutralizing antibodies during the prodromal phase of illness; Ribavirin might be effective; immune immunoglobulin or monoclonal antibodies might be useful (Enria, Briggiler, and Sanchez 2008).

1985, *Candid #1* vaccine applied to adult high-risk population; 95.5 percent effective (Maiztegui et al. 1998).

Attenuated vaccine, Candid #1, used since 1991 is immunogenic and protective (Ambrosio et al. 2006).

Formalin inactivated virus produced high neutralizing and low IFA antibody in mice and guinea pigs; guinea pigs were not protected from challenge (Videla et al. 1989).

Other remarks

SALS level 4 (Parodi 2008).

Zoonotic hemorrhagic disease of humans, transmitted from the corn mouse, *C musculus* (Mills, Ellis, et al. 1991).

First described 1958, causes an arenaviral disease known as AHF (LeDuc 1989; Ambrosio et al. 2006).

Case definitions of AHF (Maiztegui et al. 1998; Harrison et al. 1999).

Common pathogenic feature of the hemorrhagic fever viruses is ability to disable the host immune response by attacking and manipulating the cells that initiate the antiviral response (Geisbert and Jahrling 2004).

Taxonomy/antigenic relationships/synonyms

Tacaribe group, family *Arenaviridae*, genus *Arenavirus*, caused by JUN virus which is closely related to Machupo virus (Parodi 2008).

JUNV is in Tacaribe (New World) complex of *Arenaviridae* associated with subfamily Sigmodontinae (New World rats and mice) (Jay, Glaser, and Fulhorst 2005).

Mal de los rastros (Mills, Ellis, et al. 1991).

12 distinct viruses associated with hemorrhagic fever in humans are classified among four families including *Arenaviridae*, which includes Lassa, JUN, and Machupo viruses (LeDuc 1989).

At least 20 related enveloped viruses (23) divided into 2 groups: Old World (5 viruses: Lassa, lymphocytic choriomeningitis (LCM), Mobala, Mopeia, Ippy); New World (Tacaribe complex); 3+ antigenic subgroups within the Tacaribe group- Allpahuayo, Amapari, Bear Canyon, Cupixi, Flexal, Guanarito, Junin, Latino, Machupo, Oliveras, Pampa, Parana, Pichinde, Pirital, Sabia, Tacaribe, Tamiami, Whitewater Arroyo viruses (Enria and Barrera Oro 2002; Carballal, Videla, and Merani 1988).

Family *Arenaviridae* includes 23 viral species, 5 can cause viral hemorrhagic fevers with a case fatality rate of about 20 percent, JUN, Machupo, Guanarito, Sabia and Lassa virus; manipulation requires BSL-4 facilities; other viruses with known human significance- LCM, Flexal, Tacaribe, Whitewater Arroyo (Charrel and de Lamballerie 2003).

Using IFAT, cross reactions between JUNV and LCM viruses; differentiate antibodies between the two viruses using NT (Ambrosio 2001).

**C.1.2.6 Tick-borne encephalitis virus, Far Eastern sub-type, formerly known
as tick-borne encephalitis complex (Russian spring-summer encephalitis
virus) (TBEV-FE)**

Host range

a. Field

More than 10 spp of forest rodents positive for virus; 17–20 percent tested had antibodies
(Chumakov 2008).

37 percent *Irinaceus roumanicus* (hedgehog) tested had antibodies (Chumakov 2008).

Since 1995, TBE virus has been isolated from blood samples of sentinel dogs, ticks, and
rodents in Japan (Kunze 2008).

TBE isolates, Japan, 1993, Hokkaido strain, from blood of sentinel dogs, tick pools, and
rodent spleens via suckling mouse inoculations (Takashima et al. 2001).

Western European (CEE) TBE virus isolated in Austria from a mouflon (*Ovis ammon
musimon*), a ruminant species, infested with *Ix ricinus* (Bago et al. 2002).

In Finland, TBE virus [probably CEE virus or TBEV-W] isolated from red squirrels
(*Sciurus vulgaris*), snow hare (*Lepus timidus*), field vole (*Microtus agrestis*), blackbirds
(*Turdus merula*), song thrush (*T. philomelos*), yellow hammer (*Emberiza citronella*)
(Brummer-Korvenkontio et al. 1973).

In endemic forest area of Russia, seroprevalence of 27 percent HI, 25 percent CF, 25
percent NT antibodies in goats; of 17 percent HI, 29 percent CF antibodies in cattle
(Korenberg, Pchelkina, and Spitsina 1984).

Vertical transmission of TBE virus [probably Siberian TBEV] between generations of the
small rodents—red voles *M. rutilus* Pallas (previously known as *Clethrionomys rutilus*
Pallas) shown for naturally infected reservoir hosts (Bakhvalova et al. 2009). The red

1 vole is endemic to Alaska but to no other U.S. States (U.S. Department of Agriculture
2 Forest Service).

3
4 RSSE/FE-TBE first isolate via IC inoculated mice, 1937, Far East USSR, human,
5 residing in Taiga forest camp (Chumakov 2008).

6
7 W-TBE first isolated from humans in Europe in 1948 (Gunther and Haglund 2005).

8
9 2008 marked the first time that ticks infected with TBE virus were detected at more than
10 1,500 meters above sea level; medical authorities recommending vaccination (Leitner
11 2009).

12
13 Ticks act as both the vector and reservoir for TBEV (Leitner 2009).

14 15 **b. Experimental**

16 Monkeys are not uniformly susceptible to TBEV; no known satisfactory disease model
17 for TBE in monkeys; in bonnet monkeys (*M. radiata*) disease demonstrated with one
18 member of the TBE virus complex, Kyasanur Forest disease virus, but the monkeys did
19 not develop disease consistently when infected with RSSEV or CEEV; subclinical
20 infections of rhesus macaques (*M. mulatta*) were observed after intravenous inoculation
21 of a Turkish strain of a TBE complex virus (Schmaljohn et al. 1999; Kenyon, Rippey, et
22 al. 1992) intranasal infection of adult rhesus monkeys with a member of the TBE
23 complex of flaviviruses mimics the human disease but does not cause pyrexia
24 (Hambleton et al. 1983).

25
26 *M. radiata* infected with RSSE virus developed clinical signs in the central nervous
27 system; RSSE virus was isolated from the brain of one monkey and viral antigen was
28 localized in neurons (Kenyon, Rippey, et al. 1992).

29
30 One serious constraint for studying TBE pathogenesis and for vaccine development has
31 been the absence of realistic animal models that mimic the human disease. Mice have

1 been the animal species most often used for studies of flavivirus behavior in mammals,
2 but the resulting illness bears little resemblance to human infection. Both guinea pigs and
3 several macaque species become viremic after peripheral inoculation of TBE complex
4 viruses, however, clinical illness is mild to absent. Although clinical, virologic, and
5 pathologic evidence of encephalitis has been produced in rhesus macaques by intranasal
6 inoculation of CEE virus, it is likely that infection by this route subverts normal disease
7 pathogenesis by allowing virus to pass directly across the cribriform plate and into the
8 CNS (Kenyon, Rippey, et al. 1992).

9
10 TBEV-W, sq, in Rhesus monkeys, at 10^3 SMICLD₅₀ or 10^9 SCICLD₅₀—inapparent
11 infection—no clinical signs, histopathologic lesions, or viremia, but antibodies produced
12 (Slonim and Zavodova 1977).

13
14 Vertical transmission of TBE virus [probably Siberian TBEV] between generations of the
15 small rodents—red voles *M. rutilus* Pallas (previously known as *Clethrionomys rutilus*
16 Pallas) shown experimentally with different sublethal doses of viral strains. In wild red
17 voles and progeny born 240–280 days after experimental infection of their parents, the
18 TBEV was detected in up to 90 percent of samples by RT-PCR, ELISA and bioassays.
19 Small amounts of viral RNA found in embryos, placenta, and blood cells could serve as
20 evidence of prenatal transmission. Postnatal transfer of virus might occur through rodent
21 milk (Calisher 1988).

22 23 **Prevalence/incidence/attack rate**

24 Prevalence of ticks infected with TBEV in endemic areas in Europe usually varies from 0.5
25 percent to 5 percent, but in some regions of Russia, a prevalence of 40 percent has been reported
26 (Dumpis, Crook, and Oksi 1999).

27
28 51% of humans living in the taiga have Nt antibodies to RSSE virus (Gresikova 1989).

29
30 Since 1990, more than 157,500 cases of TBE [caused by the CEE virus] were recorded in
31 Europe, corresponding to 8,755 cases annually. Closely related virus in Far Eastern Eurasia,

1 RSSE virus, is responsible for a similar disease with a more severe clinical course (Leitner
2 2009).

3
4 TBE is one of the most dangerous human infections occurring in Europe and many parts of Asia,
5 and is believed to cause at least 11,000 human cases of encephalitis in Russia and about 3,000
6 cases in the rest of Europe annually (Gritsun, Lashkevich, and Gould 2003).

7
8 Total number of annual cases tabulated in Western European countries has averaged 3000 for the
9 past 5 years (Gritsun, Lashkevich, and Gould 2003).

10
11 In 1990s most of 6,000–10,000 annual TBE case numbers from Russia and increasing annually
12 (1990 = 5,486, 1993 = 7,893, 1996 = 9,548) (Takashima et al. 2001).

13
14 TBE is the most important flavivirus infection of the CNS in Europe and Russia, with 10,000–
15 12,000 people diagnosed annually (Gunther and Haglund 2005).

16
17 W-TBE endemic in scattered areas within central, eastern and northern Europe (Gunther and
18 Haglund 2005).

19
20 TBE incidence increases from West [Europe] to East [Russia, Siberia]; in some areas of
21 European Russia and Scandinavia, up to 184 cases/100,000 inhabitants; seroprevalence ranges
22 from 22 percent to 83 percent (Alciati et al. 2001).

23
24 In the past 10 years, incidence of TBE has increased in virtually all European countries where
25 TBE is endemic. Between 1974 and 2003, the number of reported cases increased by 400 percent
26 with further increases between 2004 and 2006 to the highest incidences ever reported. Between
27 1993 and 2006, the number of reported clinical TBE cases in Germany and Switzerland
28 increased by 200 percent, in Poland by more than 60 percent, Czech Republic, Slovenia, and the
29 Baltic States are most affected [probably CEE virus] (Kunze 2008).

1 Incidence of TBE varies from year to year in different geographic regions; Pre-Ural and Ural
2 region and Siberia have the highest records of hospitalized cases—during the 1950s and 1960s,
3 TBE was recorded primarily in forest workers, reaching 700–1,200 cases annually; thereafter, up
4 to 11,000 recorded cases per year among urban dwellers who became infected when they visited
5 the local forests. 35–45 percent of all infected persons are children from 2.5 to 12 years old
6 (Gritsun, Lashkevich, and Gould 2003).

7
8 Average incidence: Latvia, 30 cases/100,000, Estonia, 16.5/100,000, Slovenia, 14/100,000,
9 Lithuania, 11.2/100,000, Kemerovo Russia, 20.5/100,000, Tomsk Russia, 72.5/100,000, southern
10 Germany, 2/100,000 (Kaiser 2008).

11
12 Russia, 1990s, incidence 6.8 cases/100,000 and ranges up to 72.5/100,000 in Tomsk (Kaiser
13 2008).

14
15 Highest incidence is registered in Latvia and in the Urals and the Western Siberian regions of
16 Russia, where attack rates might reach 115–199 reported cases per 100,000 inhabitants per year
17 (Dumpis, Crook, and Oksi 1999).

18
19 Highest incidence recorded in Austria, Czech Republic, Hungary, Slovakia, Slovenia with
20 several hundred cases annually in each country; dramatic decrease in Austria because of its
21 vaccination program (Avsic-Zupanc et al. 1995).

Table C-11. Change in TBE incidence in selected European countries, 1979-1999

Country	Number of TBE cases		% Change
	1979	1999	
Austria	677	41	−94
Sweden	23	53	+130
Switzerland	41	108	+163
Lithuania	41	171	+317
Estonia	35	185	+429
Germany	11	115	+945

Data from the World Health Organization. [WHO¹⁶].

Source: (Banzhoff, Broker, and Zent 2008)

Note: Austria has an active vaccination policy

Currently, 10,000–12,000 cases of encephalitis caused by all subtypes of TBEV (W-TBEV, FEKFDV, TBEV and S-TBEV) are reported annually (Gunther and Haglund 2005).

Between 1990 and 2007 a total of 157,584 TBE cases were documented. In Europe without Russia, a total of 50,486 cases. Average of 8,755 cases per year in Europe within this 18-year period, or 2,805 cases in Europe excluding Russia (Süss 2008).

R₀/incubation period/infectious period/infectious dose

Person-to-person transmission has not been reported (Leitner 2009).

Vertical transmission from mother to fetus has occurred (Seligman and Morozova 2009; Leitner 2009).

Incubation period is 7–14 days (Takashima et al. 2001; Alciati et al. 2001).

Incubation period is 4-28 days (Banzhoff, Broker, and Zent 2008) (Lindquist and Vapalahti 2008) with a median of 8 days (Lindquist and Vapalahti 2008; Kaiser 2008).

The infectious dose in humans unknown.

1 **Morbidity/case fatality ratio**

2 Serosurveys concerning TBEV (RSSE) suggest that between 70 and 95 percent of human
3 infections in endemic regions are subclinical (asymptomatic) (Gritsun, Lashkevich, and Gould
4 2003).

5
6 RSSE is a severe human disease with a case-fatality rate of 8–54 percent (Gresikova 1989).

7
8 CEE is a relatively mild disease with a case-fatality rate of 1–5 percent (Gresikova 1989).

9
10 Three subtypes have mortality rates of 1–2 percent [European—CEE], 6–8 percent [Siberian],
11 and 20–60 percent [Far Eastern], respectively, indicating that there are important [virulence]
12 differences among them (Seligman and Morozova 2009).

13
14 Death rate from Western virus is up to 4 percent and patients with encephalitis, 5 percent; from
15 Eastern virus, average of 20 percent and patients with encephalitis, 60 percent; death rate from
16 CCHF virus might reach 50 percent (Alciati et al. 2001).

17
18 Case fatality rate for Far Eastern subtype (RSSE virus) = 5–20 percent, and 5–30 percent
19 survivors with permanent paresis; for Western European subtype (CEE virus), CFR = 0.5–2.0
20 percent with 2–10 percent permanent paresis (Schmaljohn et al. 1999) (Takashima et al. 2001).
21 Lethality of TBE in Europe is 0.5 percent and a post-encephalitic syndrome is seen in more than
22 40 percent of affected patients (Gunther and Haglund 2005).

23
24 Mortality rate with FE-TBEV = 15–20 percent, with W-TBEV, 1–4 percent (Kaiser 2008).
25 Western Siberia, high morbidity and frequency of tick bites—2.6–5.7 percent of bitten persons
26 hospitalized with TBE; children younger than 14 years = 20–30 percent cases, working adults at
27 highest risk, disease becomes chronic in 1–1.7 percent, mortality varies from 1.8–3 percent
28 (Poponnikova 2006).

29
30 With TBEV-FE, CFR = 20–40 percent with seroprevalence of 1–20 percent in Europe and 20–40
31 percent in Russia; with TBEV-S, CFR= 2–3 percent (Lindquist and Vapalahti 2008).

1 In Russia, CFR of 30–60 percent (Gould and Solomon 2008).

3 CFR in Siberia of TBEV-S is 6–8 percent (Gritsun, Lashkevich, and Gould 2003).

5 Fatality rate of Western type TBEV is low (approx 1 percent), morbidity rate high, and long-term
6 neurologic sequelae common, but 2/3 of infections inapparent (Avsic-Zupanc et al. 1995).

8 CFR (RSSE) = 30–60 percent (Gould and Solomon 2008).

10 **Aerosol infection/routes of transmission**

11 Person-to-person transmission has not been reported (Leitner 2009).

12 Infection can follow consumption of raw milk from infected goats, sheep, or cows (Leitner
13 2009).

15 Laboratory infections common before the use of vaccines and availability of biosafety
16 precautions to prevent exposure to infectious aerosols (Leitner 2009).

18 1967, lab infections reported [in the absence of appropriate biocontainment precautions] 18
19 cases, 2 deaths (Hanson et al. 1967; Pike 1979).

21 Eight laboratory infections [in the absence of appropriate biocontainment precautions] reported
22 to SALS, zero deaths; infections via aerosol (Subcommittee on Arbovirus Laboratory Safety of
23 the American Committee on Arthropod-Borne Viruses 1980).

25 Vertical transmission from an infected mother to fetus has occurred (Leitner 2009).

27 Humans are infected in rural areas through tick bites (Leitner 2009).

29 Infection can persist, particularly with the Siberian subtype (Seligman and Morozova 2009).

1 Vertical transmission in laboratory animals demonstrated to be widespread; virus detected for
2 five generations in small rodents without involvement of arthropod vectors (Seligman and
3 Morozova 2009).

4
5 Aerosols either as water droplets or in the form of powder present an infectious hazard in the
6 laboratory and should be avoided by appropriate [bio]containment (Gritsun, Lashkevich, and
7 Gould 2003).

8
9 Humans walking through dense vegetation in forests are most likely to become infected
10 following the bite of an infected tick (Gritsun, Lashkevich, and Gould 2003).

11
12 Consumption of goat milk; experimentally demonstrated that TBEV can be isolated from the
13 milk of goats for 5–25 days following infection and the infectivity survives in various milk
14 products such as yoghurt, cheese and butter; drinking infected milk might cause biphasic milk
15 fever (Gritsun, Lashkevich, and Gould 2003).

16
17 TBEV complex viruses are secreted into the feces and urine of infected mice; possible route of
18 infection (Gritsun, Lashkevich, and Gould 2003).

19
20 Laboratory infections are associated with accidental needle-stick injuries during injections of
21 animals. Aerosol infections among laboratory personnel were reported in laboratories when glass
22 bottles containing high virus concentrations were accidentally broken in walk-in incubators
23 (Gritsun, Lashkevich, and Gould 2003).

24
25 France, 2003, cases linked to consumption of imported goat cheese; via breast milk reported
26 (Randolph 2008).

27
28 Slovenia, handling of TBE viruses potentially hazardous, as indicated by number of LAIs in the
29 pre-vaccination era. Laboratory-acquired, full-blown TBE was reported in a microbiologist who
30 isolated the virus from blood sample of tick-bite patient, probably acquired by aerosol. The

causative virus strain was isolated in Slovenia similar to European prototype strain [CEE virus= Western TBEV= TBE (Western type) = TBEV Western European] (Avsic-Zupanc et al. 1995). Transmission to humans via ixodid ticks in moist, lush, organic under burden of forests; 3,500–10,000 cases/yr in Russia with estimated 5 percent infection rate in ticks (Gould and Solomon 2008).

Virus titers/concentrations/pathogenesis

In Vero, BHK-21, pig kidney cells, 10^6 – 3×10^7 CCID₅₀/mL in roller bottles/flasks (Johnson 2008).

In tick cell lines from *Ix ricinus* and *Ix scapularis*, TBE, European subtype replicates to titers of 10^{7-8} PFU/mL; in *Boophilus microplus*, *Ornithodoros moubata*, and *Rhipicephalus appendiculatus* cell lines, 10^{4-6} 10^6 PFU/mL (Ruzek et al. 2008).

Chick embryo or pig embryo cell cultures produce virus titers to 10^7 – 10^8 /MID₅₀/mL (Chumakov 2008).

Newborn, IC and IP, death, titers 10^7 – 10^9 ID₅₀/mL [test system not reported]; weanling mice, IC, death, titers 10^7 – 10^8 ID₅₀/mL [test system not reported], IP, 10^6 – 10^7 ID₅₀/mL [test system not reported] (Chumakov 2008).

3–4 wk Syrian hamster, IP and IC, death, 10^5 – 10^8 ID₅₀/mL [test system not reported] (Chumakov 2008).

1–2 d white rats, IC, death, $10^{7.2}$ ID₅₀/mL [test system not reported] (Chumakov 2008).

3–4 wk pigs, death, 10^7 ID₅₀/mL [test system not reported] (Chumakov 2008).

Guinea pigs, IC, death, 10^4 – 10^6 ID₅₀/mL [test system not reported] (Chumakov 2008).

Chick embryos, 10^6 – 10^8 ID₅₀/mL [test system not reported] (Chumakov 2008).

1 Virus replicates in many cell culture systems (Gresikova 1989).

2
3 Chick embryo and pig embryo cell cultures, 10^7 to 10^8 MID₅₀/mL (Chumakov 2008).

4
5 Mice inoculated SQ or IC with 10,000 focus forming units (FFU) of Hokkaido isolate produced
6 more than 10^9 FFU/gm of brain (Takashima et al. 2001).

7
8 Sheep, death; rhesus monkey, paralysis; no virus titers reported (Chumakov 2008).

9
10 In *M. radiata*, no viremia and no RSSE virus detected by plaque assay in organs; blind passage
11 of brain tissue, IC, in suckling mice caused death and high viral titers isolated from their brains;
12 virus identified as RSSE virus by neutralization with specific antiserum (Kenyon, Rippey, et al.
13 1992).

14
15 Siberian strain of TBEV, passage in mice = $10^{7.5}$ MICLD₅₀/mL (Bakhvalova et al. 2009).

16
17 **Pathogen stability**

18 Stable for at least 6 hours in liquid aerosol suspension at room temperature and 23–80 percent
19 humidity (Gritsun, Lashkevich, and Gould 2003).

20
21 The D₃₇ value for West Nile virus was calculated to be 24 [HL=56 min at maximum solar UV
22 conditions](Lytle and Sagripanti 2005). RSSE virus and West Nile virus are classified in the
23 genus *Flavivirus*.

24
25 Virions stable for up to 2 hours in normal gastric juice at pH 1.49–1.80 and in gastric juice with
26 reduced acidity (pH 1.87–2.21); in gastric juice taken from humans after a meal (pH 2–7) the
27 virus is stable for 2 hours. Milk foods move out of the stomach quickly (the first milk consumed
28 reaches the duodenum within minutes, and after 1.5–2 hours, there is no milk in the stomach).

29 Hydrochloric acid is secreted in the stomach between 45 minutes and 60 minutes after
30 consumption of milk. The human digestive tract is an efficient route of infection (Gritsun,
31 Lashkevich, and Gould 2003).

1 Survives in milk for prolonged periods, even when passing through the acidic stomach
2 environment (Kaiser 2008).

3
4 Heat labile and inactivated by pasteurization (Kaiser 2008).

5
6 Ether and deoxycholate reduce virus titer by 50 percent in 24 hours (Chumakov 2008).

7
8 1 M MgCl₂ at 25 °C inactivates virus within 6 days (Chumakov 2008).

9
10 Readily inactivated by organic solvents and detergents; nonionic detergents such as Triton X
11 solubilize the entire envelope releasing M and E proteins. Sodium deoxycholate appears to
12 remove only E, leaving M associated with the nucleocapsid (Gritsun, Lashkevich, and Gould
13 2003).

14
15 Envelope protects the genome from cellular nucleases. The naked nucleocapsids released by
16 detergent treatment are degraded by ribonuclease. Purified naked RNA infectious following
17 direct intracerebral injection of mice (Gritsun, Lashkevich, and Gould 2003).

18
19 Infectivity optimally stable at pH 8.4–8.8; residual infectivity over the broader pH range 1.42–
20 9.19 being roughly comparable with the stability of enteroviruses; at acidic pH the E protein
21 undergoes specific conformational changes that reduce virus infectivity, virions remain
22 infectious in curdled milk and gastric juice, which could explain why the virus can infect via the
23 alimentary route (Gritsun, Lashkevich, and Gould 2003).

24
25 Rapidly inactivated at 50 °C, 50 percent of infectivity lost in 10 minutes. The total inactivation
26 of the virus suspended in blood or other protein solutions occurs within 30 minutes at 56 °C
27 (Gritsun, Lashkevich, and Gould 2003).

28
29 Ultra-low temperatures preserve infectivity almost indefinitely (Gritsun, Lashkevich, and Gould
30 2003).

1 In freeze-dried form, they survive almost indefinitely at room temperature (Gritsun, Lashkevich,
2 and Gould 2003).

3
4 Inactivated by UV light, gamma-irradiation, and disinfectants, including 3–8 percent
5 formaldehyde, 2 percent glutaraldehyde, 2–3 percent hydrogen peroxide, 500–5,000 ppm
6 available chlorine, alcohol, 1 percent iodine, and phenol iodophors (Gritsun, Lashkevich, and
7 Gould 2003).

8
9 Indication that viruses with structural lipids survive best in aerosols at low RH (Benbough 1971).
10 UV radiation inactivates viruses by chemically changing the RNA and DNA; most effective UV
11 is 250 nm; filoviruses [MAR and EBOV] most sensitive to solar UV₂₅₄, requiring 20–100
12 minutes at mid-day exposure to inactivate 1 log₁₀ of virus: bunyaviruses (hantaviruses [AND
13 virus] and RVFV), arenaviruses (Lassa, JUN), and flaviviruses (TBE complex viruses) more
14 resistant (Lytle and Sagripanti 2005).

15 16 **Vectors**

17 The virus can chronically infect ticks and is transmitted both transtadially (from larva to nymph
18 to adult ticks) and transovarially (from adult female tick through eggs (Leitner 2009).

19
20 Relatively ancient divergence separates the western populations of the North American *Ixodes*
21 deer ticks from the eastern array of populations, and another apparently more recent divergence
22 separates the northeastern from the southeastern arrays of ticks. Indeed, those in the western
23 clade, designated *Ix pacificus*, are more closely related to Eurasian *Ix persulcatus* than to the
24 more *Ix ricinus*-like ticks of eastern North America [phylogenetic relationships do not
25 necessarily reflect potential ability of the North American tick species to transmit TBE viruses;
26 ticks in MA are genetically more closely related to *Ix ricinus*, the primary vector of CEE virus]
27 (Rich et al. 1995).

28
29 Canadian and northern United States, *Ixodes scapularis*, among other *Ixodes* species, are
30 reservoirs and vectors of Powassan virus, which is closely related to viruses of the TBE-complex
31 (Turell 2008).

1 It is likely that indigenous mice would be competent hosts for amplification of viruses of the
2 TBE complex (Turell 2008).

3
4 Ticks flourish best at a humidity above 85 percent, in temperatures of 6–7 °C, and in the
5 presence of large numbers of blood-delivering hosts; in many areas in Europe, those three basic
6 requirements have been changing in favor of the tick population allowing tick movement
7 northward and upward, now inhabiting mountainous areas higher than 1,000 meters above sea
8 level. The number of tick life cycles will increase, tick habitats will expand, and the density of
9 the tick population will continue to rise (Kunze 2008).

10
11 In Russia, the range of taiga ticks has been extending southward during the 1990s (Poponnikova
12 2006).

13
14 **a. Field**

15 *Ixodes persulcatus* ticks transmit RSSE virus (Gresikova 1989).

16
17 *Ix ricinus* ticks transmit CEE virus (Gresikova 1989).

18
19 Many isolates from *Ixodes* spp, *Dermacentor* spp, and *Hyalomma* spp ticks (Chumakov
20 2008).

21
22 Isolates from Laelapid (Gamasoid) mites (Chumakov 2008).

23
24 Most important tick spp. in Europe: *Ixodes persulcatus* and *Haemaphysalis spinigera*,
25 responsible for transmission of RSSE virus; *Ix ricinus*, responsible for transmission of
26 middle European TBE virus; and *Hyalomma* spp, responsible for transmission of CCHF
27 virus (Alciati et al. 2001).

28
29 Middle European or Western subtype of TBE virus transmitted by *Ix ricinus* and RSSE
30 (Eastern or Russian TBE virus) transmitted by *Ix persulcatus* (Alciati et al. 2001).

1 Ticks remain infected throughout their life cycle and transmit the virus to uninfected ticks
2 when co-feeding on small wild rodents (Gritsun, Lashkevich, and Gould 2003).

3
4 Persistence in ticks occurs via viremic, transstadial, or transovarial transmission.
5 Transmission of virus from infected to noninfected ticks occurs when they co-feed on the
6 same host (virus replicates at a local skin site), and it is not necessary for the host to
7 develop a detectable viremia (Gritsun, Lashkevich, and Gould 2003).

8
9 Isolated sporadically from at least 15 other ticks species and from flies, fleas, lice
10 (Gritsun, Lashkevich, and Gould 2003). There is a report of virus having been isolated
11 from mosquitoes (Gritsun, Lashkevich, and Gould 2003). However, Dr. M. Turell
12 (USAMRIID) states that he knows of no reproducible experimental work showing any
13 mosquitoes species capable of being infected with TBE viruses. He states there is one
14 discredited report from the former Soviet Union in older literature (Turell 2008).

15
16 High prevalence of *Ix persulcatus* correlated more frequently with severe and fatal cases;
17 milder cases were recorded in years when *Hy concinna* was the dominant tick species.
18 When these tick species were at equivalent levels in any one focus, there was a relatively
19 similar proportion of severe and mild forms of TBE. Ticks can select high and low-
20 virulence TBEV strains [also demonstrated experimentally] (Gritsun, Lashkevich, and
21 Gould 2003).

22
23 Main vector in Japan is *Ix ovatus* (Kunze 2008).

24
25 Principal vector of the European TBEV subtype is the tick *Ix ricinus* ; virus infects ticks
26 chronically for the duration of their life and circulates between ticks and their vertebrate
27 hosts. The virus is also transmitted transovarially and during co-feeding of ticks on the
28 same host (Ruzek et al. 2008; Labuda and Nuttall 2004).

29
30 *Ix trianguliceps*, *Ix hexagonus*, and *Ix arboricola* are considered amplifying vectors.
31 Secondary vectors, *Haemaphysalis inermis* and *Dermacentor reticulatus* exhibit lower

1 transmission rates. The virus was isolated from *Hae inermis* in the Czech Republic
2 (Ruzek et al. 2008).

3
4 TBE virus was isolated from *Ix ricinus* nymphs (Danielova et al. 2002).

5
6 The virus spread in ticks includes transovarial, transtadial, sexual, and nonviremic
7 transmission (Bakhvalova et al. 2009).

8 9 **b. Experimental**

10 There is no known experimental work (as of October 2008) assessing whether the viruses
11 of TBE complex can survive in tick species indigenous to North America, and there is no
12 reproducible work showing mosquitoes capable of being infected (Turell 2008).

13
14 In *Ix persulcatus* ticks that fed on viremic mice, titers reach 10^6 MLD₅₀ (Gresikova
15 1989).

16
17 Transstadial and transovarial infection demonstrated in ticks (Gresikova 1989).
18 Sexual transmission demonstrated in ticks from infected *Ix persulcatus* males to
19 noninfected females (Gresikova 1989).

20
21 *Haemaphysalis spinigera* and *Hae turturis* transmit TBEV under laboratory conditions, *D*
22 *marginatus* and *D reticulatus* are possible vectors, though infection and transmission
23 rates were lower than in vector species of the genera *Ixodes* and *Haemaphysalis* (Ruzek
24 et al. 2008).

25
26 Saliva-activated viremia demonstrated when ticks feed on infected hosts; non-viremic
27 transmission from infected to noninfected *Ix ricinus* during co-feeding (Danielova et al.
28 2002; Labuda and Nuttall 2004).

1 **Other epidemiological/ecological data**

2 Cases occur during the highest period of tick activity (between April and November) [seasonal
3 activity](Leitner 2009).

4
5 Despite their names [European, Siberian, Far Eastern] , all three subtypes co-circulate throughout
6 most of the TBEV endemic areas. The Siberian subtype dominates in many endemic regions
7 from Eastern Europe to Eastern Siberia (Seligman and Morozova 2009).

8
9 Maintained in a natural cycle involving ticks and wild vertebrate hosts in forests of Europe and
10 Asia where ticks find high humidity in dense undergrowth (Gritsun, Lashkevich, and Gould
11 2003).

12
13 The TBE virus is endemic in several non-European countries (Mongolia, China, Japan, and
14 South Korea); Heilongjiang province in the northeast of the People's Republic of China, 2,202
15 cases between 1980 and 1998, 420 of them between 1995 and 1998; cases in Japan (Kunze
16 2008).

17
18 Ticks transmit a greater variety of pathogenic microorganisms than any other arthropod vector
19 group; TBE is the most important tick-borne viral disease of humans in Europe and Asia;
20 distribution of TBEV extends from Western Europe to China and Japan, Hokkaido strain (Ruzek
21 et al. 2008).

22
23 TBE virus isolates from Japan, 1993, Hokkaido strain, are the same as Russian subtype
24 (Takashima et al. 2001).

25
26 Overview of tick-borne encephalopathies in humans (Gunther and Haglund 2005).
27 FE-TBE is endemic in Latvia, Russia, Asia, Japan; FE-TBE in eastern Russia more severe than
28 other TBE types (Gunther and Haglund 2005).

29
30 Satellite imagery used for prediction of tick seasonal dynamics and presence of TBE (Gunther
31 and Haglund 2005).

Table C-12. TBE subtype locations, vectors, and conditions

Pathogen	Region	Vector	Condition
Western TBEV	Central, eastern/northern Europe, Russia, Baltic States	<i>Ix ricinus</i> , <i>Ix persulcatus</i>	Meningo-encephalitis, spinal nerve paralysis
Siberian TBEV	Russia, eastern Europe	<i>Ix persulcatus</i>	Meningo-encephalitis, spinal nerve paralysis
Far-eastern TBEV	Eurasia, Asia	<i>Ix persulcatus</i>	Meningo-encephalitis, spinal nerve paralysis

W-TBE isolates homogeneous across all European endemic areas; S-TBEV and FE-TBEV activity overlap in Asian Russia and China; 96 percent identity in E-protein amino acid sequences between the S- and FE-TBEV and the W-TBEV (Kaiser 2008).

Once considered a local health issue in certain regions of Russia and Central/Eastern Europe, TBE is now an international health problem with expansion of endemic areas and rapidly increasing numbers of cases and due to travel to and pursuit of leisure activities into high-risk areas (Banzhoff, Broker, and Zent 2008).

W-TBEV, endemic in scattered areas in central, eastern, and northern Europe from the Alsace-Lorraine area in the west to Scandinavia to the north to Italy, Greece, and Crimea in the south; FE-TBEV found in Russia, northeastern China, parts of northern Japan, and as far west as the Baltic states; S-TBEV (Siberian) found westward to Finland; all three subtypes co-circulate in Estonia (Banzhoff, Broker, and Zent 2008).

Reservoirs are wild living vertebrates capable of transmitting infection (reservoir competence). In the natural foci, these reservoirs need to be available in high numbers coupled with a high-reproduction rate and a rapid generation change. In case of TBEV, they need to be receptive to the virus and enable virus multiplication, including viremia, for a long period of time with high-virus titer without becoming clinically ill at the same time. The significance of antiviral immunity of the vertebrate host for virus transmission has changed during the last years. In

contrast to a vector, Spielman et al. defined a reservoir host as the passive member in the vector–reservoir relationship. *Indicator hosts* cannot transmit the virus to other vectors as they can endure only brief viremia with low-virus titers. Indirectly, they support virus circulation by enabling the ticks to multiply in masses (roe, deer). In addition, they are highly valuable sentinels for antibody detection in epidemiological studies. *Accidental hosts* can be infected by the pathogen and can develop viremia, in case of TBEV. In general, they do not participate in virus circulation (Suss 2003).

More than 70–95 percent of human infections are subclinical (Gritsun, Lashkevich, and Gould 2003).

Through vertical transmission among generations of its adapted mammal reservoir hosts, virus transfer might occur before, during, or after birth of the small rodents with high frequencies. In the wild it could provide the TBEV long-term persistence in mammal hosts without involvement of arthropod vectors thus selecting dangerous mammal-adapted variants (Bakhvalova et al. 2009).

TBEV circulate harmlessly in forests, on moorlands, in steppe regions of Europe and Asia until humans enter the ecosystem; normal transmission between ticks and rodents/other animals; eastern strains now found as far west as Latvia possibly carried via ticks on migratory birds (Gould and Solomon 2008).

Therapeutics/vaccines

Formalin-inactivated mouse brain origin vaccine used in the USSR (Gresikova 1989).

Formalin-inactivated embryonating hen’s egg origin vaccine used in the USSR (Gresikova 1989).

Formalin-inactivated chick embryo cell culture origin vaccine used in the USSR (Gresikova 1989).

Only successful way of prevention [western Europe] is active immunization (Kunze 2008).

1 European TBE virus vaccine effective in Japan in humans against Hokkaido strain (Takashima et
2 al. 2001).

3
4 Specific immunoglobulin used in Russia; several vaccines used in Europe and Russia. Purified,
5 formalin-inactivated virus vaccine (FSME Immune InjectTM) is used effectively in Europe
6 (Takashima et al. 2001).

7
8 Two inactivated vaccines (FSME - IMMUNTM, Baxter Vaccine AG and EncepurTM, Chiron)
9 licensed in Europe for active immunization against TBEV: (Gunther and Haglund 2005).

- 10 • Austrian vaccine (predecessor related to FSME-IMMUN) active against both W- and FE-
11 TBEV was introduced in 1976; FSME-IMMUN vaccine introduced in 2001—product
12 based on a formalin-inactivated Austrian W-TBEV, propagated on primary chick embryo
13 cells with several modifications, most importantly a switch from propagation on mouse
14 brain cells to chick embryo cells, highly purified using continuous-flow zonal
15 ultracentrifugation; contains 2–3.5µg of viral antigen; protection rate of from 94 to
16 greater than 98 percent reported (Gunther and Haglund 2005).
- 17 • German vaccine (Encepur), 1991, W-TBE strain, contains 0.1µg of viral antigen;
18 protection rate not reported; chick embryo cell culture-derived (Gunther and Haglund
19 2005; Schmaljohn et al. 1999).
- 20 • Both the German and Austrian vaccines induce neutralizing antibodies against both the
21 W-TBE and FE-TBE viruses (Gunther and Haglund 2005).

22
23 Rhesus macaques were vaccinated by gene gun inoculation of DNA vaccines expressing the *prM*
24 and *E* genes of RSSEV, CEEV, or both DNA vaccines. The antibody titers similar in monkeys
25 vaccinated with both DNA vaccines or with inactivated virus vaccine (Austria), protective
26 immunity, as measured by passive transfer of serum from monkeys to mice, also appeared very
27 similar. All mice that received sera from monkeys vaccinated with both DNA vaccines or in
28 groups that received sera from monkeys vaccinated with the inactivated-virus vaccine remained
29 healthy after RSSEV challenge [monkeys do not respond predictably to infection with TBEV, so
30 vaccine efficacy was measured by cross-protection of mice via serum] (Schmaljohn et al. 1999).

1 From vaccine studies, presence of virus-neutralizing antibodies in serum provides an excellent
2 correlate for protection against virus challenge. Protection by TBE vaccination in Austria ranges
3 to 99 percent with no significant differences between age groups (Heinz et al. 2007).

4
5 Inactivated vaccine prepared after continuous-flow zonal ultracentrifugation produce fewer
6 problems than other inactivated vaccines (Gresikova 1989).

7
8 Attenuated vaccines have been used for CEEV in cattle to prevent human infection from
9 consumption of raw milk (Gresikova 1989).

10
11 Human immune serum used for prophylaxis (Gresikova 1989).

12
13 Noninfectious, self-replicating RNAs generated by deletion mutagenesis of the capsid protein C
14 represent a promising new future for TBE virus vaccines. The study used a Western subtype of
15 TBE virus [probably a strain of CEE virus]. No indication that the vaccine-induced antibody will
16 protect against RSSE virus (Kofler et al. 2004).

17
18 New genetic vaccine based on self-replicating, noninfectious RNA, which contains the necessary
19 genetic information to establish its replication machinery in the host cell, thus mimicking a
20 natural infection. Genetic modifications in the region encoding the capsid protein simultaneously
21 prevents the assembly of infectious virus particles and promotes the secretion of noninfectious
22 subviral particles that elicit neutralizing antibodies. Mice challenged IP with more than 1,000
23 LD₅₀ of TBEV-W (Kofler et al. 2004).

24
25 DNA vaccine TBEV tested in mice alone or in various combinations; TBEV expressed preM and
26 E genes; vaccine delivered by gene gun; TBEV DNA vaccine elicited antibodies and protected
27 mice from challenge when delivered alone or in combination with other DNAs (Spik et al. 2006).

28
29 **Other remarks**

30 RSSE first described in 1932 as a severe encephalitis in humans residing in the far eastern
31 regions of the Russia [USSR] (Gresikova 1989).

CEE first described in 1949 as a mild form of RSSE in the European USSR and eastern Europe (Gresikova 1989).

Tick transmitted encephalitis was first described in Austria in 1927, [CEE] virus isolated in 1937 (Alciati et al. 2001).

SALS level 4 (Chumakov 2008).

Caused by TBEV, previously known as RSSE virus; discovered in 1937 in far-east Russia (Gritsun, Lashkevich, and Gould 2003).

Flaviviruses transmitted by *Ixodes* spp ticks cause neurologic or hemorrhagic disease (Gould and Solomon 2008).

Viruses in the TBE virus complex can produce mild febrile illness, biphasic fever, encephalitis, or hemorrhagic fever in humans (Gould and Solomon 2008).

Note: While the RSSE virus is the NEIDL/BU/NIH preferred pathogen, frequently in the literature no distinction is made between RSSE virus, CEE virus, and the other viruses in the TBE virus complex. While the literature is replete with references to *TBE virus*, there is no single TBE virus, and there is no official registration of or recognition of a virus by that name in the Arbovirus Catalog, which stands as the authoritative publication on arthropod-borne viruses. The point is not academic because there are substantial differences in virulence and pathogenicity among the viruses in this complex (Calisher 1988).

Taxonomy/antigenic relationships/synonyms

Family Flaviviridae, genus *Flavivirus* (Gresikova 1989).

TBE virus complex [close antigenic relationship between RSSE and CEE viruses with different primary tick vectors] (Gresikova 1989):

- RSSE = Spring-summer TBE; Far East encephalitis; forest spring encephalitis; Far Eastern TBE; Taiga encephalitis; Far Eastern Russian encephalitis; TBE (Eastern type) (Gresikova 1989);
- CEE = TBE; Central European TBE; Czechoslovak TBE; diphasic milk fever; biphasic meningoencephalitis; TBE (Western type) (Gresikova 1989).

Two antigenic complexes (Gresikova 1989):

- Tyuleny complex;
- RSSE virus complex: RSSE virus; Powassan virus; Karshi virus; Royal Farm virus;

Seven subtypes of RSSE virus are recognized (Gresikova 1989).

- RSSE virus in Far Eastern Russia;
- CEE virus in central and western Europe;
- Kumlinge virus in Finland;
- Louping ill virus in the British isles (Scotland, England, Ireland);
- Omsk hemorrhagic fever in western Siberia;
- Kyasanur Forest disease in India;
- Langat virus in Asia.

Although a new subdivision of the virus species into four subtypes has been suggested, the currently accepted classification (ICTVdB - The Universal Virus Database, version 3.

<http://www.ncbi.nlm.nih.gov/ICTVdb/ICTVdb/> does not separate TBEV into two species but lists three subtypes: European, Siberian, and Far Eastern (Seligman and Morozova 2009). TBEV species includes three subtypes, Far Eastern (previously RSSE), Siberian (previously west-Siberian) and Western European (previously Central European Encephalitis, CEE) virus (Gritsun, Lashkevich, and Gould 2003).

In recent literature [~2000 and on], TBE virus = RSSE virus (Gritsun, Lashkevich, and Gould 2003).

TBE virus taxonomically classified into European, Siberian, and Far Eastern subtypes (Ruzek et al. 2008).

Far Eastern subtype = RSSE virus, CEE virus = Western European subtype (Takashima et al. 2001).

Antigenically related TBE viruses (Gunther and Haglund 2005; Kaiser 2008):

- Central European encephalitis W-TBEV or Western TBEV (W-TBEV);
- Siberian subtype TBEV (S-TBEV);
- Russian spring-summer encephalitis virus or Far Eastern TBEV (FE-TBEV);
- Louping-ill virus;
- Powassan virus (POWV);
- Omsk hemorrhagic fever virus (OHFV);
- Kyasanur forest virus (KFDV);
- Langat virus.

Nipah virus (NIPV)

Host range

a. Field

Broad species tropism and highly pathogenic (McEachern et al. 2008).

Flying fox (fruit bats)—*Pteropus* sp natural reservoir (Chua et al. 2002).

Grey-headed fruit bats (*P. poliocephalus*) a reservoir species for NIPV (Weingartl, Berhane, and Czub 2009).

Flying foxes (*Pteropus* sp.), the natural reservoir for the NiV (Blum et al. 2009).

Pigs (Aljofan et al. 2009).

1 Dogs and cats are susceptible to NIPV infection. In Malaysia, 46–55 percent of the
2 domestic dogs living in the regions of the epidemics were seropositive (Wild 2009).
3 Cats (Torres-Velez et al. 2008).

4
5 Dogs, cats, horses, and goats (pigs being the original source for these animals) as dead
6 end hosts (Chua 2003).

7
8 Dead-end hosts: dogs, cats, ferrets, pigs, horses (Lo and Rota 2008).

9
10 Serological evidence of infection with NIPV in the field in humans, pigs (amplifying
11 host), dogs, cats, horses, and goats (Weingartl, Berhane, and Czub 2009) (Chua 2003).

12
13 Bats (flying foxes) serve as natural host but also naturally infect humans, cats, dogs, and
14 pigs (Eaton, Broder, and Wang 2005).

15
16 Evidence of NIPV found in four fruit bat species and one insectivorous bat in Malaysia—
17 also evidence of Cambodian bats being infected as well as pigs, dogs, and cats (Bellini et
18 al. 2005).

19
20 Natural reservoirs: *Pteropus* sp as well as non-*Pteropus* sp from Cambodia, Thailand,
21 Indonesia, Bangladesh, and Madagascar (Lo and Rota 2008).

22
23 In Malaysia, 46–55 percent of dogs and cats in the epidemic regions were seropositive for
24 NIPV while in other areas they were sero-negative (Wild 2009).

25
26 In some regions (India) 54 percent of bats tested had ab's to NIPV. Laboratory studies
27 with infected bats show they manifest a subclinical infection (Wild 2009).

28
29 **b. Experimental**

30 8 African green monkeys, oral and/or intratracheal inoc ranging from 2.5×10^3 – $1.3 \times$
31 10^6 . All symptomatic, one survived (Geisbert et al.)

1 Squirrel monkeys (Marianneau et al.)

3 Pigs (Berhane et al. 2008).

5 Female piglets (Weingartl et al. 2005).

7 Guinea pig, cats, hamsters, mice (did not appear to be susceptible), grey headed fruit bats
8 (seroconversion) (Torres-Velez et al. 2008).

10 Mice, guinea pigs, hamsters infected with 10^7 PFU IP. Mice and guinea pigs were not
11 susceptible (Wong et al. 2003).

13 Cat and golden hamster are considered suitable small animal models of NIPV infection
14 (Weingartl et al. 2009).

16 Feline vaccine model, 5×10^3 TCID₅₀ given oronasally (McEachern et al. 2008).

18 Hamster vaccine model (Guillaume et al. 2004).

20 Golden hamster model became infected with as little as 100 pfu NIPV inoculated
21 intraperitoneally or 1,000 pfu NIPV inoculated intranasally and appeared to reproduce the
22 pathology and pathogenesis of acute NIPV infection in humans, with lesions most severe
23 in the brain (Halpin and Mungall 2007) (Wong et al. 2003).

25 Golden hamster model mimics human infection (Bellini et al. 2005).

27 Chicken embryos (Tanimura et al. 2006).

1 **Prevalence/incidence/attack rate**

2 Study of the 24 months after initial outbreak (1998–1999) showed a prevalence of relapsed and
3 late-onset encephalitis (thought to be the same disease entity) of 7.5 percent and 3.4 percent,
4 respectively (Tan et al. 2002).

5
6 Survey of NIPV infection among various risk groups in Singapore (after 1999 outbreak): 1.5
7 percent of people tested had antibodies to NIPV. Of those, 54.6 percent were symptomatic,
8 while 45.4 percent were asymptomatic, historically. All 1.5 percent were abattoir workers
9 (responsible for the slaughter of pigs) (Chan et al. 2002).

10
11 Survey of (pig) abattoir workers in Malaysia after the 1998 outbreak showed 1.6 percent
12 prevalence of NIPV antibodies in those tested (Sahani et al. 2001).

13
14 Seroprevalence study of 2004 outbreak in Bangladesh shows nosocomial transmission risk small
15 (Gurley, Montgomery, Hossain, Islam, et al. 2007).

16
17 **R₀/incubation period/infectious period/infectious dose**

18 R₀ was estimated to be 0.48 for outbreaks in rural Bangladesh. Four limitations of the estimate
19 were noted: (1) It is likely that not all human infections were identified; (2) The estimated rate
20 assumed all persons infected by a primary case-patient were identified, which might not have
21 been true; (3) Only 9 persons were identified as having transmitted the virus, so statistical power
22 of the calculations is limited; (4) It was assumed that persons who developed Nipah illness
23 within 5–15 days after exposure to a Nipah patient were infected from that patient rather than
24 from an unrelated environmental exposure; (Luby et al. 2009).

25
26 Among the 10 clusters, 5 involved person-to-person transmission ranging from 2 to 5 generations
27 of transmission. The 60 primary Nipah case-patients infected 29 subsequent persons (Luby et al.
28 2009).

29
30 Incubation period ranged from 4 days to 2 months with more than 90 percent of patients giving a
31 history of 2 weeks or less (Chua 2003).

1 In Sigiluri West Bengal, India 2001 outbreak clear evidence of person-to-person transmission
2 pointing to an incubation period of 5 to 10 days (Harit et al. 2006).

3
4 Incubation 2 days to 2 months with most 2 weeks or less (Bellini et al. 2005).

5
6 Incubation period in original outbreaks was 4 days–2 months (average 2 weeks) while in
7 additional outbreaks incubation was 6–11 days with an increased frequency of respiratory
8 symptoms, altered mental status, and vomiting (Lo and Rota 2008).

9
10 Duration of illness ranged from 2-34 days (Wong, Shieh, Kumar, et al. 2002).

11
12 An LD₅₀ was determined for guinea pigs. Death required infection by two routes simultaneously,
13 and the LD₅₀ for this approach was 270 PFU given by intraperitoneal injection in conjunction
14 with 47,000 PFU given intranasally (Wong et al. 2003).

15
16 10⁴ TCID₅₀ was a lethal dose (as intended) for golden hamsters (control group N=2) (Freiberg et
17 al.).

18
19 **Morbidity/case fatality ratio**

20 Results from serologic study following the 1999 Singapore outbreak found 22 people with anti-
21 NIPV antibodies indicative of infection with NIPV. Ten of the 22 were asymptomatic, which
22 suggests that clinically asymptomatic infections do occur (Chan et al. 2002).

23
24 Asymptomatic or mild infection might occur in 8–15 percent of infected persons, with some
25 suggesting subclinical infection rates up to 60 percent (Sejvar et al. 2007).

26
27 Rate of subclinical infection ranged from 8 to 15 percent (Chua 2003).

28
29 Estimated symptomatic versus asymptomatic 3 to 1 (Wong, Shieh, Kumar, et al. 2002).

1 Symptoms consist of fever, headache, myalgia, altered sensorium (confusion to coma),
2 respiratory distress, convulsions, and vomiting (Chadha et al. 2006).

3
4 Main presenting clinical features are fever, headache, dizziness, and vomiting with more than 50
5 percent of the patients having a reduced level of consciousness and prominent brainstem
6 dysfunction (Chua 2003).

7
8 Direct cause of death thought to be mainly due to the direct consequence of encephalitis (Chua
9 2003).

10
11 In humans, widespread multisystemic vasculitis with clinical and pathologic manifestations in
12 the brain, lung, and spleen (Torres-Velez et al. 2008).

13
14 Fever, headache, dizziness, and vomiting, reduced level of consciousness and prominent
15 brainstem dysfunction nonproductive cough, myalgia, focal neurologic signs (Goh et al. 2000).

16
17 NIPV causes a severe, rapidly progressive encephalitis with a high mortality rate and features
18 that suggest involvement of the brainstem. Neurological relapse can occur in mild or
19 asymptomatic cases (Goh et al. 2000).

20
21 Infection with NIPV can also take a more chronic course, with serious neurological disease
22 occurring late (in excess of 4 years) following a non-encephalitic or asymptomatic infection
23 (Eaton et al. 2006).

24
25 Sudden onset—fever, headache, dizziness, vomiting, and reduced level of consciousness (Bellini
26 et al. 2005).

27
28 Poor prognostic factors: brainstem involvement, virus in CSF, diabetes mellitus (Wong, Shieh,
29 Zaki, et al. 2002).

30
31 Persistent neurological deficits in 15 percent of survivors (Sejvar et al. 2007).

1 Relapse or late onset encephalitis appears to be the same disease and is distinct from acute NiV
2 encephalitis and can manifest up to 53 months after initial exposure (Tan and Chua 2008).

3
4 Patients infected with NiV excreted the virus in their respiratory secretions and urine (Chua et al.
5 2001).

6
7 The brain was the most severely affected organ, but other organs including the lungs, heart, and
8 kidneys were also involved (Chua 2003).

9
10 Widespread vasculitis → thrombosis, vascular occlusion, ischemia and microinfarction in many
11 organs but most severely in the CNS (Wong et al. 2003).

12
13 Endothelial cells are a particular target of the viruses (henipaviruses) in all species (Weingartl,
14 Berhane, and Czub 2009).

15
16 In the original Malaysian outbreak, the primary pathology was multiorgan vasculitis associated
17 with infection of endothelial cells. Infection was most prominent in the CNS (Chua et al. 2000).

18
19 Pathology found is similar to other viral encephalitis but presence of syncytial multinucleated
20 endothelial cells is characteristic of Nipah and Hendra virus infection (Epstein et al. 2006).

21
22 Multiorgan vasculitis with infection of endothelial cells most pronounced in CNS (Bellini et al.
23 2005).

24
25 Two distinct clinicopathological forms of NIPV encephalitis: (1) Acute encephalitis occurring 1–
26 2 weeks post exposure; (2) late-onset (relapsed) encephalitis several weeks after acute infection
27 has subsided (Wong et al. 2009).

28
29 Main necropsy finding in initial outbreak was disseminated micro-infarction associated with
30 vasculitis and direct neuronal involvement (Tan and Chua 2008).

1 Original outbreak in Malaysia, 1998, 265 cases of encephalitis resulting in 105 deaths (Aljofan et
2 al. 2009).

3
4 In subsequent outbreaks (India and Bangladesh), case mortality rate was approximately 70
5 percent (Aljofan et al. 2009; Luby et al. 2009).

6
7 Eight outbreaks between 2001–2008 avg fatality 70 percent (Blum et al. 2009).

8
9 Original outbreak case-fatality rate 38.5 percent (Chua 2003).

10
11 Mortality rates as high as 92 percent in later outbreaks, which no longer involved contact with
12 swine (Torres-Velez et al. 2008).

13
14 Rapidly progressive encephalitis that carried a high mortality rate (Chua 2003).

15
16 Outbreak in Siliguri, India 2001 case-fatality rate 74 percent (Chadha et al. 2006).

17
18 Bangladesh, 8 outbreaks between 2001–2008 with average case fatality ratio greater than 70
19 percent (Blum et al. 2009).

20
21 Nearly a 10 percent incidence rate of late encephalitic manifestation, with a mortality rate of 18
22 percent (Eaton et al. 2006).

23
24 Initial outbreaks in Malaysia and Singapore transmission was through close contact with infected
25 pigs and CFR was 38.5 percent. Subsequent outbreaks in Bangladesh and India transmission was
26 food-borne, person-to-person as well as nosocomial with CFR as high as 92 percent in some
27 outbreaks (Lo and Rota 2008).

28
29 **Aerosol infection/routes of transmission**

30 Bangladesh, eight outbreaks between 2001–2008 with average case/fatality ratio greater than 70
31 percent; current hypothesis is virus spillover from bats (date palm sap and partially bat eaten fruit

1 consumption) to humans, then person-to-person spread (requiring close contact, caregiver)
2 (Blum et al. 2009).

3
4 “NIPV is highly infectious and transmitted via the respiratory tract, it can be amplified and
5 spread in livestock serving as a source for transmission to humans, and recently it has been
6 shown to be transmitted directly from person to person and via contaminated food” (Aljofan et
7 al. 2009).

8
9 “NIPV has continued to re-emerge causing fatal encephalitis in humans and person-to-person
10 transmission has been documented” (Aljofan et al. 2009).

11
12 Epidemiological evidence suggests that person-to person transmission occurs, related to the
13 degree of close contact with a highly infectious case (Blum et al. 2009; Luby et al. 2009).
14 Appeared to be direct transmission of the virus from its natural host, the flying fox, to
15 humans(Aljofan et al. 2009).

16
17 NiV spills over from bats to people when a person ingests bat secretions that contain virus, for
18 example, by eating a piece of partially eaten fruit dropped by a bat or drinking date palm sap
19 contaminated by a bat (Blum et al. 2009).

20
21 In original outbreak transmission of the virus to humans, was through close contact with infected
22 pigs (Chua 2003).

23
24 Transmission of the virus from infected human to human and from infected dogs to human has
25 been documented (Chua 2003).

26
27 Transmission thought to be of the oro-nasal route (Torres-Velez et al. 2008).

28
29 Oral ingestion and/or aerosol inhalation of infected secretions is thought to be responsible for
30 pig-to-human viral transmission (Wong et al. 2003).

1 “Human-to-human transmission of NIPV was not shown in the Malaysia and Singapore
2 outbreaks, but several findings from the Bangladesh outbreaks suggest that close contact might
3 have resulted in transmission. In Meherpur and in Naogaon Bangladesh), clusters of cases
4 occurred within family households” (Hsu et al. 2004).

5
6 In Sigiluri West Bengal, India 2001 outbreak, clear evidence of person-to-person transmission
7 (Harit et al. 2006).

8
9 Nipah case patients with respiratory difficulty were much more likely to be Nipah spreaders
10 (Luby et al. 2009).

11
12 In 62 (51 percent) case-patients illness developed from apparent person-to-person transmission
13 (Luby et al. 2009).

14
15 Transmission from patients to healthcare workers is uncommon (Hsu et al. 2004) (Gurley,
16 Montgomery, Hossain, Bell, et al. 2007).

17
18 Malaysia and Singapore outbreaks—swine intermediate host, Bangladesh outbreak case control
19 study supports person-to-person transmission, Siliguri, India, outbreak supports nosocomial
20 transmission (Gurley, Montgomery, Hossain, Bell, et al. 2007).

21
22 Food-borne (date palm sap) transmission of the NiV infections in the Tangail district of
23 Bangladesh outbreak of December 2004 (Luby et al. 2006).

24 25 **Virus titers/concentrations/pathogenesis**

26 Squirrel monkeys (*Saimiri sciureus*), IV or intranasal inoc of 10^3 or 10^7 PFU (3 animals per
27 group); 10^3 PFU intranasal failed to infect (Marianneau et al.),

28
29 1×10^8 TCID₅₀/mL cell culture for Hendra (not Nipah) virus (Aljofan et al. 2009; Cramer et al.
30 2002). Authors state, “Nipah virus replicated and formed syncytia in Vero cells with the same
31 kinetics as that observed with Hendra virus (data not shown)” (Cramer et al. 2002).

1 In MRC-5 (human lung fibroblast cells) cells Viral RNA peaked at 7.7 log PFU/uL – in PS
2 (porcine stable kidney cells) cell 8.3 log PFU/uL (Chang et al. 2006).
3
4 $10^{7.1}$ PFU/mL Vero cells, 10^7 PFU/mL PT-K75 (porcine turbinate) cells.
5 50,000 TCID₅₀ of a low passage NIPV isolate (EUKK 19817; stock virus titer 4.3×10^6
6 TCID₅₀/mL (McEachern et al. 2008).
7
8 Virus titers reached 2×10^7 pfu/mL (Guillaume et al. 2004).
9
10 Virus titer of the stock was 3.2×10^7 TCID₅₀/ml (Yoneda et al. 2006).
11
12 NIPV grows in cultured cells to titers as high as 10^8 TCID₅₀ or PFU/mL (Daniels, Ksiazek, and
13 Eaton 2001).
14
15 Virus titer of 2×10^6 (Field et al. 2001).
16
17 NIPV stock titers were adjusted to 1×10^6 TCID₅₀/mL (Mungall et al. 2008).
18
19 $10^{5.2}$ PFU at dose volume 0.1 mL and $10^{3.9}$ at dose volume 0.1 mL (Tanimura et al. 2006).
20
21 Gray headed fruit bats, subcutaneous inoculation with 50,000 TCID₅₀ of NIPV, guinea pigs
22 inoculated with same dose IP (Middleton et al. 2007).
23
24 500 TCID₅₀ for SQ inoculation of cats from stock titer 1.1×10^7 TCID₅₀/mL (Mungall et al.
25 2007).
26
27 Viral concentrations in tissue of exp. Piglets: Respiratory tract $10^{5.3}$ PFU/g; spleen 10^6 PFU/g;
28 nervous system $10^{7.7}$ PFU/g of tissue (Weingartl et al. 2005).
29
30 In experimentally infected piglets NIPV enters CNS via blood-brain barrier and possibly infects
31 the CNS directly via peripheral nerves (Weingartl et al. 2005).

Pathogen stability

“Survival of henipaviruses in the environment is highly sensitive to temperature and desiccation. Under most conditions survival time was brief, with half-lives limited to a few hours, indicating that transmission to a new host requires close contact with an infected animal or exposure to contaminated material shortly after excretion. However, under optimal conditions henipaviruses can persist for a number of days and under these circumstances, vehicle-borne transmission may be possible” (Fogarty et al. 2008).

Henipavirus viable for more than 4 days in bat urine and viable 1–4 days in various fruit juices at 22 °C, tolerates a wide range of pH. It is inactivated in 1 day at 37 °C and is highly susceptible to dessication (Fogarty et al. 2008).

Irradiation of sera or pretreatment by heat inactivation at 56 °C for 30 minutes following a 1:5 dilution in PBS buffer containing 0.5 percent between 20 and 0.5 percent Triton-X100. These treatments had been shown previously at AAHL and CDC to inactivate HeV (Selleck P., Kzaisak T., unpublished results) (Daniels, Ksiazek, and Eaton 2001).

Evidence of virus persisting in humans up to 4 years before causing a recurrence of often fatal disease—no evidence of late onset or recurrence in the outbreaks in Bangladesh or India (Halpin and Mungall 2007).

Virus isolation rate in challenged grey headed fruit bats reflects extensive field surveillance, suggesting that there are very narrow windows of opportunity for Henipavirus transmission among and from bats (Middleton et al. 2007).

Vectors

a. Field

To date (2004) there is no evidence of vector or vehicle transmission of NIPV (Hyatt et al. 2004).

1 **Other epidemiological/ecological data**

2 Initial outbreak in Malaysia route of transmission was bat (*Pteropus* sp) to pig (amplifying host)
3 to human, additional. Five subsequent outbreaks in Bangladesh (2001–2005) shows no evidence
4 of amplifying host, and there is evidence of human-to-human transmission. All five outbreaks
5 between Jan. and May (Epstein et al. 2006).

6
7 Deforestation, planting of fruit orchards in close proximity to pig farms and the natural reservoir
8 of the NIPV (*Pteropus* sp) all contributed to the initial 1998 Malaysian outbreak (Epstein et al.
9 2006).

10
11 Deforestation is probably responsible for fruit bats leaving their ecological niches and
12 approaching farms and villages (Wild 2009).

13
14 “A scenario emerges of fruit bat populations under stress, of altered foraging and behavioral
15 patterns, of niche expansion, and of closer proximity to man” (Field et al. 2001).

16 “Henipaviruses likely exist across the entire global distribution of pteropid bats” (Epstein et al.
17 2006).

18
19 “Our recent studies have identified a high prevalence of antibodies to NIPV in colonies of both
20 *P. vampyrus* and *P. hypomelanus* throughout peninsular Malaysia, suggesting that these bats are
21 true reservoirs and that the virus is endemic to the region (Rahman et al., unpublished
22 observations)” (Epstein et al. 2006).

23
24 The distribution of *Pteropus* ranges from Madagascar eastward across the Indian Ocean islands,
25 South Asia, Southeast Asia, Australia, and much of the Pacific islands and includes some of the
26 most densely populated regions on earth (Epstein et al. 2006).

27
28 Results indicate that henipavirus is present within West Africa (henipavirus seropositive fruit
29 bats in Ghana) (Hayman et al. 2008).

Horizontal and vertical transmission of NIPV is possible in cats and virus has been previously shown to be shed via urine and nasopharynx in cats (Mungall et al. 2007).

Although no NIPV outbreaks to date in Thailand bat species (*P. lylei*) have been infected with the NIPV with highest recovery of Nipah RNA occurring in May (Wacharapluesadee et al. 2009).

A total of 12 NIPV outbreaks since 1998—Malaysia, Singapore, India, and Bangladesh (Wacharapluesadee et al. 2005).

No evidence of Australian pteroid bats being infected with NIPV in the wild, although they have been infected experimentally (Daniels et al. 2007).

Study showed evidence of NIPV infection in bats of Thailand by demonstrating IgG ab's in serum and RNA in urine and saliva (Wacharapluesadee et al. 2005).

Therapeutics/vaccines

Combination chloroquine/ribavirin treatment was not effective in a hamster model, in contrast to results in vitro (Freiberg et al.).

Ribavirin treatment was associated with a 36 percent reduction in mortality in initial outbreak (Epstein et al. 2006).

No commercially available vaccines or approved therapeutics for NIPV; however, in the initial outbreak, Ribivirin treatment was associated with a 36 percent reduction in mortality in patients with acute encephalitis (Epstein et al. 2006).

There are no vaccines or post-exposure therapeutics specifically indicated for henipavirus infection (Halpin and Mungall 2007).

As of 2008, no active or passive therapeutic procedures exist for preventing or treating NIPV infection (McEachern et al. 2008).

Ribavirin useful in treatment with one limited study indicating 36 percent↓ in mortality (Tan and Chua 2008).

No vaccine available, but Ribavirin has some efficacy (Aljofan et al. 2009).

Other remarks

In the initial outbreak in Malaysia in 1998, almost all cases involved contact with swine that were also clinically affected though with a lower mortality rate (Torres-Velez et al. 2008).

Unique genetic makeup, wide host range and high virulence set the henipaviruses apart from other paramyxoviruses (Eaton et al. 2006; Eaton, Broder, and Wang 2005).

No serological evidence for NIPV infection of rodents in Malaysia (Eaton, Broder, and Wang 2005).

NIPV IgM present shortly after onset, all pts. + in 3 days, all IgG+ in 17–18 days (Bellini et al. 2005).

Taxonomy/antigenic relationships/synonyms

NIPV is a member of the *Henipavirus* genus (along with Hendra virus) in the *Paramyxoviridae* family. It is a single stranded negative sense RNA virus with a large genome and a high mutation rate (Lo and Rota 2008).

“A new genus was created, named Henipavirus (Hendra/Nipah) to accommodate these two phylogenetically closely related viruses with HeV as the type species and NIPV as the second member of the genus” (Chua 2003).

NIPV is a large enveloped virus (Weingartl, Berhane, and Czub 2009).

RVFV	Rift Valley fever virus
SARS-CoV	SARS-associated coronavirus
SECPop	Sector Population program
TBEV-FE	tick-borne encephalitis virus, Far Eastern sub-type, formerly known as Tick-borne encephalitis complex (Russian spring-summer encephalitis virus)
TCID ₅₀	median tissue culture infective dose
<i>Y. pestis</i>	<i>Yersinia pestis</i>

4. Event Sequence Analysis

Chapter Highlights: This chapter explains the process of identifying, selecting, and analyzing postulated events that have the potential to expose workers or the public to pathogens. The events selected and analyzed in this chapter are:

- Aerosol release from a centrifuge
- Needlestick
- Earthquake
- Aircraft crash
- Malevolent acts

Worker and public infections and fatalities resulting from direct exposure and secondary transmission are analyzed in Chapters 8 and 9 for the centrifuge release, needlestick, and earthquake postulated events. These analyses were performed for the three sites (i.e., urban, suburban, and rural) and all 13 pathogens being evaluated.

Transportation accidents, malevolent act, and environmental persistence in the environment were also selected for analysis and these analyses are reported in Chapters 5, 6, and 7, respectively.

Section 4.1 describes the methodology that was employed to select events for analysis and identifies the selected events. Section 4.2 presents the results of the analysis for the events selected. Appendices E and F provide the details that support this chapter.

4.1 Selection of Events for Analysis

4.1.1 Introduction and Scope

One of the key recommendations provided by the NRC in its advice on the development of the NEIDL RA is to identify: *What can go wrong, what are the probabilities, and what would be the consequences?* (NIH 2009). This RA began with a broad consideration of what can go wrong and then selected a smaller set of potential events for analysis that involve a compromise of biocontainment. This RA analyzed multiple potential loss of biocontainment events to provide insights into the following:

1. What are the risks to the workers?
2. What are the risks to the public?
3. Are there differences in risks if NEIDL were located at a less-densely populated site?

This analysis follows the guidance for analyses of this type provided by the U.S. Department of Energy (DOE) *Recommendations for Analyzing Accidents under the National Environmental Policy Act* (DOE

2002, referred to as the DOE NEPA Guidance). The DOE NEPA Guidance was used for this analysis because it is the most relevant and detailed guidance available for this type of analysis. Use of the DOE NEPA Guidance is consistent with the recommendations of the NRC, which reviewed the DOE NEPA Guidance and concluded the following (NRC 2010):

U.S. Department of Energy's (DOE) recommendations for the preparation of EISs [Environmental Impact Statements] contain some of the most detailed explanations and guidelines for discussing human health impacts in an EIS. Although DOE's recommendations for analyzing human health effects are limited to exposure to radiation and chemicals, they also are relevant to pathogen exposures.

DOE NEPA Guidance recommends that the analyses consider the spectrum of reasonably foreseeable events,¹ "including low probability/high consequence accidents and higher probability/(usually) lower consequence accidents" (DOE 2002). To ensure that a broad range of events is comprehensively addressed, reasonably foreseeable events were considered for the following three types of events:

- **Maximum reasonably foreseeable (MRF) event**—The state courts and the NRC have expressed interest in analysis of a *worst-case* scenario, but the NRC noted that that is a nebulous term that is not well defined (NIH 2009). The DOE NEPA Guidance is used here to define the worst-case scenario as (DOE 2002):

A maximum reasonably foreseeable accident is an accident with the most severe consequences that can reasonably be expected to occur for a given proposal. ... *Reasonably foreseeable* events include events which may have catastrophic consequences, even if their probability of occurrence is low, provided that the analysis of the impacts is supported by credible scientific evidence, is not based on pure conjecture, and is within the rule of reason.

For this RA, the MRF event was defined solely in terms of the accident with the maximum pathogen release from the facility.

¹ The term *reasonably foreseeable* extends to events that may have catastrophic consequences, even if their probability of occurrence is low, provided that the analysis of the impacts is supported by credible scientific evidence, is not based on pure conjecture, and is within the rule of reason (DOE 2002).

- **Representative events**—To better understand the nature of the risks posed by each pathogen, representative events (i.e., an event selected as a surrogate for multiple other events because it has greater or similar frequency and consequences as a group of other events) were analyzed for each pathogen, route of exposure, and exposed group.
- **Unique events**—As appropriate, additional events were selected to explore unique characteristics of a given pathogen or differences between the sites being considered. Those unique events could address such factors as differences in natural phenomena at the sites.

The following events were considered: (1) accidental loss of biocontainment at the facility, which includes internal hazards (e.g., equipment failures and personnel errors), external hazards (e.g., aircraft crash and loss of offsite power), and natural phenomena (e.g., earthquake and strong wind hazards that could result in partial or complete loss of biocontainment); and (2) transportation accidents. Operating experience at similar other BSL-3 and BSL-4 laboratories was used as one input for the identification and evaluation of these events.

The scope includes the spectrum of reasonably foreseeable events. Reasonably foreseeable events are defined as events “including low probability/high consequence accidents and higher probability/(usually) lower consequence accidents.” (DOE 2002) The analysis of reasonably foreseeable events is generally limited to events with a frequency greater than 10^{-6} /yr (a frequency equivalent to once in a million years), but this is not an absolute cutoff. Lower frequency events are included if the resulting consequences could be disproportionately greater than those with a higher frequency (DOE 2002).

Operating Experience at BSL-3 and BSL-4 Laboratories: *This RA relies on past experience at similar laboratories to the extent data are available and useful. Appendix D summarizes various sources of this operating experience. Appendix D includes the recent CDC report of 395 “potential release events” and 7 laboratories associated infections (LAIs) from 2003 to 2009 nationwide at laboratories working with select agents (see Section D.1.1 of Appendix D).*

The operating experience was used to identify potential initiating events, develop scenarios, and estimate the scenario frequencies. While helpful for qualitative analyses, the data were not used for quantitative analyses as details of appropriate measures of operating time (e.g. researcher-hours), descriptions of individual incidents leading to loss of biocontainment and biosafety protocols in place at the time of the events are not specified in available reports.

Therefore, past BSL-3 and BSL-4 experience was used to support the RA wherever appropriate, but they are not suitable for quantitative use.

The scope of this analysis was limited to the 13 pathogens selected for study by the NIH BRP and NRC in a teleconference (see NIH 2009). The scenarios analyzed include consideration of NEIDL-specific preventive and mitigative features, which tend to reduce the frequency and severity of events.

4.1.2 Methodology

The event identification and selection process began with a comprehensive identification of candidate initiating events. The candidate initiating events were then evaluated to determine the applicable routes of exposure, NEIDL locations, and potentially exposed groups. Then, a multi-step process incorporating frequency (probability of occurrence) and exposure categories (the number of people potentially exposed) was used to select events for more detailed analysis. Each of those steps is described in the following subsections.

4.1.2.1 Identification of Candidate Initiating Events

The first step in the process was the comprehensive identification of candidate initiating events that could lead to loss of biocontainment. The process of tabulating candidate events included the following activities:

- Operating experience at other high biocontainment facilities was reviewed because incidents that have occurred at other facilities might also occur at the NEIDL.
- Previous analyses of the NEIDL were reviewed to identify the postulated events considered appropriate for analyses in those documents.
- The NRC list of scenarios to be studied (NIH 2009) was reviewed to ensure that all events identified were considered.
- NEPA documents for other BSL-3 and BSL-4 facilities were reviewed to identify the postulated events considered for analysis.
- The NEIDL facility design and operating plans were reviewed to identify potential scenarios.
- The site characteristics for the three sites were reviewed to consider the potential for unique external and natural phenomenon hazards.

On the basis of those reviews, a preliminary list of candidate initiating events was developed. The candidate initiating events were then evaluated, as explained in Section 4.1.2.2, to select the events to be analyzed in detail.

4.1.2.2 Evaluation of Candidate Initiating Events

Each candidate initiating event that could result in worker or public exposure was evaluated to determine the relevant routes of potential exposure, NEIDL locations, potentially exposed groups, frequency categories, and exposure categories (i.e., number of people exposed). Those evaluations are explained in sections 4.1.2.2.1 through 4.1.2.2.5.

4.1.2.2.1 Routes of Exposure

This analysis considered exposures to pathogens via inhalation, ingestion, direct contact, puncture, and animal-related exposure (including arthropod vectors). Inhalation exposure is typically only considered for particles with an aerodynamic equivalent diameter no greater than 10 micrometers (μm) (DOE 2000). Ingestion can occur via a liquid contaminated with a pathogen or by contaminated hand-to-mouth exposure. Direct contact is exposure to broken skin, eyes, mucous membranes, or nasal passages. Puncture is a general term used to address a condition whereby microorganisms are potentially placed below the outermost layer of the skin through a mechanical means such as a syringe needle or other sharp object. Animal-related exposures are those exposures resulting from contact with infectious animals. These exposures could occur via animal bite, scratch, or airborne dispersal or infectious particles.

4.1.2.2.2 NEIDL Locations

Each event was assigned to each of the NEIDL locations that are relevant for the event. The NEIDL locations are as follows: (1) BSL-3 laboratories; (2) BSL-4 laboratories; and (3) other locations (e.g., the loading dock or off-site).

4.1.2.2.3 Potentially Exposed Groups

As recommended by DOE NEPA Guidance (DOE 2002), this analysis considers impacts associated with the following potentially exposed groups: (1) laboratory worker (e.g., people working in the laboratory room when the event occurs); (2) facility worker (e.g., people working in the NEIDL but not in the laboratory room when the event under consideration occurs. For example, they might work in the administrative areas); and (3) the public (e.g., any person outside the NEIDL-controlled perimeter, specifically referring to the population in the surrounding communities).

4.1.2.2.4 Frequency Categories

The likelihood of events can be described and calculated in several ways. Table 4-1 compares several equivalent ways of describing (using numbers and measures) the likelihood of events.

Table 4-1 Measures of likelihood.

Average Return Period ^a (years)	Average Frequency ^b (per year)	Probability / Chance of Occurrence in Facility Lifetime ^c (in 50 years)	
1	1	Virtually 100%	Virtually 100-in-100
10	0.1	99%	99-in-100
100	0.01	39%	1-in-2.5
1,000	0.001	4.9%	1-in-21
10,000	0.0001	0.5%	1-in-200
100,000	0.00001	0.05%	1-in-2000
1,000,000	0.000001	0.005%	1-in-20,000
10,000,000	0.0000001	0.0005%	1-in-200,000

^a **Average return period in years:** This is the average time, in years, before the event would be expected to occur. If the event was to occur multiple times, this would be the average time between occurrences. This way of describing events is often used in characterizing flood levels; for example, a “1000-year flood” is a water level that is estimated to occur with a 1,000-year average return period or “once per 1,000 years”.

^b **Average frequency per year:** This is the average number of occurrences of the event per year.

^c **Probability / chance of occurrence in facility lifetime (50 years):** This is the chance that the event would occur at least once in a given 50-year period.

The operational data from research laboratories like the NIEDL (see Appendix D) are not adequate for development of quantitative frequency estimates (e.g., mean rate plus uncertainties) for the events analyzed, so alternate approaches were used. A technique commonly used when quantitative estimates of frequency are not possible is the use of categories (i.e., ranges of values), which is used by the U.S. Environmental Protection Agency (EPA), U.S. Department of Energy (DOE), and National Aeronautics and Space Administration (NASA). (EPA 1987, NASA 2005, NASA 2009, DOE 1994) Each event sequence is assigned to a frequency category based the initiating event, and the number and nature of concurrent failures of preventive and mitigative features. The assignment of frequency categories often relies on comparison with events in other industries and use of judgment. For this analysis, when it was not clear which of two frequency categories should be assigned, the higher frequency category was used to avoid underestimating the risk. Table 4-2 identifies the frequency categories (i.e., A, B, C, and D) used in this RA and provides a verbal description and average return period for each category.

Table 4-2 Frequency categories

Category	Verbal description	Average return period (once in “this many” years)
A	An event sequence was assigned to this category if its likelihood is sufficiently high to assume that it will occur during the operational lifetime of the NEIDL (i.e., during 50 years of operation).	1 to 100 years
B	An event sequence was assigned to this category if one or more of the events in this category could occur during the NEIDL’s operating life, but any specific event sequence in the group is not expected to occur.	100 to 10,000 years
C	An event sequence was assigned to this category if collectively none of the events in this category is expected to occur during the operating life of the facility, but the events in this category are still reasonably foreseeable.	10,000 to 1 million years
D	An event sequence was assigned to this category if it does not meet the criteria for <i>reasonably foreseeable</i> . An event sequence is categorized as category D if it is impossible or highly improbable (i.e., beyond reasonably foreseeable).	>1 million years

4.1.2.2.5 Exposure Categories

The exposure categories were defined in terms of the number of people potentially exposed to a pathogen by an event sequence. The number of people potentially exposed can vary depending on the type of event and the operational parameters at the time of the event. For example, the number of people in a room can vary from event to event depending on the activities involved. In addition, some events, such as a needle stick, might affect only one person, while another event such as an aerosolized pathogen release could affect multiple people in the room. Therefore, the exposure categories were generally defined as a range in the number of people potentially exposed. Table 4-3 defines the exposure categories for each potentially exposed group because the total population and potential for exposure is different for each group.

Table 4-3. Exposure categories

Exposure category	Laboratory workers	Facility workers	Members of the public (number of people within the radius)
NONE	0	0	≤ 30 m
LOW	A single individual (1)	A few individuals on the same floor (≤10)	> 30 m to ≤ 300 m
MODERATE	Most individuals in the room (1 to 4)	Most individuals on the floor (≤ 87 for BSL-3 and ≤ 30 for BSL-4)	> 300 m to ≤ 3 km
HIGH	An atypical number of individuals (>4) ^a	Most individuals in the building (≤ 300)	> 3 km
a Although the possibility exists, it is not expected that activities will involve more than four workers in a room (BUMC 2009).			

4.1.2.3 Selection of Events for Analysis

From the list of candidate events, a subset was selected for detailed analysis as the MRF event, representative events, and unique events. The objective of the selection process was to provide broad coverage of the risk profile by judicious select of events. The events were selected to ensure that all routes of exposure, NEIDL locations, and potentially exposed groups are addressed. Selections were based on the frequency and exposure categories of the events and their applicability to multiple routes of exposure, NEIDL locations, and potentially exposed groups.

4.1.3 Results

The following results are based on the methodology presented in Section 4.1.2.

4.1.3.1 Candidate Initiating Events

More than 300 candidate incidents and postulated events were identified (see Section 4.1.2.1). Numerous incidents and postulated events are similar to others in the list, so common incidents were consolidated into more than 30 candidate initiating event groups presented in Table 4-4. Table 4-4 also identifies the relevant NEIDL locations, exposed groups, and routes of exposure for each candidate event group.

1

Table 4-4. Candidate events for the NEIDL RA

Candidate event group	NEIDL location			Exposed group			Route of exposure				
	BSL-3	BSL-4	Other	Laboratory worker	Facility worker	Public	Inhalation	Ingestion	Direct contact	Puncture	Animal-related
Aircraft crash	X	X	X	X	X	X	X	X	X		X
Animal bite/scratch	X	X		X						X	X
Animal escape or pathogen release to environment	X	X	X	X	X	X					X
Animal-related infectious aerosol in the laboratory	X	X		X							X
Breach of containment (wall cracks or open doors)	X	X	X	X	X	X	X				
Centrifuge release	X	X		X			X	X	X		
Container leak/spill/open	X	X		X			X	X	X		
Contaminated waste (e.g., not inactivated)	X	X	X	X	X	X	X	X	X		
Contamination inside laboratory	X	X		X			X	X	X		
Contamination outside laboratory			X		X	X	X	X	X		
Deflagration	X	X	X	X			X				
Fire	X	X	X	X	X	X	X				
Flooding inside laboratory	X	X		X					X		
Fomite/vector	X	X		X					X	X	X
Hand to mouth/eyes/nose contamination	X	X		X				X	X		
HVAC ^a failure	X	X	X	X	X	X	X				
Inadequate animal control	X	X		X							X
Inadequate pathogen accountability	X	X		X			X	X	X		
Inadequate PPE ^b use	X	X		X			X	X	X	X	X
Liquid waste leak	X	X	X	X	X	X		X	X		
Loss of power	X	X	X	X	X	X	X				
Malevolent act	X	X	X	X	X	X	X	X	X	X	X
NPH—earthquake	X	X	X	X	X	X	X	X	X	X	X
NPH ^c —tornado and strong wind	X	X	X	X	X	X	X				
NPH—other (flooding, snow, etc.)	X	X	X	X	X	X	X				
PAPR ^d failure (addressed separately from other PPE)	X	X		X			X				
Pathogen not inactivated	X	X	X	X	X		X	X	X	X	
Pathogen used with inappropriate biocontainment	X	X		X			X	X	X	X	
PPE failure (excluding PAPR ^c)	X	X		X			X	X	X	X	
Puncture—during necropsy	X	X		X						X	
Puncture—needlestick	X	X		X						X	
Puncture—general	X	X		X						X	
Spill/splash	X	X		X			X	X	X		
Transportation mishap			X		X	X	X	X	X	X	

2 a Heating, ventilating, and air conditioning system (HVAC)

3 b Personal protective equipment (PPE). Powered air-purifying respirator (PAPR) are PPE, but PAPR are addressed separately here because of their unique role in the BSL-3 centrifuge release scenarios.

4 c Natural phenomena hazards

5 d PAPR are addressed separately because of their significance in the BSL-3 centrifuge release scenarios.

4.1.3.2 Evaluation of Candidate Events

The next step in the selection process was to assign frequency and exposure categories (see Sections 4.1.2.2.4 and 4.1.2.2.5) to each candidate event. Table 4-5 provides the results of that categorization of candidate event groups. A dash is shown for cells where the exposure category is not appropriate for an exposed group. For example, the public is not at risk of a direct primary exposure from a needlestick event. The assignment of frequency and exposure categories were assigned on the basis of the operational incidents described in Appendix D with the selection of the next higher category in cases where there was a question of which of two categories to use. The assignments were also reviewed by the Tetra Tech team and reviewers from the NIH and BRP. Adjustments to the category assignments were made in consideration of these reviews. As the detailed analyses were being completed, the assignments were again reviewed and adjusted where appropriate.

Table 4-5. Event and exposure categories for candidate events

Candidate event group	Frequency category	Exposure category		
		Laboratory worker	Facility worker	Public
Aircraft crash	C	High	High	Moderate
Animal bite/scratch	A	Low	-- ^a	--
Animal escape or pathogen release to environment	B	Moderate	Low	Low
Animal-related infectious aerosol	B	Moderate	--	--
Breach of containment (wall cracks or open doors)	B	Low	Low	Low
Centrifuge release	A	Moderate	--	--
Container leak/spill/open	A	Moderate	--	--
Contaminated waste (e.g., not inactivated)	B	Moderate	Low	Low
Contamination inside laboratory	B	Moderate	--	--
Contamination outside laboratory	B	-	Low	Low
Deflagration	C	High	Moderate	Low
Fire	C	High	Low	Low
Flooding inside laboratory	C	Moderate	Low	--
Fomite/vector	B	Moderate	Low	Low
Hand to mouth/eyes/nose contamination	B	Low	--	--
HVAC ^b system failure	B	Moderate	Low	Low
Inadequate animal control	B	Moderate	--	--
Inadequate pathogen accountability	A	Moderate	Low	Low
Inadequate PPE ^c use	A	Low	--	--
Liquid waste leak	B	Moderate	Low	Low
Loss of power	B	Moderate	Low	Low
Malevolent act	not defined	High	High	Moderate

Candidate event group	Frequency category	Exposure category		
		Laboratory worker	Facility worker	Public
NPH ^d —earthquake	C	High	High	Moderate
NPH—tornado and strong wind	C	High	Low	Low
NPH—other (flood, snow, etc.)	C	High	Low	Low
PAPR ^e failure (addressed separately from other PPE)	A	Low	--	--
Pathogen not inactivated	A	Moderate	Low	--
Pathogen used with inappropriate biocontainment	A	Moderate	--	--
PPE failure (excluding PAPR ^c)	A	Low	--	--
Puncture—during necropsy	A	Low	--	--
Puncture—needlestick	A	Low	--	--
Punctured—general	A	Low	--	--
Spill/splash	A	Moderate	--	--
Transportation mishap	C	--	Low	Low

a -- indicates that the cell is not applicable.

b Heating, ventilating, and air conditioning system (HVAC)

c Personal protective equipment (PPE). Powered air-purifying respirator (PAPR) are PPE, but PAPR are addressed separately here because of their unique role in the BSL-3 centrifuge release scenarios.

d Natural phenomena hazards

e PAPR are addressed separately because of their significance in the BSL-3 centrifuge release scenarios.

4.1.3.3 Events Selected for Analysis

4.1.3.3.1 Maximum Reasonably Foreseeable (MRF) Event

The MRF event selected for analysis was a severe earthquake. A severe earthquake was selected for the following reasons:

- Has the potential to affect the entire facility inventory of pathogens;
- Has the potential to compromise all biocontainment features;
- Can occur under any meteorological conditions;
- Results in the potential for higher airborne concentrations than tornadoes and hurricanes, which result in much greater mixing, thereby resulting in much lower concentrations;
- Is less likely to have advanced warning than tornadoes or hurricanes;
- Has the potential for ground level unfiltered release as opposed to the filtered exhaust stack releases;
- Can result in escape of animals (mammals and arthropods); and
- Typically *bounds* (i.e., is at least as severe as) other natural phenomena events (DOE-HDBK-3010).

1 Because of the importance of the MRF event, an evaluation of an aircraft crash was performed to confirm
2 the expectation that the severe earthquake bounds (i.e., has consequences and frequencies that are not
3 exceeded by) an aircraft crash. Appendix F presents this comparison and demonstrates that the severe
4 earthquake bounds an aircraft crash in terms of both frequency and consequences.

5 Malevolent acts were not considered in the selection of the MRF event, “because the potential number of
6 scenarios is limitless and the likelihood of attack is unknowable” (DOE 2002). As recommended by the
7 DOE NEPA Guidance, malevolent acts were evaluated by comparison to accidents with similar
8 consequences (see Chapter 6).

9
10 Therefore, a severe earthquake was selected as the MRF event for BSL-3, BSL-4, and other areas.

11 12 **4.1.3.3.2 Representative Events**

13 A subset was selected for analysis that represents or bounds a large number of events. This process
14 consisted of selecting candidate events were qualitatively assessed to represent or bound the frequency
15 and exposure category for each potentially exposed group. Table 4-6 provides the results of this process
16 with the selected events in bold at the top of each subsection and the events considered adequately
17 addressed by the selected event indented in normal font.

Table 4-6. Events selected for analysis

Candidate event group	Frequency category	Exposure category for potentially exposed groups		
		Laboratory worker	Facility worker	Public
Centrifuge release	A	Moderate	Low	-- ^e
Container leak/spill/open	A	Moderate	--	--
Spill/splash	A	Moderate	--	--
Inadequate pathogen accountability	A	Moderate	Low	Low
Pathogen not inactivated	A	Moderate	Low	--
Pathogen used with inappropriate biocontainment	A	Moderate	--	--
Inadequate PPE ^a use	A	Low	--	--
PAPR ^b failure (addressed separately from other PPE)	A	Low	--	--
PPE failure (excluding PAPR)	A	Low	--	--
HVAC ^c failure	B	Moderate	Low	Low
Animal--related infectious aerosol	B	Moderate	--	--
Breach of containment (wall cracks or open doors)	B	Moderate	Low	Low
Hand to mouth/eyes/nose contamination	B	Moderate	--	--
Contamination inside laboratory	B	Moderate	--	--
Loss of power	B	Moderate	Low	Low
Liquid waste leak	B	Moderate	Low	Low
Puncture--needlestick	A	Low	--	--
Animal bite/scratch	A	Low	--	--
Puncture--during necropsy	A	Low	--	--
Punctured--general	A	Low	--	--
NPH^d--earthquake	C	High	High	Moderate
Aircraft crash	C	High	High	Moderate
Fire	C	High	Low	Low
Deflagration	C	High	Moderate	Low
NPH--tornado and strong wind	C	High	Low	Low
NPH--other (flooding, snow, etc.)	C	High	Low	Low
Flooding inside laboratory	C	Moderate	Low	--
Contaminated waste not inactivated	B	Moderate	Low	Low
Contamination outside laboratory	B	--	Low	Low
Animal escape or pathogen release to environment	B	Moderate	Low	Low
Inadequate animal control	B	Moderate	Low	Low
Fomite/vector release	B	Moderate	Low	Low
Transportation mishap	C	--	Low	Low
Malevolent act	not defined	High	Moderate	Moderate

a Personal protective equipment (PPE). Powered air-purifying respirator (PAPR) are PPE, but PAPR are addressed separately here because of their unique role in the BSL-3 centrifuge release scenarios.

b PAPR are addressed separately because of their significance in the BSL-3 centrifuge release scenarios.

c Heating, ventilating, and air conditioning system (HVAC)

d Natural phenomena hazards

e -- indicates that the cell is not applicable.

Table 4-7 provides a brief textual rationale for the selection of the events being carried forward for further analysis and dismissal of others. The events selected tended to achieve the following: (1) highest

- 1 frequency, (2) highest exposure category for each exposed group, and (3) events that could incorporate or
 2 bound other events.

Table 4-7. Rationale for event selection

Candidate event group	Discussion
Centrifuge release	This event was selected for analysis because it has occurred relatively frequently in research laboratories and results in one of the higher airborne aerosol concentrations for relevant events (Bennett and Parks 2006). A PAPR failure and HVAC failure were considered as part of this scenario.
Container leak/spill/open	The centrifuge event has the potential for a larger release (Bennett and Parks 2006) and has a similar frequency.
Spill/splash	The centrifuge event has the potential for a larger release (Bennett and Parks 2006) and has a similar frequency.
Inadequate pathogen accountability	A review of incidents at other facilities shows that although there have been several incidents, they seldom have resulted in exposures or infections. Therefore, the risk from the centrifuge release and needlestick events is at least as great as the risk of this event.
Pathogen not inactivated	The concern here is that the pathogen is used with inappropriate biocontainment features because it was incorrectly thought to be inactivated. In terms of exposure, the effect operating in a lower BSL level facility can be similar to a failure of biocontainment features. The centrifuge release includes consideration of multiple biocontainment failures and is expected to be in the same frequency category.
Pathogen used with inappropriate biocontainment	The absence of a biocontainment feature has an effect similar to a failure of the same biocontainment feature. The centrifuge release includes consideration of multiple biocontainment failures and is expected to be in the same frequency category.
Inadequate PPE use	The inadequate use of PPE is similar to the failure of the PPE; however, both generally require a loss of biocontainment in order to result in an exposure. For example, failure to wear mesh gloves when changing knife blades can only result in exposure if there is a mishap when changing the blade. The centrifuge release and needlestick events include consideration of some PPE failures.
PAPR failure (addressed separately from other PPE)	This is included as part of the centrifuge release event.
PPE failure (excluding PAPR)	The centrifuge release and needlestick events include consideration of some PPE failures.
HVAC failure	HVAC failure will not result in exposure by itself and a concurrent release is require. Animals or incidents could produce aerosols in the room, but the release is unlikely to be spread to other parts of the building because of the HVAC isolation dampers. Alarms would notify workers of the HVAC failure and would have been trained to take appropriate action. The centrifuge release includes consideration of HVAC failure, so there is a concurrent release.
Animal-related aerosol	The centrifuge release is expected to result in comparable or greater aerosol release and it can occur in non-animal laboratories. While animals can be a continuous source of aerosol generation, the HVAC in the animal holding areas is designed with about double the air exchange rate to purge these release more rapidly and dilute the release. Therefore, the centrifuge event is selected.
Breach of containment (wall cracks or open doors)	This condition does not result in potential exposure without an initial release. The centrifuge release event includes loss of HVAC.

Candidate event group	Discussion
Hand to mouth/eyes/nose contamination	The potential for ingestion and direct contact exposure are included in the centrifuge release event.
Contamination inside laboratory	The centrifuge release has the potential to contaminate the laboratory and the potential for ingestion and direct contact exposure are included in the centrifuge release event.
Loss of power	By itself, total loss of power could result in a loss of biological safety cabinet (BSC) flow and a release to a room; however, it is improbable that it would result in significant exposure outside the room because the isolation dampers and limited-leakage rooms would retard release. The centrifuge release includes consideration of HVAC failure.
Liquid waste leak	Liquid leaks inside the laboratory are readily detected and do not pose as great a risk as an aerosol release. Contaminated liquid released to the sewage system from the facility would be diluted to extremely low concentrations and would likely be inactivated.
Puncture – needlestick	This event was selected for analysis.
Animal bite/scratch	The needlestick has the potential for a greater level of exposure and is at least as frequent.
Puncture—during necropsy	The needlestick has the potential for a greater level of exposure and is at least as frequent.
Punctured—general	The needlestick has the potential for a greater level of exposure and is at least as frequent.
NPH – earthquake	This event was selected for analysis.
Aircraft crash	Both frequency and consequences are expected to be no greater than those of the earthquake. However, because this is a topic of special interest following the 9/11 attack, this event will be considered further to confirm the expectations.
Fire	The temperatures associated with a fire will tend to inactivate a release, and the consequences will be less than those of the earthquake.
Deflagration	A deflagration is unlikely to fail the walls or compromise as many biocontainment features as an earthquake.
NPH—strong wind	A strong wind is unlikely to fail the walls or compromise as many biocontainment features as an earthquake.
NPH—other	Other NPH (e.g., snow and flooding) are unlikely to fail the walls or compromise as many biocontainment features as an earthquake.
Flooding inside laboratory	Flooding inside the laboratory does not have the potential for public exposure.
Contaminated waste	The earthquake has the potential to spread contamination to more people, though likely at a lower level of exposure. In addition, solid waste is double bagged, so any internal contamination is not likely to result in exposure.
Contamination outside laboratory	The earthquake includes the potential for public exposure and is likely to affect more people.
Animal escape or pathogen release to environment	This candidate was selected for analysis
Inadequate animal control	The centrifuge release considers inhalation, ingestion, and direct contact potential; needlestick considers puncture potential; and animal escape a loss to the environment. Therefore, analysis of this event is not likely to provide additional insights.
Transportation mishap	This event was selected for analysis.
Malevolent act	This event was selected for analysis.

Note: It has been noted that fomites (i.e., inanimate objects or substances capable of carrying infectious pathogens) were identified as one of the more significant risks for the National Bio and Agro-Defense Facility (NBAF) (DHS 2008) but fomites were not selected as one of the events analyzed in detail for the NEIDL. Fomites are considered a lesser risk for NEIDL than for NBAF for several reasons.

BSL-3 and BSL-4 biocontainment precautions for NBAF and NEIDL are highly similar. However, much of NBAF research involves BSL-3Ag (agricultural) biocontainment precautions, which pertain to agricultural pathogens. BSL-3Ag precautions are used when infected animals cannot be readily housed in a primary biocontainment device, as in the case of very large animals such as swine, cattle, and horses. In this circumstance, it is the room itself that provides primary biocontainment of the pathogen. Much of NBAF research will involve foot and mouth disease virus (FMDV). Cattle and swine that are infected with FMDV shed enormous amounts of the virus into room air during the course of the infection (as much as $10^{8.6}$ TCID₅₀ in a 24 hour period) (Donaldson 2002). As a result, all objects and personnel in the room routinely become contaminated with the virus. Moreover, FMDV has significant stability under favorable ambient conditions, as shown by airborne infections that have occurred as far as 250 km downwind from a release point (Kitching 2005). Furthermore, FMDV is highly infectious for susceptible animal species. As a result, the risk of an FMDV release via fomite became a leading event for consideration in the NBAF risk assessment.

In contrast, BSL-3 work at NEIDL will use primary containment devices, such as bioaerosol containment caging systems, for infected animals. NEIDL will not use BSL-3Ag biocontainment precautions. As a result, pathogens routinely are contained within the primary device rather than being released into room air. Accordingly, the potential for fomite contamination in laboratory rooms at the NEIDL is not comparable to that of NBAF BSL-3Ag facilities. Therefore, although fomites were considered in this RA for the NEIDL, they were not selected for detailed analysis.

4.1.3.3.3 Unique Events

Potential exposure of the laboratory workers, facility workers, and the public was analyzed for the MRF event and representative events for each of the 13 pathogens at each of the three sites. The earthquake and representative event analyses provide a basis for examination of both pathogen and site differences from direct exposure and human-to-human exposure (initial infection is addressed in Chapter 8, and secondary transmission is addressed in Chapter 9); however, those analyses do not address the potential persistence of a pathogen in the environment as a result of an animal escape or a pathogen release. Therefore, each of the 13 pathogens was evaluated in Chapter 7 to determine if it possibly could persist or replicate in air,

soil, water, or in arthropods or other animal species in the local environments outside the biocontainment space.

4.2 Analysis of Selected Events

4.2.1 Introduction

This section provides the analysis of potential loss of biocontainment events selected in Section 4.1 for analysis. Scenarios that account for NEIDL-specific biocontainment features were developed for the potential initiating events selected for analysis. The potential initiating events addressed in this section are as follows:

- *Centrifuge release*—The centrifuge release event provides representative results for aerosol release events.
- *Needlestick*—The needlestick event provides representative results for puncture events.
- *Earthquake*—An earthquake was selected as the MRF event. To investigate the severity of the MRF earthquake, an earthquake that is slightly beyond the design basis was also analyzed.
- *Aircraft crash*—The aircraft crash was expected to pose less risk than the earthquake, and this analysis confirms that expectation.
- *Malevolent acts*—Malevolent act scenarios are identified in Chapter 6.

In addition, transportation events are addressed in Chapter 5, and the potential for environmental persistence is addressed in Chapter 7.

The analysis has been conducted in accordance with the DOE NEPA Guidance discussed in Section 4.1.1. A key element of the DOE NEPA Guidance for the accident analyses is the application of a *sliding scale*. The sliding scale allows for adjustment of the level of detail of an accident analysis in accordance with the frequency and consequences of the accident and the level of information available. While realism is important, the DOE NEPA Guidance also supports use of *bounding* (i.e., analyses based on conservative assumptions that envelope potential factors) when its use is consistent with the sliding scale approach. Bounding approaches can have several potential benefits including streamlining the analysis and potentially being more defensible than more rigorous approaches because they are unlikely to underestimate potential accident consequences (DOE 2002).

The analysis in this section summarizes the detailed information presented in Appendix F. That appendix describes the additional analyses that were performed to develop inputs to determine the potential impacts

from the postulated events that could result in a loss of biocontainment. The input analyses included the following:

- *Biocontainment features*—The frequency and consequence of a potential loss of biocontainment event is dependent on the biocontainment features.
- *Inventory*—The pathogen and animal inventories are a required input for all loss of biocontainment analyses.
- *Airborne dispersion analysis*—An analysis of the airborne dispersion is required for all potential infectious aerosol release events (e.g., an earthquake).
- *Population estimates*—Population estimates are required to determine the population consequences for all potential infectious aerosol release events (e.g., an earthquake).

Appendix F also discusses the MELCOR Accident Consequence Code System, Version 2 (MACCS2), POSTMAX, and SECPOP 2000 computer codes that were used in the analysis. MACCS2 is a DOE/Nuclear Regulatory Commission-sponsored code that has been used widely in support of probabilistic RAs (PRAs) for the nuclear power industry and for consequence analyses for safety documentation throughout the DOE complex. The MACCS2 module used performs all the calculations pertaining to atmospheric transport, dispersion, and deposition. POSTMAX is a code developed at Los Alamos National Laboratory to facilitate calculation of site-specific consequence metrics from MACCS2 output files. The SECPOP 2000 code formats U.S. Census Bureau population data to be consistent with the MACCS2 code. The codes and the parameters used in the analysis are explained in Appendix F.

4.2.2 Centrifuge Events

4.2.2.1 Introduction

Centrifuges use centrifugal force to separate mixtures of materials having differing densities and will be used in the NEIDL to concentrate pathogen particles in suspensions. A pathogen aerosol release resulting from a centrifuge-related event sequence has been selected as a representative event sequence to be analyzed for LAIs. A centrifuge-related initiating event was selected because it is one of the more frequent sources of infectious aerosol releases in the laboratory setting and infectious aerosol releases pose a threat to the laboratory workers, as demonstrated by Appendix D, which reports several centrifuge incidents.

4.2.2.2 Methodology

This analysis focuses on centrifuge operations and potential exposures to a pathogen (or pathogens) that could result. Operations associated with centrifuges have the potential to expose workers as a result of

1 infectious aerosol formation and release. The aerosol has the potential of exposing laboratory workers via
2 inhalation to the lungs, direct contact with mucous membranes and eyes, and ingestion via an open mouth
3 while breathing or speaking.

4
5 The laboratory worker exposure is dependent on the aerosol concentration in the room, which was based
6 on experimental data for this type of event (Bennett and Parks 2006), and the effectiveness of the powered
7 air-purifying respirator (PAPR) at removing the aerosol. The laboratory worker and public exposures are
8 dependent on the quantity of the aerosol released and the effectiveness of the HVAC system.

9 10 **4.2.2.3 Results**

11 This section presents the results of the analyses for the BSL-3 event sequence. There are a number of
12 biocontainment features that prevent and/or mitigate the consequences of this event sequence (for a
13 description of several biocontainment features, see Section F.2 of Appendix F). Modern centrifuges have
14 safety features that minimize the risk of an aerosol release. These features could include imbalance
15 detection and shutdown circuitry, certified aerosol-tight rotor/bucket seals, incorporation of a fluid
16 containment annulus in the rotor, HEPA-filtered air evacuation systems, and automatic rotor identification
17 systems that prevent operation at speeds beyond the recommendations for the rotor/bucket. Other
18 biocontainment features important to this scenario include respiratory protection (i.e., PAPR for BSL-3)
19 and the HVAC system. The role of each biocontainment feature for this event sequence is shown in Table
20 4-8. Section F.2 in Appendix F provides a description of the biocontainment features.

Table 4-8. Exposed group protected by each biocontainment feature—BSL-3 centrifuge infectious aerosol release with full respiratory protection

Exposed group	Admin. controls		Safety equipment							Facility	
	Procedures	Training	Container ^e	Rotor/buckets ^e	Centrifuge chamber ^a	BSC ^f	PPE ^g	Respiratory protection	Positive-pressure suit	HVA ^h C system	Sealed walls, ceilings, and floors
Laboratory worker	M ^b /P ^c	M/P	M ^e	M/P	-- ^d	---	--	M	--	M	--
Facility worker	P	P	M	M/P	--	--	--	--	--	M	M
Public	P	P	M	M/P	--	--	--	--	--	M	M

a Centrifuge chambers are not necessarily aerosol-tight and could provide only partial mitigation even when closed. Centrifuge lids provide no mitigation when open, so this is a minor mitigating effect and, therefore, not considered in this evaluation.

b M – signifies a mitigative feature, which reduces the consequences

c P – signifies a preventive feature, which reduces the likelihood

d This biocontainment feature is either not relevant for this event sequence or it does not have a preventive or mitigative role for this exposed group.

e The cells with cross-hatching indicate a biocontainment feature that is assumed to fail or have partial performance for this event sequence.

f Biological safety cabinet (BSC)

g Personal protective equipment (PPE). Powered air-purifying respirators (PAPR) are PPE, but PAPR are addressed separately here because of their unique role in the BSL-3 centrifuge release scenarios.

h Powered air-purifying respirator

The postulated event sequences analyzed involve an undetected/unreported release because a detected and reported event has very limited potential to result in secondary transmission to the public due to medical intervention. Centrifuge release events are analyzed for the BSL-3 laboratories with laboratory workers receiving both full respiratory protection and partial respiratory protection, as well as centrifuge events in BSL-4 laboratories. The results of those scenarios are addressed below.

4.2.2.3.1 BSL-3 Centrifuge Infectious Aerosol Release with Full Respiratory Protection

Frequency Category. This event sequence requires three distinct events or conditions to occur: (1) a pathogen leakage into the rotor; (2) failure of the aerosol-tight rotor seal to contain the aerosol; and (3) a failure to detect or report the incident. If those events or conditions were all independent, the event sequence would be considered to be in the frequency category B (1 in 100 to 10,000 years). However, because the laboratory worker plays a significant role in the prevention and identification of this event sequence, this sequence is conservatively assigned to frequency category A (1 in 1 to 100 years).

1
2 **Exposure Category and Exposures.** It is assumed that one to four laboratory workers are in the room at
3 the time of the release, and they could all be exposed to the aerosolized pathogen.

4
5 **Laboratory worker.** The laboratory workers could be exposed via various routes, but the analysis focused
6 on the inhalation route as the surrogate for all other routes because it is expected to be the most likely and
7 result in the highest exposure. All laboratory workers in the room (i.e., from one to four) could be
8 exposed to the aerosolized pathogen, so the exposure category is MODERATE.

9
10 **Facility worker.** No reasonable mechanism for exposure of facility worker was identified and the facility
11 worker exposure category for a centrifuge aerosol release event is NONE.

12
13 **Public.** Any aerosolized release from a BSL-3 centrifuge would be drawn into the HVAC system, diluted
14 with air from other portions of the facility (i.e., non-contaminated) and HEPA-filtered before discharge.
15 The BSL-3 HEPA filter is at least 99.97 percent efficient at removing airborne particles 0.3µm in
16 diameter (NIH 2008), with higher efficiencies for all other particle sizes, thereby removing nearly all the
17 aerosol particles. The HEPA-filtered air from the HVAC system is ultimately discharged through the
18 stack, where any particles not filtered out will undergo atmospheric dispersion. Atmospheric conditions
19 (e.g., sunlight) will inactivate some infectious particles over time (Bozzette 2011), but that inactivation is
20 conservatively ignored for this analysis. As a result of the dilution, filtration, and dispersion, the public
21 exposure category for a centrifuge aerosol release event is NONE.

22
23 Table 4-9 summarizes the results of the analysis of a BSL-3 centrifuge infectious aerosol release with full
24 respiratory protection. The inhalation exposures are assumed to also be applicable for direct contact and
25 ingestion exposure to laboratory workers because inhalation exposures are expected to exceed exposures
26 from the other routes and the data necessary to estimate the exposure is not available. The risks associated
27 with centrifuge events would be the same for the three sites being evaluated (i.e., urban, suburban, and
28 rural).

Table 4-9. Summary of results—BSL-3 centrifuge infectious aerosol release with full respiratory protection

Frequency category	Exposed group: category	Route of exposure	Pathogen ^a	Exposure range ^b
A (1 in 1 to 100 years)	Laboratory workers: MODERATE (1-4)	Direct contact Ingestion Inhalation	<i>B. anthracis</i> ^c	0–2 CFU
			<i>F. tularensis</i>	0–2 CFU
			<i>Y. pestis</i>	0–0.09 CFU
			1918 H1N1V	0–0.9 PFU
			SARS-CoV	0–0.09 PFU
			RVFV	0–0.9 PFU ^d 0–9 CCID ₅₀ ^d
			ANDV	0–0.009 CCID ₅₀
	Facility worker: NONE (0)	-- ^e	--	--
	Public: NONE (0)	--	--	--

a *Bacillus anthracis* (*B. anthracis*), *Francisella tularensis* (*F. tularensis*), *Yersinia pestis* (*Y. pestis*), 1918 H1N1 influenza virus (1918 H1N1V), SARS-associated coronavirus (SARS-CoV), Rift Valley fever virus (RVFV), and Andes virus (ANDV).

b Exposures are given in terms of colony forming units (CFU) for bacteria. For viruses, exposures are given in terms of plaque forming units (PFU), median cell culture infective dose (CCID₅₀), or median mouse intracerebral lethal dose (MICLD₅₀).

c Spores in a liquid suspension

d Two values are reported for RVFV using different units as reported in the literature. The CCID₅₀ value is an order of magnitude greater because this measurement is more sensitive than the PFU measurement. The units of MICLD₅₀ also apply to the CCID₅₀ value.

e -- indicates that the cell is not applicable.

4.2.2.3.2 BSL-3 Centrifuge Infectious Aerosol Release with Partial Respiratory Protection

This scenario is similar to the one addressed in the preceding section, with the exception that it includes the potential for one laboratory worker to have a PAPR operating with only partial efficiency. The PAPR efficiency can be reduced by such conditions as a cracked filter housing, defective filter, filter installation error, or a breached filter. A two order of magnitude reduction in the filtration efficiency (i.e., the aerosol passing through the filter increases from 0.1 to 10 percent) is assumed, which is considered to be a very conservative estimate of the reduction in respiratory protection (i.e., overstates the risk).

Frequency Category. The frequency for this scenario is reduced by one category from the previous scenario to account for the likelihood that a reduced PAPR efficiency occurs coincident with the centrifuge aerosol release. A one-category reduction in the frequency (i.e., from category A to B) is considered appropriate because a two order of magnitude reduction in PAPR efficiency is an extreme reduction in efficiency that is unlikely to occur without detection. Therefore, this sequence is conservatively assigned to frequency category B (1 in 100 to 10,000 years). (Note: the results of

Appendix K show that this potential reduction in PAPR effectiveness does not significantly affect worker risk.)

Exposure Category and Exposures. The only difference between this scenario and the previous scenario is that one of the laboratory workers in the room has a PAPR with reduced respiratory protection. Table 4-10 summarizes the results of the analysis of a BSL-3 centrifuge aerosol release with partial respiratory protection. The risks associated with the centrifuge events would be the same for the three sites being evaluated (i.e., urban, suburban, and rural).

Table 4-10. Laboratory worker exposures—BSL-3 centrifuge aerosol release with partial respiratory protection

Frequency Category	Exposed group: category	Route of exposure	Pathogen ^a	Exposure range ^b

^b Exposures are given in terms of colony forming units (CFU) for bacteria. For viruses, exposures are given in terms of plaque forming units (PFU), median cell culture infective dose (CCID₅₀), or median mouse intracerebral lethal dose (MICLD₅₀).

^c Accounts for the one worker with only partial protection.

^d Spores in a liquid suspension

^e Two values are reported for RVFV using different units as reported in the literature. The CCID₅₀ value is an order of magnitude greater because this measurement is more sensitive than the PFU measurement. The units of MICLD₅₀ also apply to the CCID₅₀ value.

^f -- indicates that the cell is not applicable.

4.2.2.3.3 BSL-4 Centrifuge Infectious Aerosol Release

This event sequence is similar to the event sequence analyzed in Section 4.2.2.3.1 with the exception that it occurs in a BSL-4 laboratory rather than in a BSL-3 laboratory. One-piece, totally encapsulating positive-pressure suits are required for NEIDL BSL-4 laboratories, whereas PAPRs are required for NEIDL BSL-3 laboratories. The positive-pressure suits are supplied with air from an external source, so infectious aerosol releases will not result in laboratory worker exposures. Scenarios involving the compromise in respiratory protection from positive-pressure suits were also considered, but no credible scenarios were identified. Therefore, no credible BSL-4 centrifuge release scenarios were identified that result in exposure to laboratory workers. As with the BSL-3 scenario, facility workers and the public are not at risk. Therefore, further analysis is not warranted.

4.2.3 Needlestick Events

4.2.3.1 Introduction

A needlestick is an inadvertent penetration of the skin with by a syringe needle. Needlestick and other puncture events involving sharp objects are some of the more common potential exposure incidents in BSL-3 and BSL-4 laboratories, as discussed in Section F.7.3.2 of Appendix F. If the needle contains any infectious material, a needlestick in a BSL-3 or BSL-4 laboratory could result in an LAI of a laboratory worker. It is reasonable to expect that the majority of the 13 pathogens evaluated could be used to inoculate animals; however, some pathogens are more likely to be used in syringes than others. Wild-type SARS-associated coronavirus (SARS-CoV) and 1918 H1N1 influenza virus (1918H1N1V) are not expected to be used as injectable live inocula. However, it is possible that blood samples could be taken from animals infected with the pathogens using needle and syringe, and a needlestick would be possible in that case. If those viruses are used, the pathogen concentration in the animal blood is taken to be the same as the maximum working concentration of the pathogen. There is also a risk of exposure to SARS-CoV and 1918H1N1V via other sharp objects (such as a scalpel), and a needlestick scenario is used as a surrogate for all sharps exposure.

4.2.3.2 Methodology

The laboratory worker experiencing the needlestick is the only person with the potential to be directly exposed, so facility workers and the public are considered for secondary transmission only (see Appendix L).

Estimating the extent of exposure (e.g., the number of bacteria or virions received) is speculative for needlestick events because it could result in a broad range of pathogen exposures for the laboratory

worker. The extent of exposure depends on such factors as the extent to which the needle penetrates the skin, whether pathogen is present in the needle/syringe, the amount and concentration of pathogen present in the needle/syringe, and whether the syringe plunger is depressed in conjunction with the needlestick. If no pathogen is present, the extent of exposure is zero. Conversely, if a pathogen is present and the syringe plunger is depressed, the exposure could be very large. Instead of speculating on the extent of exposure, it is conservatively assumed that an infectious dose was administered for each needlestick event. That conservatism will result in an overestimate of the number of infections that result from needlestick events.

4.2.3.3 Results

Needlestick events can occur in both BSL-3 and BSL-4 laboratories. Prompt detection and reporting of a needlestick event can maximize the effectiveness of medical intervention for some pathogens; thus, potentially lowering the likelihood that an initial exposure results in infection to the worker and lowering the likelihood of secondary transmissions to other workers or the public. Needlesticks that are promptly detected and reported were analyzed in Appendix F, but they do not pose a significant threat to the public because of NEIDL medical intervention. Medical interventions could include quarantine of the potentially exposed worker if appropriate. Therefore, only those scenarios involving a failure to promptly detect and report the incident are addressed here.

A needlestick scenario with a failure to promptly detect and report the incident could be representative of a worker who does not feel comfortable reporting the injury for fear of reprisal, believes it was a near-miss event that does not require reporting, or does not notice the needlestick, for example. The risks associated with needlestick events would be the same for the three sites being evaluated (i.e., urban, suburban, and rural).

4.2.3.3.1 BSL-3 Needlestick without Prompt Detection and Reporting

Frequency Category. The operational incident data (see Attachment C in Appendix F) identifies some incidents that have occurred at other BSL-3 and BSL-4 facilities and provide insights into the types of incidents that might occur at NEIDL. Needlestick events that are promptly detected and reported frequency category A (1 in 1 to 100 years) Needlestick events in BSL-3 that are not promptly detected and reported are assigned to frequency category B (1 in 100 to 10,000 years). This frequency category assignment is appropriate and even conservative because: (1) the historic estimate is on the boundary of frequency categories A and B, (2) historic values likely overstate the value for current facilities due to enhanced practices, equipment, and facilities (see Section D.1.1 of Appendix D), and (3) the NEIDL is expected to have lower incident rates due to its attention to sharps safety (see Section F.7.2.1 of Appendix

F) and the enhancement of safety (see Section 2.1 of Chapter 2). Section F.7.3.2 of Appendix F provides additional details.

Exposure Category and Exposures. Because this analysis is limited to the point of primary exposure, exposure categories to facility workers and members of the public are not applicable. For laboratory workers, at most one worker will be exposed from a needlestick event. Therefore, an exposure category of LOW is chosen.

Table 4-11 summarize the results for a needlestick in a BSL-3 laboratory, assuming the incident is not promptly detected and reported.

Table 4-11. Summary of results—Needlestick in BSL-3 laboratory without prompt detection and reporting

Frequency category	Exposure group category	Pathogen ^a	Exposure range
B (1 in 100 to 10,000 years)	Laboratory workers: LOW (1)	<i>B. anthracis</i>	Infection assumed
		<i>F. tularensis</i>	Infection assumed
		<i>Y. pestis</i>	Infection assumed
		1918 H1N1V ^b	Infection assumed
		SARS-CoV ^b	Infection assumed
		RVFV	Infection assumed
		ANDV	Infection assumed
	Facility worker: NONE (0)	-- ^c	--
	Public: NONE (0)	--	--

^a *Bacillus anthracis* (*B. anthracis*), *Francisella tularensis* (*F. tularensis*), *Yersinia pestis* (*Y. pestis*), 1918 H1N1 influenza virus (1918 H1N1V), SARS-associated coronavirus (SARS-CoV), Rift Valley fever virus (RVFV), and Andes virus (ANDV).

^b SARS-associated coronavirus, and 1918 H1N1 influenza virus are not expected to be used in syringes as wild type inocula but are analyzed here for completeness. Additionally it is assumed that if these viruses are used, then the pathogen concentration in the animal blood concentration is taken to be the same as the maximum working concentration of the pathogen.

^c -- indicates that the cell is not applicable.

4.2.3.3.2 BSL-4 Needlestick without Prompt Detection and Reporting

A needlestick incident is also possible in a BSL-4 laboratory. This scenario is the same as the incident addressed in Section 4.2.3.3.1 with the exception that it occurs in a BSL-4 laboratory with BSL-4 pathogens. Table 4-12 summarizes the results for a needlestick in a BSL-4 laboratory assuming the incident is not promptly detected and reported.

Table 4-12. Summary of results—Needlestick in BSL-4 laboratory without prompt detection and reporting

Frequency category	Exposure group category	Pathogen ^a	Exposure range
B (1 in 100 to 10,000 years)	Laboratory workers: LOW (1)	EBOV	Infection assumed
		MARV	Infection assumed
		LASV	Infection assumed

		NIPV	Infection assumed
	Facility worker: NONE (0)	-- ^b	--
	Public: NONE (0)	--	--

a Ebola virus (EBOV); Marburg virus (MARV); Lassa virus (LASV); Junin virus (JUNV); tick-borne encephalitis virus, Far Eastern sub-type, formerly known as Tick-borne encephalitis complex (Russian spring-summer encephalitis virus) (TBEV-FE); and Nipah virus (NIPV).

b -- indicates that the cell is not applicable.

4.2.4 Earthquake Events

4.2.4.1 Introduction

The NEIDL facility was designed and constructed in compliance with strict seismic criteria. Attachment D of Appendix F provides an overview of the relevant design criteria and compliance of the NEIDL design with those criteria. As required by the Massachusetts State Building Code, the effective peak velocity-related acceleration and the effective peak acceleration are each 0.12 g (g is the standard acceleration due to gravity). This 0.12 g peak acceleration cannot be related to a Richter magnitude because the Richter magnitude is a measure of energy involved and the acceleration is affected by factors such as the depth, ground conditions, and focusing. For Seismic Performance Category C, the building structure must stay functional after a seismic event. (Massachusetts 1997). The BSL-4 suites are structurally separated from the adjoining floors. Such a structural separation allows for movement if an earthquake occurs, while maintaining structural integrity of the BSL-4 suites. BSL-4 suites have 12-inch-thick, reinforced concrete walls with special epoxy covering that acts as a sealant. The critical equipment (e.g., HVAC, air-locks, fire protection system, building automation system, etc.) are designed to survive the design basis earthquake and all equipment is designed so that it does not compromise biocontainment features. All fixtures for the BSL-4 suite were designed specifically for the facility and are Underwriters Laboratories tested to ensure that the facility retains its air-tightness.

4.2.4.2 Methodology

Two earthquake scenarios were selected for analysis; one was an MRF (total collapse) earthquake, which was selected as the MRF event, and another less severe earthquake referred to as a slightly beyond design basis (BDB) earthquake. While there may be many earthquake-related impacts such as building collapse

and fires associated with neighboring buildings, this analysis only addresses NEIDL-related consequences because the non-NEIDL impacts are not directly related to the action being evaluated herein. The initial conditions for both earthquakes event sequences are as follows:

- There are no warnings of potential seismicity and the facility is operating without forewarning of the earthquake.
- Any or all pathogen(s) could be in use in the facility at its maximum volumes and maximum concentrations in a liquid suspension. The pathogen(s) could be in one or more containers at the time of the earthquake.
- The facility contains infected animals (mammals and arthropods) at the time.

A severe earthquake is postulated to occur that results in the following events and conditions:

- It is assumed that a fire does not result from the earthquake. A fire would inactivate most pathogens and would tend to loft releases over the immediately surrounding population, so this assumption results in the highest potential consequences.
- As a result of building motion or falling debris from the earthquake, an aerosolized pathogen release results from the container(s) of pathogens in liquid suspension. Containers of frozen pathogen suspensions could be breached, but their release would be minimal because they are initially frozen and a large-scale, prompt release is unlikely; therefore, they are dismissed from further consideration for this analysis.
- Per guidance, this event occurs during median meteorological conditions.
- Infected animals (mammals and arthropods) could escape from the facility.

For both accident scenarios, the level of exposure is dependent on the amount of pathogen released and how the pathogen is dispersed. Both the airborne dispersion factors and the number of people are site-specific, and they have been developed using the same radial (or polar) grid with sixteen 22.5°-sectors.

For the earthquake analysis, each annulus is 100 m wide (i.e., outer radius minus inner radius), and the grid extends to a maximum radius of 1 km. While a radius of 1 km (0.6 mile) captures the majority of the impacts, the expected number of infections would be somewhat higher if the calculation were performed for a larger radius.

The maximum radius of 1 km was selected for several reasons including the following:

- The 1-km radius is consistent with U.S. Nuclear Regulatory Commission recommendations for the NEPA environmental justice evaluation of proposed actions in cities (Nuclear Regulatory Commission 2003b).
- The highest density of nonresidents surrounding the urban site is within 0.5 km of NEIDL and is included in the 1-km radius (see Section F.4 of Appendix F).
- There are no high-population communities just beyond 1-km radius that would significantly affect the results at any of the sites (see Section F.4 of Appendix F).
- The average exposure levels are extremely low at 1 km and would be even lower for greater distances. The MRF (total collapse) earthquake analysis (as shown later) estimates the average exposure level to be less than one one-thousandth (1/1,000) of a unit for all but one pathogen and less than one one-hundredth (1/100) of a unit for all pathogens at 1 km. The calculated exposures at even greater distances would result in even lower exposure levels.

After release from the facility, the aerosolized pathogen would be transported and dispersed as a result of winds and meteorological conditions. The computer code and parameters used to estimate the airborne dispersion are consistent with guidance (DOE 2002, DOE 2004a) and are addressed in Section F.5.2 of Appendix F. The input parameters for the analyses were the recommended or conservative values (i.e., overestimate aerosol concentrations). For example, wet deposition the dry deposition and building wake effect parameters were the recommended default values. Conservative parameters include the suppression of wet deposition, buoyant plume rise, building wake effect plume rise, and plume meander. The results of these dispersion analyses were compared with the results of other dispersion analyses and wind tunnel tests for NEIDL and were found to be in good agreement. In the case of the MRF earthquake, the assumption of a ground-level release is very conservative and compensates for uncertainties in the analyses. For example at the urban site, concentrations are over 200 times greater at the 30-m exclusion fence for a ground-level release than for an elevated release (see Table F.5.3-1 of Appendix F). See Section F.5 of Appendix F for additional details.

The methodologies for analysis of both earthquake events are described in the following sections.

4.2.4.2.1 MRF Earthquake

A bounding analysis was performed for the MRF (total collapse) earthquake event sequence. *American National Standard Categorization of Nuclear Facility Structures, Systems, and Components for Seismic Design* (ANSI 2004), provides guidance specifically for analysis of earthquake events. That document is based on the methodology developed by DOE and is intended for facility design purposes; however, this

methodology is frequently used in safety analyses. The relevant guidance provided for the impact analysis includes the following recommendations:

1. “The unmitigated consequence analysis shall be performed considering only the inherent physical or chemical characteristics of the hazardous material and the energy sources for dispersing the material.”
2. The “...engineered mitigating features shall be assumed not to function unless the robustness of each mitigating feature can be demonstrated to survive the postulated event.”
3. “ANSI/ANS-5.10-1998, *Airborne Release Fractions at Non-Reactor Nuclear Facilities* provides guidance concerning mechanisms for release of the hazardous material into the air or water and shall be used to support similar calculations required by this standard.” Because the document referred to is based on DOE-HDBK-3010 (DOE 2000) and because DOE-HDBK-3010 is more comprehensive, this analysis uses DOE-HDBK-3010 as its basis.
4. The “...consequence analysis shall strive to use mean values for the parameters related to material release, dispersal in the environment, and health consequences.”

In summary, that guidance results in development of bounding scenarios with the use of median factors when analyzing the bounding scenarios. The assumption that engineered mitigation to fail means that the building effectively collapses with no walls or HVAC to mitigate release. This is an extremely severe scenario that is extremely unlikely to occur and whose airborne releases are highly unlikely to be exceeded.

4.2.4.2.2 Beyond Design Basis (BDB) Earthquake

DOE NEPA Guidance stresses the importance of realism in the analysis, and the MRF (total collapse) earthquake is an extremely unlikely event. To put the risks associated with the MRF earthquake into perspective, an earthquake that is less severe and more likely than the MRF event is also analyzed. Earthquakes that are within the seismic design basis of the facility were not analyzed because the NEIDL structures, systems, and components were designed to perform their functions during and following design basis earthquakes, thereby not resulting in a significant loss of biological containment. A BDB (minor damage) earthquake that is more likely than the MRF earthquake but still slightly beyond the design basis was selected for analysis. The BDB earthquake is postulated to result in partially mitigated releases. The NEIDL building is not expected to lose structural integrity until well beyond the design basis, as discussed in Section F.8.3.2 of Appendix F. Therefore, a stack release with some degradation in HEPA filtration is assumed to occur. After release from the stack, the aerosolized pathogen would be transported and dispersed as a result of winds and meteorological conditions.

4.2.4.3 Results

This section documents the analysis results for both the MRF earthquake and the BDB earthquake. The seismic design information available does not distinguish between the BSL-3 and BSL-4 areas when addressing the design criteria or seismic capacity, so there is no basis for distinction of the two events, even though it is expected that the BSL-4 has a higher seismic capacity. Because there is no basis for distinguishing between the two areas and all biocontainment features are assumed to fail, the event sequence for both BSL-3 and BSL-4 are the same and are addressed together in the following section.

4.2.4.3.1 Maximum Reasonably Foreseeable Earthquake Affecting BSL-3 and BSL-4

Frequency Category. The NEIDL structure was designed to withstand an earthquake with a peak acceleration of 0.12g (g is the acceleration of gravity), per the requirements of the Massachusetts Building Code. The fundamental period of the NEIDL structure is 2 seconds and seismic shaking at the fundamental period has the potential of causing the greatest damage. Based on the U.S. Geological Survey (USGS) seismic hazard maps, the annual exceedance probability for a 2-second 0.12 earthquake that results in severe damage to the facility is assigned to frequency category C (1 in 10,000 to 1 million years). The MRF earthquake is assigned to frequency category C, but this is considered conservative because a significantly more severe, hence less likely, earthquake would be required to result in a total collapse of the NEIDL structure. See Attachment E of Appendix F for details of this frequency category assignment.

Exposure Category. The exposure category for the laboratory workers is HIGH because all people in all rooms have the potential to be exposed. The exposure category for the facility workers is HIGH because all people in the facility have the potential to be exposed. The estimated exposure category for the public is expected to be MODERATE. Aerosolized pathogen particles could be dispersed beyond 300 m, but concentrations would be extremely low beyond 3 km.

Extent of Exposure. The DOE NEPA Guidance (DOE 2002) provides the following guidance: ...in many cases the acceleration forces associated with extremely rare earthquakes (e.g., frequencies of less than 10^{-6} per year) may be so great that destructive impacts unrelated to the proposed action or alternatives would overwhelm impacts associated with the proposed action or alternatives. Such an analysis would not be informative regarding the proposed action or alternatives because a decision maker would be unable to distinguish the consequences resulting from the proposed action or alternatives from the general destructive effects of the earthquake.

1
2 That caution is certainly applicable for the MRF earthquake because of the low frequency of the event
3 and the extremely conservative assumptions used for the analyses. However, the exposures are estimated
4 for this event because this scenario provides insight into the maximum biological consequences that could
5 reasonably be expected from operation of the facility and also provide insight into potential site
6 differences.

7
8 **Laboratory Worker.** If a severe earthquake were to result in total structural failure of the NEIDL, it is
9 unlikely that laboratory workers would survive if they were in the BSL-3 or BSL-4 laboratories.
10 Estimation of exposures to workers in a collapsed building provides no insight into worker risk from such
11 an event. Therefore, the laboratory workers are assumed to have escaped the building and congregate at
12 the NEIDL exclusion fence for the duration of the release. In such a case, the laboratory workers are no
13 different than any other facility worker and are included in the following exposure estimate.

14
15 **Facility Worker.** For this analysis, it is assumed that facility workers exit the building promptly and
16 congregate at the NEIDL exclusion fence, which is at least 30 m from the NEIDL. A person at the
17 exclusion fence is defined as the maximally exposed individual (MEI), so the MEI exposure will be used
18 for laboratory workers. The MEI exposure is calculated in the public exposure section below.
19 Approximately 300 workers are present at NEIDL about 25 percent of the year (about 50 weeks at 40
20 hours per week out of an 8,760 hour year), which results in an average worker population of 75 people for
21 all 16 radial sectors combined. The average population for a single sector would be about five workers.
22 Because of the very low levels of exposure and the small number of workers potentially exposed, a
23 facility worker infection is considered to be in frequency category D (1 in more than 1 million years),
24 which is beyond reasonably foreseeable and is dismissed from further consideration.

25
26 **Public.** Airborne dispersion of the pathogen organisms can result in inhalation, ingestion, and direct
27 contact routes of exposures. Tables 4-13a, 4-13b, and 4-13c present a composite of exposures results to
28 BSL-3 pathogens resulting from a MRF earthquake for the urban, suburban, and rural sites for each
29 annulus. The average RVFV exposure is 0.66 CCID₅₀ for people located at the NEIDL exclusion fence
30 for the urban site, which is approximately the same as two people receiving 1 CCID₅₀ and one person
31 having no exposure if three people were located at the fenceline. The average exposure at the urban site
32 is 1.6×10^{-3} CCID₅₀ for people located 1 km from the release, which is approximately the same as one person
33 receiving 1 CCID₅₀ and 625 people having no exposure. Tables 4-14a, 4-14b, and 4-14c present a
34 composite of exposures results to BSL-4 pathogens resulting from a MRF earthquake for the urban,

1 suburban, and rural sites for each annulus. The average segment population in each of the 16 radial
2 sectors is shown in Table 4-15 for each of the three sites.

3
4 ***Escaped Animals.*** The NEIDL could contain a number of infected animals (mammals and arthropods) at
5 any time. In the event of a MRF earthquake, it is likely that enclosures would be breached and there is the
6 potential that infected animals (mammals and arthropods) would survive and escape to the environs.
7 There is also the potential for contaminated inanimate objects to be released from the facility. As a result,
8 there is the potential for some pathogens to become established in the environment. The animals and the
9 pathogen with which they could be infected are identified in Section F.3 of Appendix F. The potential
10 impact of the infected escaped animals is analyzed in Chapter 7.

4.2.4.3.2 Beyond Design Basis Earthquake Affecting BSL-3 and BSL-4

Frequency Category. The NEIDL structure was designed to withstand an earthquake with a peak acceleration of 0.12g (g is the acceleration of gravity), per the requirements of the Massachusetts Building Code. The fundamental period of the NEIDL structure is 2 seconds and seismic shaking at the fundamental period has the potential of causing the greatest damage. (BUMC 2005) Based on the U.S. Geological Survey (USGS) seismic hazard maps, the annual exceedance probability for a 2-second 0.12 that results in significant damage to the facility is assigned to frequency category C (1 in 10,000 to 1 million years). See Attachment E of Appendix F for details of this frequency category assignment.

Note: The risks associated with a BDB earthquake are beyond reasonably foreseeable (see Section 8.6.2) and an increase in the frequency category from C (1 in 10,000 to 1 million years) to B (1 in 100 to 10,000 years) would not alter that conclusion.

Exposure Category. The exposure category for the laboratory workers is HIGH because all people in all rooms have the potential to be exposed. The HVAC system, including its dampers, sealed walls, and the room airlocks confine the release and protect laboratory workers from potential exposure during their prompt evacuation, so the exposure category for the facility worker is HIGH. The estimated exposure category for the public is expected to be LOW. Dispersion calculations indicate that pathogens could be transported beyond the 30-m exclusion zone, but that are unlikely to spread beyond 300 m. It is possible for pathogen particles to be spread beyond 300 m, but the concentrations would be so low that they would be a minimal risk to health.

Extent of Exposure. Airborne dispersion of the pathogen organisms can result in inhalation, ingestion, and direct contact routes of exposures. Inhalation exposures are calculated for the laboratory worker and the general public because that is the most likely route of exposure and there is very limited dose-response information for the other routes. The extent of exposure was calculated for the laboratory worker, facility worker, and the public. The laboratory worker exposures are site-independent because the same facility design and operations are assumed for all three sites. However, the facility worker and public exposures are site-dependent and are calculated separately for each site.

Laboratory Worker. The laboratory worker's potential exposure to pathogenic airborne aerosols is presented in Section F.8.3.2.4.1 of Appendix F. The laboratory worker exposures resulting from a BDB earthquake are considerably less than the exposures resulting from the centrifuge release event (see Section 4.2.3.3). For example, the highest exposure level is for RVFV where the BDB earthquake

exposure is 0.3 CCID₅₀ and the centrifuge release event exposure to RVFV is 0 to 9 CCID₅₀ with full respiratory protection, which is as much as a factor of thirty times greater than the exposure from the BDB earthquake. The centrifuge release event is in frequency category A (1 in 1 to 100 years) and the BDB earthquake is in frequency category C (once in 10,000 to 1 million years). The number of infections and secondary transmissions is not calculated for laboratory worker for the following reasons:

- On the basis of the results in Chapter 8 (Health Effects–Initial Exposure) for the centrifuge release, the frequency of a laboratory worker infection caused by a BDB earthquake is expected to be either in or on the cusp of frequency category D (1 in more than 1 million years). Events that are in frequency category D are considered beyond reasonably foreseeable and are dismissed from further consideration.
- The analysis would not provide additional insight into either laboratory worker or public risk because the risk associated with the centrifuge release event is much greater (nominally four orders of magnitude based on the frequency of the release sequence).

For the BSL-4 laboratories, the positive-pressure suits provide clean external air to the BSL-4 laboratory workers so the laboratory workers in the room would not be exposed the aerosolized pathogen released into the room. For an exposure to result, the following must all occur concurrently:

1. A BDB earthquake, which is assigned to frequency category C (1 in 10,000 to 1 million years)
2. A large release of aerosolized pathogen in a room
3. A large breach in a positive-pressure suit in the specific room containing the aerosolized pathogen release, and
4. The laboratory worker with the breached suit remains in the room long enough to receive a significant exposure

The combination of all those events occurring is in frequency category D (1 in more than 1 million years), which is beyond reasonably foreseeable and, therefore, the exposure for the BSL-4 laboratory worker is dismissed from further consideration.

Facility worker. Following an earthquake of this magnitude, it is expected that all facility workers in BSL-3 and BSL-4 laboratories would promptly exit the facility and intuitively move away from the building. Facility workers that would remain in the building would be protected from aerosolized pathogen because the HVAC system, including its dampers, sealed walls, and the room airlocks would confine the release if still operational. The HVAC is assumed to be operational because this maximizes the potential for public exposure, which is the primary focus of this RA. Cracks in the wall and leaks in the airlocks would not affect the potential for public exposure for the following reasons: 1) only cracks

(rather than gaping breaches) would be expected for the BDB, 2) the negative pressure of the HVAC would ensure that any leakage is into the operating HVAC system, and 3) the outer shell of the building provides an additional confinement barrier.

For this analysis, it is conservatively assumed that facility workers and laboratory workers exit the building promptly and congregate at the NEIDL exclusion fence (at least 30 m from the NEIDL). A person at the exclusion fence is defined as the MEI, so the MEI exposure will be used for facility workers. The MEI exposure is calculated in the public exposure section below. Approximately 300 workers at NEIDL are present about 25 percent of the year (about 50 weeks at 40 hours per week out of an 8,760 hour year), which results in an average worker population of 75 people for all sectors combined. The average population for a single sector would be about five workers. Because of the very low levels of exposure (less than one-millionth of a unit, as shown in the subsequent results for public exposures), a facility worker (and laboratory workers able to exit promptly) infection is considered to be in frequency category D (1 in more than 1 million years), which is beyond reasonably foreseeable and is dismissed from further consideration.

Public Exposure. Following an aerosolized pathogen release inside a laboratory room, the HVAC system would purge aerosol from the room, filter out aerosol particles, and exhaust the air through the stack. Members of the general public could be exposed to aerosol particles that are not filtered out of the building exhaust. Tables 4-16a, 4-16b, and 4-16c present a composite of exposures results to BSL-3 pathogens resulting from a BDB earthquake for the urban, suburban, and rural sites for each annulus. For the BSL-4 laboratories, all stack source term values are much less than 1 unit. That means that less than one unit of pathogen would be expected to be released from the BDB earthquake. As a result, the average public exposures would be extremely small, and a significant exposure is in frequency category D (1 in more than 1 million years), which is beyond reasonably foreseeable and is dismissed from further consideration.

Escaped Animals. The NEIDL could contain many infected animals (mammals and arthropods) at any time (see Section F.3.3.4 of Appendix F). The NEIDL structure is only expected to experience minor damage as a result of the BDB earthquake and the enclosures would not be expected to breach, though it is possible that one or more enclosures would be breached. For an animal to escape the facility in the event of an enclosure breach, it would need to escape through interlocking laboratory doors and escape the building through exterior doors or other openings. In an animal were to escape, there is the potential

- 1 for some pathogens to become established in the environment. The potential consequences of an animal
- 2 escape are addressed in Chapter 7 (Environmental Persistence of Pathogens).

4.2.5 Aircraft Crash

4.2.5.1 Introduction

An accidental aircraft crash into the NEIDL is a postulated externally initiated accident scenario for the potential release of pathogens from the NEIDL facility to the public. This analysis demonstrates that the risk of an aircraft crash is bounded by the risk of other analyzed accident scenarios, namely the MRF earthquake event, and therefore does not necessitate a detailed analysis. Risk is a function of (1) the frequency of an adverse event, and (2) the consequences of the adverse event. Thus, the frequency and consequence of a postulated aircraft crash scenario will be compared to that of the MRF earthquake event.

This scenario involves an accidental aircraft crashing into the NEIDL facility resulting in an aerosol release of a pathogen and potentially exposing the public. Only the Boston site is analyzed because the large Boston Logan International Airport has many more flights than the municipal airports near the two comparable sites and, therefore, a higher anticipated frequency for such an event. An aircraft crash scenario initiated by a malevolent act is not specifically addressed by this section.

4.2.5.2 Methodology and Results

Frequency. The DOE has detailed guidance for estimating the frequency of an aircraft crash probability at a given location, as opposed to crash frequencies on a per flight basis. The DOE guidance, *Accident Analysis for Aircraft Crash into Hazardous Facilities* (DOE-STD-3014-2006, DOE 2006), was used in this evaluation.

DOE 2006 uses a four-factor formula to estimate the annual aircraft crash frequency at a given location. The four factors are (1) number of aircraft operations; (2) the probability that an aircraft will crash; (3) given a crash, the probability that the aircraft will crash into a one-square-mile (mi^2) area where a facility is; and (4) the size of the facility.

As discussed in Appendix F (Section F.9), the potential crash frequency was calculated to be approximately $6 \times 10^{-5}/\text{yr}$. The frequency of $6 \times 10^{-5}/\text{yr}$ (return period of approximately 16,700 years) places the aircraft crash into frequency category C (1 in 10,000 to 1 million years). However, this is the frequency of an aircraft crashing into NEIDL, and it does not take into account the conditional probability of conditions that must exist for a pathogen release to occur. For an aircraft crash to result in a pathogen release, the following conditions are necessary:

1. The aircraft crashing must have sufficient energy (speed and mass of a projectile) to penetrate the

1 building. It is not known which aircraft would be capable of penetrating the walls of the building
2 exterior and the laboratory walls (BSL-3 or BSL-4), but not all are likely to be capable of
3 penetrating both walls. That is especially true of the general aviation flights, which dominate the
4 frequency for non-airport operations, because those flights include small planes.

5 2. The angle of impact must be sufficiently perpendicular for penetration to result. Impacts at lower
6 angles could result in the aircraft ricocheting off the building or hitting with a grazing blow,
7 without penetrating the interior laboratory spaces.

8 3. The impact must be at a location that results in a pathogen release. An aircraft impact into
9 administrative areas is not likely to result in a pathogen release. The BSL-3 and BSL-4 areas
10 compose 29 percent of the facility floor space (13 percent BSL-3 and 16 percent BSL-4) (BUMC
11 2011). The laboratory rooms will contain pathogens in a releasable form (i.e., a liquid suspension)
12 for only a portion of the time. Rooms where pathogens are stored are not in an easily releasable
13 form (i.e., frozen).

14
15 On the basis of the conditional probabilities, the frequency of an aircraft crash that results in a pathogen
16 release is judged to be in frequency category C (1 in 10,000 to 1 million years), but it is likely in the low
17 frequency (high return period) end of that category. The MRF earthquake scenario frequency category is
18 also in frequency category C (1 in 10,000 to 1 million years). However, given the multiple extreme
19 conservative assumptions for the calculation of the aircraft crash frequency (e.g., all airport operations are
20 considered take-offs or landings) and the conditional probabilities stated above, it is judged that that
21 aircraft crash frequency is considered comparable to or lower than the MRF earthquake frequency.

22
23 **Consequences.** While a structural evaluation of aircraft crash per the guidance of DOE-STD-3014-2006
24 has not been performed, the consequences (i.e., the number and extent of potential exposures) to the
25 public are qualitatively judged to be less than that of a MRF earthquake event for the following reasons:

26 1. The MRF earthquake event assumes total collapse of the NEIDL building [i.e., all available
27 material at risk (MAR) has the potential to be release and appropriate release factors applied to
28 the entire inventory]. An aircraft crashing into the building would likely affect only the
29 immediate portion of the building that is involved at point of impact, and to a lesser degree, the
30 surrounding areas. That means that only a portion of the available MAR has the potential to be
31 released in any given crash. In the unlikely event of a total facility collapse after an aircraft
32 collision (similar to that from the September 11, 2001, terrorist strikes on the World Trade Center
33 and the Pentagon) could affect all the available MAR. In such a case, the amount of MAR
34 affected would be equal to, but not exceed, that assumed in the MRF earthquake event.

2. An aircraft provides a considerable fuel source and an ignition potential when crashed into a building; thus, the potential of a fire exists. A fire would raise the local and surrounding temperatures of the crash site (i.e., areas where MAR is affected), thus likely inactivating the pathogens before or during their release. An inactive pathogen presents no hazard to a public receptor.
3. NEIDL rooms containing pathogens are in the interior of the facility, and there is at least one exterior wall plus one primary containment wall protecting the pathogens. Therefore, an aircraft projectile would have to penetrate two walls to affect the pathogens and result in a potential airborne release. In addition, the BSL-4 area is constructed as a box-within-a-box with interior walls that are more robust than (and seismically independent from) the rest of the building structure.
4. The BSL-3 and BSL-4 laboratories are several stories above ground level, so any release would be an elevated release that would allow dilution as the plume is dispersed, while the MRF earthquake scenario was analyzed on the basis of a ground-level release. Because a ground-level release would tend to result in higher concentrations in the respirable zones/altitudes than an elevated release, the MRF earthquake scenario will tend to bound the aircraft crash scenario.

Therefore, the consequences of an aircraft crash are expected to be less than the consequence estimates for the MRF earthquake.

In summary, both the frequency and consequences of an aircraft crashing would be less than or no greater than the frequency and consequences of the MRF earthquake as analyzed. Therefore, the MRF earthquake analysis is considered bounding for the aircraft crash and further detailed aircraft crash analysis is not deemed to be necessary.

4.3 Summary

The following conclusions are drawn from the analyses reported above.

- Operational data appropriate for informing estimates for the frequency and extent of exposures from events were found to be inadequate. To compensate for inadequate data, frequency categories spanning wide ranges were employed and conservative assumptions (i.e., assumptions that tend to overestimate the frequency or consequences) were made. The overall risk estimates are sensitive to these assumptions, as they contribute significantly to the uncertainty in overall estimates. Better operational data with respect to past and potential accidents would serve to significantly decrease uncertainty for risk assessment of biocontainment laboratories.

- 1 • It was determined that undetected exposure of 1-4 laboratory workers from a centrifuge
2 bioaerosol release could credibly occur under BSL-3 laboratory conditions. The amount of
3 exposure estimated from this scenario could result in infection of at least one laboratory worker
4 from any of the BSL-3 pathogens analyzed. Some pathogens are estimated to be much more
5 likely than others to cause infection because of differences in bioaerosol concentration and dose-
6 response.
- 7 • Because of the requirement for the use of positive pressure encapsulating suits in BSL-4
8 laboratories, no credible scenario was found in which a bioaerosol exposure of a laboratory
9 worker to a BSL-4 pathogen would go undetected. A detected exposure may occur, but is not
10 considered a risk to the public because operating procedures would prevent the exposed
11 laboratory worker from interacting with public contacts until risk of transmission is ruled out.
- 12 • It was determined that undetected exposure and subsequent infection of a laboratory worker from
13 a needlestick could credibly occur for any BSL-3 or BSL-4 pathogen. It was estimated that, for
14 most pathogens, undetected needlestick infections would occur more frequently than infections
15 resulting from an undetected centrifuge bioaerosol release. However, this comparison could
16 change if the conservative assumptions that were used to compensate for incomplete data were
17 altered.
- 18 • Airborne dispersion calculations for the MRF earthquake show that individual members of the
19 public beyond the NEIDL exclusion fence (i.e., at least 30 m from the facility) would receive an
20 average exposure that is smaller than any dose proven to cause infection in humans or animals via
21 inhalation, with the possible exception of RVFV. While this is an extremely severe event that
22 includes the loss of all biocontainment features and results in the maximum credible release
23 amount, the public exposure estimates are still small due to the small quantities of pathogen in the
24 laboratory, the limited potential for release of this inventory, and the dilution of any release in the
25 atmosphere.
- 26 • A threat assessment was performed that included a comparison of the three sites (see Chapter 6).
27 The security systems (e.g. electronic systems, personnel, policy, procedure, etc.) are assumed to
28 be the same at each of the three sites, so the threat from any malevolent action(s) was the same at
29 all three sites. Therefore, the analysis provides no basis for discerning any differences in the
30 frequency among the three sites. The consequences may be slightly different for malevolent acts
31 that involve release of pathogens from the facility; however, the analysis determined that any
32 exposures resulting from such releases would be no greater than the exposures from the
33 earthquake event.

Note: This appendix is provided as a general indicator of biocontainment safety level (BSL) 3 and 4 laboratory safety experience. As such, it reflects experience with a broad range of microbes in research and clinical laboratories throughout the world. Not all the microbes included herein necessarily will be studied at the NEIDL.

D. A Review of Reported Incidents, Exposure, and Infections in BSL-3 and BSL-4 Laboratory Facilities

D.1 Part I.

D.1.1 Reporting of Laboratory-Associated Infections

Accounts of laboratory-associated infections (LAI) began to appear in the literature in the late 19th century. The earliest incidents involved diphtheria, cholera, typhoid fever, and brucellosis. Infections described in these reports originated by oral, cutaneous, and subcutaneous exposure, and in one instance the route of infection was unknown (Kruse, Puckett, and Richardson 1991). Subsequently, sporadic surveys of LAI in general were published, beginning in 1915 and most recently in 2006, 2008, and 2011 (Harding 2000, 2006; Centers for Disease Control and Prevention 1999; Kimman, Smit, and Klein 2008; Pedrosa and Cardoso 2011). Methods used in those reviews included examining the literature for published reports, submitting questionnaires to thousands of laboratories, and soliciting personal accounts of unpublished incidents. However, there has been no mechanism for centralized and systematic reporting of LAI as a whole. As a result, data that have been collected to date are incomplete.

In the United States, infections in the general population caused by approximately 80 pathogens are voluntarily reported to the Centers for Disease Control and Prevention (CDC) by state health agencies, and these can include infections associated with laboratory activities. In addition, provisions of the Select Agent Program that took effect in 2002 now require laboratories to report infections and other biocontainment releases involving particular pathogens that have been designated as select agents due to their potential impact on human health or agriculture or both (APHIS and CDC 2009). Furthermore, any institution receiving NIH funding is required to report to the NIH any LAI and other biocontainment releases that involve genetically

1 recombinant pathogens or organisms (National Institutes of Health 2011). Biocontainment
2 releases, including LAI, that involve other pathogens do not have reporting requirements.

3
4 It has been suggested that retrospective reviews of reported LAI substantially under-represent the
5 true number of such infections (Harding 2006). There are two reasons for that. First, the findings
6 from the reviews cannot account for subclinical infections that can occur in the laboratory
7 setting. Because such infections are asymptomatic, it is unlikely that they would be detected
8 unless an accompanying breach of biocontainment is suspected or unless periodic serologic
9 surveys of laboratory workers are conducted as part of an ongoing occupational health
10 maintenance program. Second, there can be reluctance by personnel to report laboratory
11 accidents and potential exposures. As noted by Harding and Byers (Harding 2000, 2006),
12 collection of accurate data regarding potential laboratory-related exposures continues to be
13 "...hampered by an indifference to and, frequently, an unwillingness to report these incidents" in
14 part "...due to fear of reprisal and the stigma associated with such events." Recent congressional
15 testimony suggests that a no-fault reporting system for biocontainment failures, similar to that
16 used by the Federal Aviation Administration, could be beneficial to the field of biosafety
17 (Subcommittee on Oversight and Investigations 2007). The potential advantage of such an
18 approach is two-fold. First, incidents could be reported without fear of penalty or stigma for
19 personnel or for the institution. Second, root cause analysis of failures often will demonstrate
20 common factors that, when identified and shared, can be used to reduce the likelihood of similar
21 events in the future.

22
23 Comparisons of previous reports with recent literature can be used to consider whether there has
24 been downward trend in the number of reported LAI in general over various periods of time.
25 However, it is important to note that such compilations cover clinical as well as research
26 laboratories, and that BLS-2 laboratory data often are included. At least one comparison based
27 on data reported by Harding and Byers (Harding 2006) led to an inference that LAI reported
28 from these various laboratory settings appeared to have declined for some pathogens (Centers for
29 Disease Control and Prevention 2007). However, a later review by Harding and Byers found
30 such comparisons to be inconclusive because of incomplete data on the total numbers of
31 infections and the numbers of workers at risk (Harding 2006). Other authors have reached the

1 same conclusion, namely, that information on laboratory incidents is incomplete regarding the
2 total number of infections and the total number of people at risk. Without this information, the
3 actual incidence of LAI cannot be determined (Kimman, Smit, and Klein 2008; Centers for
4 Disease Control and Prevention 2007).

5
6 However, information on LAI recently has been compiled from reports on pathogens currently
7 listed as select agents. This 2011 retrospective review showed a marked decrease in reported
8 LAI for these particular pathogens during the years 1930-2009 (Committee on Special
9 Immunizations Program for Laboratory Personnel Engaged in Research on Countermeasures for
10 Select Agents: National Research Council 2011). In their review, the Committee considered
11 three time periods: 1930-1978, 1979-2004, and 2005-2009. Total infections were determined to
12 be 2107, 379, and 8, during the three periods, for a yearly average of 44, 15, and 2 LAI,
13 respectively (Figure D-1a). The Committee attributed the sharp decline in LAI involving select
14 agents to improvements over time in biosafety procedures, primary biocontainment systems,
15 personal protective equipment, and facilities engineering. Examples of these improvements
16 include progress in the design of safety equipment (such as the advent of powered air-purifying
17 respirators for use as personal respiratory protective equipment to be used as part of BSL-3
18 biocontainment precautions) and laboratory facilities (such as the requirement for HEPA
19 filtration of exhaust air from BSL-3 facilities), the development of safer work practices (such as
20 the elimination or reduction of sharps), improvements in training, and the refinement and
21 implementation of biosafety and biosurety programs (i.e. an emphasis on achieving a biosafety
22 culture).

23
24 The Committee also found that, although the number of LAI from select agents has sharply
25 decreased, the number of reports of select agent releases has increased dramatically from 2003
26 through 2009 (Figure D-1b). The Committee has attributed the increase in release reports "...at
27 least in part, to the broad definition of a release event and to the expansion in Select Agent
28 research since 2001". These two trends reported for select agents by the Committee reflect the
29 widespread expectation among members of the biosafety profession that ongoing progress in the
30 field of biosafety and biocontainment will continue to contribute to the prevention, minimization,
31 and mitigation of laboratory-associated infections.

Figure D-1a. Average annual number of select agent LAI over various time periods.

Figure D-1b. Annual number of select agent release reports 2003-2009.

Source: Based on Committee on Special Immunizations Program for Laboratory Personnel Engaged in Research on Countermeasures for Select Agents (Committee on Special Immunizations Program for Laboratory Personnel Engaged in Research on Countermeasures for Select Agents: National Research Council 2011)

It is significant that the operating experience of BSL-4 biocontainment facilities shows there have been no laboratory-associated infections among the public in conjunction with the operation of these facilities (Centers for Disease Control and Prevention 1999) (see Part II. Johnson Reports). As for BSL-3 pathogens, data from the CDC between 1947 and 1973 showed that, for 109 LAI diagnosed among its personnel, no secondary infections occurred among family or community members, and the National Animal Disease Center (Ames, Iowa) similarly found no secondary infections associated with 18 LAI at their institution between 1960 and 1975 (Centers for Disease Control and Prevention 1999). Recently there has been speculation based on strong scientific evidence that the 1977 H1N1 influenza virus outbreak in the Soviet Union and Asia originated from a laboratory source (Zimmer and Burke 2009). These 1977 H1N1 infections could be informative about the potential for a respiratory virus to spread following release from a laboratory setting. However, if speculation about a laboratory origin for this outbreak is true, it must be noted that the extent of any biocontainment precautions that might have been in place are unknown, and it is likely that those would not have consisted of BSL-3 biocontainment precautions applied in a BSL-3 facility. Accordingly, the 1977 H1N1 outbreak is noted here but is not included in the tabulated information on laboratory biosafety incidents that follows.

Operating experience from BSL-3 biocontainment facilities reported since then shows an LAI with SARS-CoV that resulted in seven secondary infections among the public in China (one of which was fatal)(World Health Organization 2004). Reviews conducted after the 2004 SARS incident in China, that would have addressed LAIs linked to BSL-3 or BSL-4 laboratory operations, reported no infections in the community at large (Kimman, Smit, and Klein 2008; Harding 2006; Johnson 2009; (Pedrosa and Cardoso 2011)).

D.1.2 BSL-3 And BSL-4 Laboratory Biosafety Experience Summarized Findings From The Johnson Reports 1970-2009

In 2003 Dr. Karl Johnson, the lead scientist who isolated and named Ebola virus in 1977, undertook surveys of the biosafety experience for BSL-4 facilities worldwide and for key BSL-3 facilities in the United States. Methodology included on-site review of laboratory and institution records, in-depth interviews with senior scientists, and compilation and assessment of written responses from senior scientists. In 2009 Dr. Johnson updated his report on BSL-4 facilities with data and findings from 2003 through 2009. The findings of those surveys are known as the Johnson Reports. In his review of BSL-4 facilities, Dr. Johnson surveyed the U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID), the CDC's Special Pathogens Branch, the National Institute for Communicable Diseases in Johannesburg (NICD), the Southwest Foundation for Biomedical Research, and the University of Texas Medical Branch-Galveston. For the five BSL-4 facilities reviewed during 1970–2009, Dr. Johnson determined that no infections occurred during 700,000 worker hours of facility operation. Those findings reflect the efficacy of biocontainment precautions employed at the BSL-4 level. BSL-4 precautions are the most stringent that can be applied to biocontainment of pathogens.

In addition to the surveys of BSL-4 facilities, Dr. Johnson undertook surveys for three BSL-3 biocontainment intramural laboratories of the National Institute of Allergy and Infectious Diseases. Those laboratories composed part of the biological research facilities on the Bethesda and Rockville, Maryland, campuses, and the Rocky Mountain Laboratories in Hamilton, Montana. Those three BSL-3 facilities were reviewed during 1982–2003. In his review, Dr. Johnson found that only one clinical infection and four asymptomatic infections had occurred for 3.2 million worker hours of operation during those years.

1
2 The biosafety data compiled in the Johnson Reports for BSL-4 and BSL-3 facilities are
3 compelling evidence of robust and effective engineering controls, training programs, operating
4 procedures, safety awareness, and professional skill in effect at the facilities surveyed. Moreover,
5 the data from those laboratories are particularly informative because they include the number of
6 hours worked for the infections tallied. That allows for facility-specific incidences to be
7 characterized in a form that allows estimation of worker risk for purposes of risk assessment
8 (RA). Because the data include denominators of worker hours, they have been chosen as the best
9 data available for use in estimating frequency of infections in BSL-3 and BSL-4 facilities. Dr.
10 Johnson's findings are detailed in the Supplement to this Appendix, as the Johnson Reports.

11 12 **D.1.3 Additional Biosafety Experience in Laboratories**

13 Another strength of the data in the Johnson Reports is that the BSL-4 facilities surveyed fully
14 represent the extent of BSL-4 operations in the United States. This is necessarily less true for the
15 BSL-3 facilities, which number in the hundreds in the United States. To address this, other
16 reports from various sources that address BSL-3 and BSL-4 facilities have been compiled and
17 summarized in tabular form (Tables D.1 through D.7). Sources for the data include peer-
18 reviewed scientific literature, reports and presentations from federal governmental agencies,
19 reports from nonprofit entities, and the media in general. The credibility of the accounts and
20 sources has been reviewed carefully, and they serve to expand the data on biosafety in a
21 qualitative manner. However, as discussed previously, reporting of incidents is not mandatory
22 for BSL-3 facilities, and the reporting that does take place is not transparent for the public. As a
23 result, information for additional incidents is incomplete with regard to the total number of
24 infections, the total number of people at risk, and other details, and they do not by themselves
25 represent a sound basis for determining LAI frequency for use in quantitative assessments of risk
26 (Kimman, Smit, and Klein 2008; Centers for Disease Control and Prevention 2007). In that
27 regard, the Johnson Reports offer the best available validated data that can be applied in
28 quantitative RA. The additional materials listed below that concern BSL-4 laboratories are
29 consistent with the findings in the Johnson Reports, and they document three, perhaps four,
30 infections that occurred in Russia and Germany. The additional materials listed below that
31 concern BSL-3 laboratories show several dozen LAI, in contrast to the experience detailed in the

Johnson Reports. As discussed previously, these reports are difficult to interpret on a quantitative basis but can be helpful in understanding the biosafety experience from a qualitative broader viewpoint.

Particular attention in these materials is given to LAI, but biocontainment failures and other protocol lapses that did not result in an LAI are included for certain cases that might have posed potential risk to workers or the community. Also, some incidents reported here under the category of BSL-3 pertain to BSL-2 facilities, either because they involved facilities at Boston University (and therefore are, or could be perceived as, relevant to this RA) or because they are Select Agent pathogens that can be handled using either BSL-2 or BSL-3 biocontainment precautions, depending on circumstances of the work involved. Because U.S. federal requirements for reporting these kinds of incidents exist only for pathogens specified by the Select Agent Program and for incidents that occur in conjunction with research on recombinant DNA, incidents involving other pathogens might be incompletely represented in the tables.

D.1.3.1 BSL-3 Facility Experience at Two NIH Virology Laboratories, 2003-2008 and 1976-2008

Data for the period 2003–2009, collected in the form and manner of those compiled by Dr. Johnson for the three National Institute of Allergy and Infectious Diseases (NIAID) facilities surveyed in 1982–2003, were not available. However, some data concerning two laboratories are available from a recent NIH-sponsored symposium on safe work practices for 1918 H1N1 influenza virus (Subbarao 2008). For one laboratory the reporting period consisted of 111,000 worker hours during the years 2003–2008, and the pathogens involved were highly pathogenic avian influenza virus (HPAIV) and SARS-CoV. No spills or percutaneous exposures were reported. There were five reports of fever from three employees, and laboratory testing for possible infection was indicated in one case. No infections were documented among the workers for a period that equates to 54 person years (Table D-1). For the second laboratory, the reporting period consisted of 203,000 worker hours during the years 1976–2008, and the pathogen involved was HPAIV. Four potential exposures were documented from 2005-2008. Two of the four people received post-exposure Tamiflu and none developed clinical illness. No infections were documented among the workers for a period that equates to 105 person years (Table D-1).

The data from these two laboratories comprise an extremely good biosafety record and are consistent with findings of the Johnson Reports concerning biosafety experience at other NIH BSL-3 laboratories.

Table D-1. Personnel hours worked and accidental exposures to highly pathogenic avian influenza virus (HPAIV) and SARS-CoV for two intramural NIAID laboratories: 1976–2008

	Hours at risk	Accidental exposures
SARS-CoV	41,000	0
HPAIV	273,300	0
Total	314,300	0

D.1.3.2 BSL-3 Facility Experience at USAMRIID 1989-2004

A recent review of biosafety experience at USAMRIID in 1989 through 2002 was published in 2004. During that time, four (and possibly five) clinical infections from BSL-3 pathogens were detected (Table D-2). There were no secondary infections associated with any of the exposures. These infections, as well as a flooding event concerning *B. anthracis*, are included in Table D-7.

Table D-2. Outcomes of BSL-3 accidental exposures to infectious pathogens: USAMRIID 1989–2002

		Potential exposures	Exposures for which antimicrobial compounds were given	Clinical infections	Infecting agent
Bacterial		150	75	3 ^a	<i>Burkholderia mallei</i> <i>Coxiella burnetii</i> <i>Yersinia pestis</i>
Viral		76	2 ^b	2	VEE virus ^c Chikungunya virus

Source: (Rusnak, Kortepeter, et al. 2004)

Notes:

a. Infection from *Y. pestis* was highly likely in one case but confirmatory culture was not performed.

b. Antiviral compounds were not available for most viral pathogens; investigational compounds were administered in two cases.

c. 3VEE = Venezuelan equine encephalitis virus

CDC Select Agent Incident Reports 2003–2009 (NRC (National Research Council) 2011)

Table D-3. Potential release of select agents, 2003–2009, with 7 resulting LAI*

Activity	Number of potential release events
Animal bite or scratch	11
Needlestick or sharps injury	46
Equipment mechanical failure	23
Personal protective equipment failure	12
Loss of containment	196
Procedural issue	30
Spill	77
Total events	395

*As of 9/29/11 details are unavailable, as these data are unpublished, except as Exhibit 13 in Serial No. 110-70 (Subcommittee on Oversight and Investigations 2007). Many of these events and as many as 6 of the LAI are duplicated in the Select Agent data presented before the U.S. House of Representatives on October 4, 2007, which are included in Table D-7 below.

D.1.3.3 BSL-4 Biocontainment Facilities: International

Table D-4. Recent reported incidents involving international BSL-4 biocontainment facilities

Location	Date	Research agent	Description	Results	Action
Vector Laboratory, Novosibirsk, Russia	May 19, 2004	Ebola virus (BSL-4)	A researcher several days earlier had suffered an accidental finger stick with a hypodermic needle that contained the Zaire strain of Ebola virus. She was working with a guinea pig model of the infection at the time (ProMED mail 2004).	The researcher died from Ebola infection on May 19.	No information available.
Bernhard Nocht Institute for Tropical Medicine, Hamburg, Germany (Enserink 2009)	March 12, 2009	Ebola virus	A laboratory researcher wearing protective gloves experienced a needle stick from a syringe suspected to contain Ebola virus (McGroarty 2009).	The researcher was quarantined in Hamburg University Hospital for observation. Treatment included use of the experimental Feldmann vaccine.	The worker did not become ill. No further information concerning potential seroconversion
Vector Laboratory, Novosibirsk, Russia	1990	Marburg virus (BSL-4)	One worker was infected with Marburg virus. Details are not available (ProMED mail 2004)	The infection was not fatal.	No information available.
Vector Laboratory, Novosibirsk, Russia	1988	Marburg virus (BSL-4)	One worker contracted Marburg virus infection. Details are not available (ProMED mail 2004).	The infection was fatal.	No information available.

D.1.3.4 BSL-4 Biocontainment Facilities: United States

Table D-5. Recent reported incidents involving U.S. BSL-4 biocontainment facilities

Location	Date	Research Agent	Description	Results	Action
Centers for Disease Control and Prevention, Atlanta, Georgia Bldg 18	June 8, 2007		A lightning strike knocked out electricity to BSL-3 and unoccupied BSL-4 biocontainment areas. Circuit breakers that should have remained engaged were tripped. (Young 2008; United States Government Accountability Office 2009)	Backup generators failed to start. Negative directional airflow was not maintained. A battery-powered system provided power to lights and doors for 15-20 minutes.	No exposures or infections were reported. Changes to the design of the backup system were discussed and damage to the lightning protection equipment was repaired. CDC has declined to release documents relating to the incident.
University of Wisconsin-Madison, Wisconsin	July 28, 2006	Ebola virus	The Madison IBC sought NIH guidance on whether work they had been conducting during the past year on full length cDNA made from the Ebola virus RNA genome could be continued under BSL-2 rather than BSL-3 biocontainment (Whitney 2006; Associated Press 2006; Hermes 2007).	NIH advised that all work during the 2005-2006 period should have been conducted under BSL-4 biocontainment as specified under Section III-D-2 of NIH guidelines for Research Involving Recombinant DNA Molecules.	The research was halted at Madison and moved to the National Microbiology Laboratory, Winnipeg, Canada, a BSL-4 biocontainment facility.
USAMRIID, Fort Detrick, Frederick, Maryland	February 10, 2004	Ebola virus	A civilian scientist grazed her hand with a hypodermic needle that had been used to inject antibodies into Ebola virus-infected mice (Dishneau 2004; Subcommittee on Oversight and Investigations 2007).	Scientist was sequestered in the biosafety biocontainment care suite until it could be concluded that no infection ensued.	No further information available.
Centers for Disease Control and Prevention, Division of Vector Borne Infectious Diseases, Fort Collins, Colorado	January 2004	Russian spring-summer encephalitis virus	A worker found three broken vials of the virus. Wearing only a laboratory coat and gloves, the worker used tweezers to remove broken glass and then moved the materials to another container (Margasak 2007).	No further information available.	No further information available.

D.1.3.5 BSL-3 Biocontainment Facilities: International

Table D-6. Recent reported incidents involving international BSL-3 biocontainment facilities

Location	Date	Research Agent(s)	Description	Result	Actions
Agence Francaise de Securite Sanitaire des Aliments, Maisons Alfort, France	March 26, 2009	<i>Bacillus anthracis</i>	Five technicians potentially were exposed to <i>B. anthracis</i> as a result of a protocol violation. Cultivated <i>B. anthracis</i> cells routinely are killed in the BSL-3 area and, after confirmation of death, are moved to the BSL-2 area. In this incident, the cells were moved to the BSL-2 area before confirmatory tests were completed. Test results later showed the cells had not been killed (Nasdala 2009).	Cell suspensions had been handled within a BSC located in the BSL-2 area but, as a precaution, all workers were given prophylactic antibiotic treatment.	No further information available
The National Institute of Virology in Beijing, China	February and April, 2004	Severe acute respiratory syndrome corona virus (SARS-CoV)	Two researchers working with SARS were sickened and diagnosed with the disease 2 weeks apart in April. The identity of these infections was not recognized until the mother of one of the workers sickened as well (World Health Organization 2004).	The mother died and six other persons in contact with the two individuals became infected.	An intense lab investigation revealed that two other workers had experienced SARS-compatible illnesses in Feb. 2004 and were found to have the antibodies of the etiologic SARS-CoV. The investigation also concluded that the infections stemmed from handling of viral material, in a non-BSL-3 laboratory, that had been inadequately inactivated in the facility's BSL-3 laboratory. Efficacy of the inactivation had not been tested prior to leaving the BSL-3 laboratory.
The National Defense University in Taipei, Taiwan	December 10, 2003	SARS-CoV	On Dec. 6, 2003, a senior research scientist working with SARS in a Class III BSC cleaned up waste fluid that leaked from a tightly docked transfer chamber connected to the main cabinet. From the main cabinet he sprayed alcohol into the chamber, waited 10 minutes, opened the chamber to spray more and finally physically cleaned it up. The next day	On Dec. 10, 2003, he noted fever and fatigue, which progressed into a dry cough and severe myalgia. He was hospitalized Dec. 16, and experienced moderately severe clinical illness.	Contacts, especially plane passengers, were monitored or quarantined; no secondary infections occurred. An investigation of the lab revealed that SARS-CoV nucleic acid was on the handle of an alcohol bottle in the transfer chamber and on the light switch in the Class III cabinet

Final Supplemental Risk Assessment Report for the Boston University National Emerging Infectious Diseases Laboratories (NEIDL)

Location	Date	Research Agent(s)	Description	Result	Actions
			he attended a SARS meeting in Singapore (Normile 2004).		
A BSL-3 lab at an Institute, Singapore	August 26, 2003	West Nile virus (WNV) and SARS-CoV	A graduate student working on a virulent recent New York strain of WNV became sick with fever and myalgia after making several passages of the new virus in Vero E6 cells also used to grow SARS-CoV. The student had minimal training and help from an Institute technician (Lim 2004).	On Sept. 3, he was admitted to the hospital with a dry cough and signs of pulmonary inflammation. He was transferred to isolation and developed a moderately severe evolution of the disease. The technician was not infected.	Surveillance and quarantine was maintained on several dozen contacts, but no secondary infections occurred. An investigation of the lab proved that the WNV was contaminated with the SARS-CoV.

D.1.3.6 BSL-3 Biocontainment Facilities: United States

Table D-7. Recent reported incidents involving U.S. BSL-3 laboratory facilities^a

Location	Date	Research agent	Description	Results	Action
University of Wisconsin – Madison	October 6, 2010	Influenza A/Brevig Mission/1918H1N1	The intake HEPA filter fell off of the PAPR unit during use and could have been loose for a prolonged period of time. The worker reattached the filter and continued working (NIH 2010).	Respiratory protection was not provided by the PAPR for a short time. There is no mention of whether gloves were changed before handling the filter.	Oseltamivir prophylaxis was initiated. Respiratory specimens collected at 24, 36, and 72 hours were negative (PCR). SOPs were modified to include verification of PAPR HEPA filter before entry into biocontainment areas.
Medical College of Wisconsin, Milwaukee	July 28, 2010	<i>Mycobacterium tuberculosis</i> (recombinant strain)	Power failure of a PAPR unit occurred, apparently as a result of its on/off switch unknowingly being pressed against the hard surface of a chair back. Power loss was noticed after a few seconds; power was restored by pressing the on/off switch (NIH 2010).	Respiratory protection was not provided by the PAPR for a short time. Incident details would suggest no exposure occurred.	The worker was evaluated by proper authorities. The manufacture was notified of the deficiency in equipment design. SOP was modified to require placement of PAPR motor unit to the side of the belt when using a chair.
National Institutes of Health	July 18, 2010	Highly pathogenic avian influenza virus	An infected mouse escaped from a BSL-3 facility and later was captured in a BSL-2 facility (National Institutes of Health Office of Biotechnology Activities 2010).	Investigation found inconsistent facility entry logs for the primary animal technician. Review of video surveillance for 3 days prior showed the technician used no personal protective equipment on at least one occasion when entering the BSL-3 facility.	Disinfection of the BSL-2 area was undertaken. The worker who captured the mouse was offered prophylaxis using Tamiflu. Other workers were medically screened. Standard operating procedures were revised and personnel were retrained. The animal care technician was

					relieved of duty.
University of Kentucky, Lexington	April 12, 2010	<i>Yersinia pestis</i>	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.
Colorado State University, Fort Collins	April 2, 2010	Human immunodeficiency virus	A parenteral (injection) exposure was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.
Ch'Idren's Hospital Boston, Massachusetts	May 26, 2010	<i>Mycobacterium tuberculosis</i>	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.
The University of Virginia, Charlottesville	March 8, 2010	<i>Francisella tularensis</i>	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.

Final Supplemental Risk Assessment Report for the Boston University National Emerging Infectious Diseases Laboratories (NEIDL)

Location	Date	Research agent	Description	Results	Action
U.S. Army Medical Research Institute of Infectious Diseases, Fort Detrick, Frederick, Maryland	February 20, 2010	<i>Bacillus anthracis</i>	The FBI closed its case files on the 2001 theft and deliberate release of <i>B. anthracis</i> spores, concluding that a USAMRIID scientist had acted alone (Brook et al. 2001; Cymet and Kerkvliet 2004; Perez 2010).	At least 22 people were infected and 5 were killed.	No further information is available
The University of North Carolina at Chapel Hill	January 27, 2010	SARS coronavirus	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.
East Carolina University, Greenville, North Carolina	January 26, 2010	<i>Brucella abortus</i>	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.
The University of Texas at San Antonio	January 14, 2010	<i>Coccidioides</i> sp.	A parenteral (injection) exposure was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.
U.S. Army Medical Research Institute of Infectious Diseases, Fort Detrick, Frederick, Maryland	December 4, 2009	<i>Francisella tularensis</i>	A USAMRIID military scientist was reported to have been diagnosed with tularemia, as a result of her work with <i>F. tularensis</i> (USAMRIID United States Army Medical Research Institute of Infectious Diseases 2009, 2009; Bhattacharjee 2009).	Oral antibiotics were started on an outpatient basis, followed by inpatient administration of intravenous antibiotics. Recovery was expected	No further information available

Final Supplemental Risk Assessment Report for the Boston University National Emerging Infectious Diseases Laboratories (NEIDL)

Location	Date	Research agent	Description	Results	Action
Indiana University, Bloomington	November 18, 2009	<i>Yersinia pestis</i>	Mouse dander was found outside of a mouse cage that was to be completely sealed to contain potentially infectious bioaerosols associated with infected mice (Leonard 2009).	Seven researches were given antibiotic treatment as a precaution.	Work in the BSL-3 lab was halted pending an evaluation. No further information available.
University of Massachusetts Medical School	November 5, 2009	<i>Mycobacterium tuberculosis</i>	A parenteral (injection) exposure was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.
The University of Wisconsin at Madison	October 29, 2009	Influenza virus (not further specified)	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.
Novartis Pharmaceuticals Corporation	October 28, 2009	Venezuelan equine encephalitis virus	A parenteral (injection) exposure was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.
Boston University, Massachusetts	October 25, 2009	<i>Neisseria meningitidis</i>	A microbiology researcher at BU sought medical attention for laboratory-acquired bacteremia and meningitis. Molecular typing determined the infecting strain was the same strain he had been working with. Work with <i>N. meningitidis</i> is conducted at BSL-2 using BSL-3 precautions (respiratory protection provided by Class II	Intravenous antibiotics were administered and the researcher recovered fully.	University experts determined the researcher did not consistently wear appropriate personal protective equipment, and did not consistently follow appropriate safe microbiological practices. It was surmised that the researcher touched his

Location	Date	Research agent	Description	Results	Action
			BSC) (Boston University 2009; Smith 2009, 2009)		gloved hand to his face while working with the bacterium (Ad Hoc Committee 2010). All laboratory members repeated laboratory safety re-training and organism-specific re-training.
The University of Texas Medical Branch at Galveston	September 21, 2009	Rift Valley fever virus	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.
The University of Wisconsin at Madison	September 11, 2009	<i>Brucella canis</i>	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.
University of California, Berkeley	June 26, 2009	<i>Mycobacterium tuberculosis</i>	A potential exposure was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.
University of Kentucky	June 18, 2009	<i>Yersinia pestis</i>	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.

Final Supplemental Risk Assessment Report for the Boston University National Emerging Infectious Diseases Laboratories (NEIDL)

Location	Date	Research agent	Description	Results	Action
Texas A&M University, College Station	March 5, 2009	<i>Brucella melitensis</i>	A breach of containment was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.
BD Biosciences, San Jose, California	January 2009	NA	ULPA filters used in the manufacture of aerosol biocontainment enclosures for flow cytometers were found to be faulty. Eight of 10 filters from 3 different lots tested at one site (Yale University, Jan. 22, 2009) failed to meet performance specifications. Seven of 9 units tested at a second site (Duke University, Jan 26, 2009) failed to meet performance criteria. (BD Biosciences 2009; Fontes 2009; Aldermann 2009)	Safety officials of the Universities alerted American Biological Safety Association Listserv subscribers to the issue. There was no mention of possible exposures. Duke U. protocols required use of a walk-in biosafety cabinet as an additional biocontainment feature.	BD Biosciences issued a Field Action Notice asking customers to cease use of the enclosures and await instructions regarding a filter replacement program.
The University of Iowa	November 5, 2008	<i>Francisella tularensis</i>	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.
The University of Texas at San Antonio	October 17, 2008	<i>Coccidioides</i> sp.	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.

Final Supplemental Risk Assessment Report for the Boston University National Emerging Infectious Diseases Laboratories (NEIDL)

Location	Date	Research agent	Description	Results	Action
University of Pittsburgh, Pennsylvania	September 24, 2008	<i>Mycobacterium tuberculosis</i>	An animal care technician was bitten by a macaque that was part of a vaccine study of tuberculosis (Templeton 2008).	The technician suffered bone, tendon and nerve damage as well as multiple infections (apparently not related to the research agent).	The University was fined by Occupational Safety and Health Administration (OSHA) for failing to provide training and safety equipment for lab personnel.
The University of Texas at San Antonio	August 21, 2008	<i>Francisella tularensis</i>	A parenteral (injection) exposure was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.
The University of Texas Health Sciences Center (not further specified)	July 25, 2008	<i>Bacillus anthracis</i>	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.
Centers for Disease Control and Prevention, Atlanta, Georgia Bldg 17	July 11, 2008	Program pathogens include influenza, extensively drug-resistant <i>Mycobacterium tuberculosis</i> , and rabies	A bird caused a Georgia Power transformer to fail, knocking out electricity to BSL-3 biocontainment areas (Young 2008, 2008, 2008).	Backup generators failed to start, leaving the labs without main electrical power for 75 minutes. CDC personnel did not attempt to override and start the backup generators. Negative directional airflow was not maintained.	No exposures or infections were reported. Backup failure was determined to be due to removal of two generators from service for upgrades. Their absence caused a power fluctuation when main power was lost, resulting in shutdown of the entire backup generator system. The system was tested subsequently on July 21 st ; CDC officials would not release results of the test. No further information was

					available.
The University of North Carolina at Chapel Hill	June 31, 2008	SARS virus	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.
The University of Wisconsin at Madison	May 22, 2008	<i>Brucella</i> sp.	A parenteral (injection) exposure was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.
The University of Texas Health Sciences Center (not further specified)	May 7, 2008	<i>Bacillus anthracis</i>	A potential exposure was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.
The University of North Carolina at Chapel Hill	April 7, 2008	<i>Mycobacterium tuberculosis</i>	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.

Final Supplemental Risk Assessment Report for the Boston University National Emerging Infectious Diseases Laboratories (NEIDL)

Location	Date	Research agent	Description	Results	Action
St Louis University	April 4, 2008	Yellow fever virus	A parenteral (injection) exposure was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.
The University of Wisconsin at Madison	January 2008	<i>Brucella</i> sp.	The University reported conduct of unauthorized experiments with a select agent to the U.S. Dept. of Health and Human Services.	HHS undertook investigation under authority of the Select Agent Program.	In May 2010, the university was fined \$40,000 and the Principal Investigator was suspended from related work for 5 years.
Ohio State University	September 27, 2007	<i>Francisella</i> sp.	Equipment failure was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.
The University of Texas Health Sciences Center (not further specified)	September 21, 2007	<i>Bacillus anthracis</i>	A parenteral (injection) exposure was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.
Lovelace Respiratory Research Institute, Albuquerque, New Mexico	August 28, 2007	<i>Yersinia pestis</i>	An employee potentially was exposed by being stuck by a broken scalpel blade (Subcommittee on Oversight and Investigations 2007).	APHIS/CDC form 3 (Report of Theft, Loss, or Release of Select Agents and Toxins) was filed.	Investigation was ongoing. No further information available.

Final Supplemental Risk Assessment Report for the Boston University National Emerging Infectious Diseases Laboratories (NEIDL)

Location	Date	Research agent	Description	Results	Action
University of Mississippi Medical Center, Jackson	August 11, 2007	<i>Bacillus anthracis</i>	A graduate student accidentally broke a flask containing <i>Bacillus anthracis</i> cells which spilled onto floor (Subcommittee on Oversight and Investigations 2007; Center for Infectious Disease Research & Policy 2007)	The student was exposed to <i>Bacillus anthracis</i> .	Procedures for spill biocontainment and decontamination were followed. The student received prophylactic antibacterial therapy.
St. Louis University, Missouri	August 7, 2007	Monkeypox virus	A needle stick with syringe containing the virus was reported (Subcommittee on Oversight and Investigations 2007).	APHIS/CDC form 3 (Report of Theft, Loss, or Release of Select Agents and Toxins) was filed.	Investigation was ongoing. No further information available.
University of California-Davis	July 27, 2007	<i>Brucella abortus</i>	A needle stick with syringe containing the bacterium was reported (Subcommittee on Oversight and Investigations 2007).	APHIS/CDC form 3 (Report of Theft, Loss, or Release of Select Agents and Toxins) was filed.	Investigation was ongoing. No further information available.
Battelle Memorial Institute, Columbus, Ohio	July 23, 2007	Avian influenza virus	A needle stick with syringe containing the virus was reported (Subcommittee on Oversight and Investigations 2007).	APHIS/CDC form 3 (Report of Theft, Loss, or Release of Select Agents and Toxins) was filed.	The matter was referred to USDA APHIS. No further information available.
Bioqual, Inc., Rockville, Maryland	July 23, 2007	Avian influenza virus	An employee was bitten by a ferret inoculated with the virus (Subcommittee on Oversight and Investigations 2007).	APHIS/CDC form 3 (Report of Theft, Loss, or Release of Select Agents and Toxins) was filed.	The matter was referred to USDA APHIS. No further information available.

Final Supplemental Risk Assessment Report for the Boston University National Emerging Infectious Diseases Laboratories (NEIDL)

Location	Date	Research agent	Description	Results	Action
University of New Mexico	July 23, 2007	<i>Francisella tularensis</i>	Potential exposure: an employee was bitten by a rat that had been inoculated with the bacterium (Subcommittee on Oversight and Investigations 2007).	APHIS/CDC form 3 (Report of Theft, Loss, or Release of Select Agents and Toxins) was filed.	Investigation was ongoing. No further information available.
University of South Alabama	July 19, 2007	<i>Rickettsia prowazekii</i>	Potential exposure: an employee dropped a culture vessel of the bacterium, splashing it onto lab coat, pants, and shoes (Subcommittee on Oversight and Investigations 2007).	APHIS/CDC form 3 (Report of Theft, Loss, or Release of Select Agents and Toxins) was filed.	Investigation was ongoing. No further information available.
The University of Chicago	July 16, 2007	<i>Bacillus anthracis</i>	An employee potentially was exposed via needle stick (Subcommittee on Oversight and Investigations 2007).	APHIS/CDC form 3 (Report of Theft, Loss, or Release of Select Agents and Toxins) was filed.	Investigation was ongoing. No further information available.
Lovelace Respiratory Research Institute, Albuquerque, New Mexico	July 10, 2007	<i>Bacillus anthracis</i>	A potential loss of containment was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.
National Animal Disease Center, Ames, Iowa	July 2, 2007	<i>Brucella suis</i>	Potential exposure: a needle stick with syringe containing <i>B. suis</i> occurred during necropsy (Subcommittee on Oversight and Investigations 2007).	APHIS/CDC form 3 (Report of Theft, Loss, or Release of Select Agents and Toxins) was filed.	Investigation was ongoing. No further information available.

Final Supplemental Risk Assessment Report for the Boston University National Emerging Infectious Diseases Laboratories (NEIDL)

Location	Date	Research agent	Description	Results	Action
U.S. Army Medical Research Institute of Infectious Diseases, Fort Detrick, Frederick, Maryland	June 29, 2007	<i>Bacillus anthracis</i>	Potential exposure: environmental surveillance indicated presence of the bacterium on a freezer handle, light switch, and shoes in the hot side of the change room (Subcommittee on Oversight and Investigations 2007).	APHIS/CDC form 3 (Report of Theft, Loss, or Release of Select Agents and Toxins) was filed.	No further information available.
Texas A&M University, College Station	June 26, 2007	<i>Coxiella burnetii</i>	Potential exposure to the bacterium was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.
Centers for Disease Control and Prevention, Atlanta, Georgia Bldg 18	June 8, 2007		A lightning strike knocked out electricity to BSL-3 and unoccupied BSL-4 biocontainment areas. Circuit breakers that should have remained engaged were tripped (Young 2008; Young 2007; Young 2007, 2007, 2007; United States Government Accountability Office 2009).	Backup generators failed to start. Negative directional airflow was not maintained. A battery-powered system provided power to lights and doors for 15-20 minutes. No exposures or infections subsequently were reported.	Changes to the design of the backup system were discussed and damage to the lightning protection equipment was repaired. It was later determined that a ground cable had been cut some time earlier, and prevented the circuit breakers from remaining engaged. CDC has declined to release documents relating to the incident.
National Animal Disease Center, Ames, Iowa	June 4, 2007	<i>Brucella abortus</i>	Potential exposure: an employee was scratched by a broken rib during necropsy (Subcommittee on Oversight and Investigations 2007).	APHIS/CDC form 3 (Report of Theft, Loss, or Release of Select Agents and Toxins) was filed.	Investigation was ongoing. No further information available.

Final Supplemental Risk Assessment Report for the Boston University National Emerging Infectious Diseases Laboratories (NEIDL)

Location	Date	Research agent	Description	Results	Action
Mayo Clinic	May 17, 2007	<i>Coccidioides immitis</i>	Package shipped via commercial carrier was lost in transit (Subcommittee on Oversight and Investigations 2007).	APHIS/CDC form 3 (Report of Theft, Loss, or Release of Select Agents and Toxins) was filed.	Investigation was ongoing. No further information available.
The University of Iowa	May 10, 2007	<i>Francisella tularensis</i>	An employee potentially was exposed while working with the bacterium without using BSL-3 biocontainment precautions (Subcommittee on Oversight and Investigations 2007).	APHIS/CDC form 3 (Report of Theft, Loss, or Release of Select Agents and Toxins) was filed.	Investigation was ongoing. No further information available.
University of Kentucky, Lexington	May 9, 2007	<i>Yersinia pestis</i>	A potential exposure due to a leaking autoclave bag was reported (Subcommittee on Oversight and Investigations 2007).	APHIS/CDC form 3 (Report of Theft, Loss, or Release of Select Agents and Toxins) was filed.	No further information available.
University of North Carolina at Chapel Hill	May 7, 2007	Venezuelan equine encephalitis virus	Potential exposure: a dirty cage from infected mice was dropped inside the BSL-3 suite (Subcommittee on Oversight and Investigations 2007).	APHIS/CDC form 3 (Report of Theft, Loss, or Release of Select Agents and Toxins) was filed.	Investigation was ongoing. No further information available.
University of Texas Houston Health Science Center	May 7, 2007	<i>Bacillus anthracis</i>	Tube leakage occurred inside a centrifuge used for concentration of <i>Bacillus anthracis</i> cells (University of Texas 2007; Subcommittee on Oversight and Investigations 2007) .	Four people potentially were exposed to <i>Bacillus anthracis</i> .	Prophylaxis was refused. No infections resulted. Procedures were modified to require that centrifuge buckets be opened only within a BSC, and inspected and decontaminated after each use.

Final Supplemental Risk Assessment Report for the Boston University National Emerging Infectious Diseases Laboratories (NEIDL)

Location	Date	Research agent	Description	Results	Action
The University of North Carolina at Chapel Hill	May 3, 2007	SARS virus	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.
Centers for Disease Control and Prevention, Atlanta, Georgia Bldg 18	May 2007	<i>Coxiella burnetii</i>	Malfunction of the HVAC system pulled potentially contaminated air out of the BSL-3 biocontainment area and into a clean hallway (Subcommittee on Oversight and Investigations 2007).	Nine workers were tested for possible exposure to the bacterium and no infections were diagnosed.	The HVAC system was brought back into compliance. Duct tape was used to seal the door and remained in place as of June 2008. A self sealing door will be installed by April 2009.
University of Kentucky, Lexington	April 30, 2007	<i>Yersinia pestis</i>	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH 2010).	No further information was available.	No further information was available.
The University of Texas at San Antonio	April 20, 2007	<i>Francisella tularensis</i>	Personnel entered BSL-3 biocontainment area without wearing required protective equipment (Subcommittee on Oversight and Investigations 2007).	APHIS/CDC form 3 (Report of Theft, Loss, or Release of Select Agents and Toxins) was filed.	Investigation was ongoing. No further information available.
Lovelace Respiratory Research Institute, Albuquerque, New Mexico	April 11, 2007	<i>Yersinia pestis</i>	An experimentally infected monkey scratched the hand of a laboratory worker (Subcommittee on Oversight and Investigations 2007; The Associated Press 2009).	The skin was broken, potentially infecting the worker.	The worker received medical treatment including antibiotic therapy.

Final Supplemental Risk Assessment Report for the Boston University National Emerging Infectious Diseases Laboratories (NEIDL)

Location	Date	Research agent	Description	Results	Action
University of Virginia, Charlottesville	April 11, 2007	<i>Francisella tularensis</i>	Potential exposure from needle stick with syringe that had been used on mice inoculated with the bacterium (Subcommittee on Oversight and Investigations 2007).	APHIS/CDC form 3 (Report of Theft, Loss, or Release of Select Agents and Toxins) was filed.	Investigation was ongoing. No further information available.
Boston University, Massachusetts	March 20, 2007	<i>Francisella tularensis</i>	Autoclaved biological waste bags could not be removed from the autoclave due to a malfunctioning door. The lack of a service contract caused a 16 day delay in repair. The door was repaired on March 16 but the bags were not removed due to miscommunication (Office of General Services 2007).	The bags combusted in the autoclave sometime during the next 4 days and, upon opening the autoclave door, smoke alarms activated.	Investigation led to numerous recommendations to prevent similar occurrences in the future.
National Animal Disease Center, Ames, Iowa	January 11, 2007	<i>Brucella suis</i>	Potential exposure: an employee was bitten by a pig infected with <i>B. suis</i> (Subcommittee on Oversight and Investigations 2007).	The worker potentially was exposed to <i>Brucella</i> sp. APHIS/CDC form 3 (Report of Theft, Loss, or Release of Select Agents and Toxins) was filed.	No further information available.
National Animal Disease Center, Ames, Iowa	December 2006	<i>Brucella suis</i>	The Center reported leaks of contaminated waste three times in November and December. One worker cut his finger while preparing a pipe for repairs (The Associated Press 2009; Subcommittee on Oversight and Investigations 2007).	The worker potentially was exposed to <i>Brucella suis</i> . APHIS/CDC form 3 (Report of Theft, Loss, or Release of Select Agents and Toxins) was filed.	No further information available.

Final Supplemental Risk Assessment Report for the Boston University National Emerging Infectious Diseases Laboratories (NEIDL)

Location	Date	Research agent	Description	Results	Action
Texas A & M University, College Station	December 21, 2006	<i>Coxiella burnetii</i>	A mouse infected with <i>Coxiella burnetii</i> was found to be unaccounted for, and believed to be missing (Texas A&M University 2006, 2007).	A report to CDC was filed on Dec. 22.	The reason for the discrepancy is unknown.
Armed Forces Institute of Pathology, Washington, D.C.	November 7, 2006	<i>Bacillus anthracis</i>	Viable select agent (<i>B. anthracis</i>) was taken from BSL-3 biocontainment to BSL-2 biocontainment (Subcommittee on Oversight and Investigations 2007)	APHIS/CDC form 3 (Report of Theft, Loss, or Release of Select Agents and Toxins) was filed.	Investigation was ongoing. No further information available.
CDC, Division of Vector Borne Infectious Diseases, Fort Collins, Colorado	November 2006	<i>Yersinia pestis</i>	Two culture plates of the bacterium were dropped onto the floor; the lid came off one of the plates (Subcommittee on Oversight and Investigations 2007).	Concluded by CDC to have comprised an unlikely exposure. No further information available.	No further information available.
Lovelace Research Institute, Albuquerque, New Mexico	September 25, 2006	<i>Yersinia pestis</i>	An employee was bitten on the hand by an infected monkey. The skin appeared to be broken in two or three places. (Subcommittee on Oversight and Investigations 2007; The Associated Press 2009)	The worker was referred to a physician.	No further information available. Animals infected with <i>Y. pestis</i> are handled either at ABSL-2 or ABSL-3 depending on the circumstances of the experiment.
University of Virginia, Charlottesville	August 11, 2006	<i>Francisella tularensis</i>	Laboratory workers potentially were exposed to the bacterium when a tube of liquid culture in a shaking incubator appeared to be cracked (Subcommittee on Oversight and Investigations 2007).	APHIS/CDC form 3 (Report of Theft, Loss, or Release of Select Agents and Toxins) was filed.	No further information available.

Final Supplemental Risk Assessment Report for the Boston University National Emerging Infectious Diseases Laboratories (NEIDL)

Location	Date	Research agent	Description	Results	Action
University of Wisconsin – Madison	August 7, 2006	<i>Brucella melitensis</i>	Potential exposure to two people when the cap of a liquid culture containing the bacterium came off in a shaking incubator (Subcommittee on Oversight and Investigations 2007).	APHIS/CDC form 3 (Report of Theft, Loss, or Release of Select Agents and Toxins) was filed.	No further information available.
University of Kentucky, Lexington	May 25, 2006	<i>Yersinia pestis</i>	A laboratory worker potentially was exposed when opening an autoclave bag, containing the bacterium, that had not been decontaminated (Subcommittee on Oversight and Investigations 2007).	APHIS/CDC form 3 (Report of Theft, Loss, or Release of Select Agents and Toxins) was filed.	No further information available.
University of California-San Diego	May 16, 2006	<i>Brucella abortus</i>	Potential exposure: nine individuals worked with the bacterium without using BSL-3 biocontainment precautions (Subcommittee on Oversight and Investigations 2007).	APHIS/CDC form 3 (Report of Theft, Loss, or Release of Select Agents and Toxins) was filed.	Investigation was ongoing. No further information available.
University of Texas at Austin, Texas	April 12, 2006	Recombinant Influenza A H3N2 virus, containing genes from strain H5N1 (bird flu).	A centrifuge secondary container lid broke during centrifugation of virus, causing the rotor to become unbalanced. The researcher noted loss of volume in one viral tube and, suspecting viral leakage, undertook decontamination of centrifuge, centrifuge tube, work area, adjacent equipment and himself (University of Texas at Austin 2006).	A decision was made to treat the researcher empirically using Tamiflu. Secondary decontamination of lab room was undertaken the following day.	Responsible officials maintain that it is unclear whether a leakage of virus occurred. However, their records show that proper decontamination protocol was not followed for the suspected leak.

Final Supplemental Risk Assessment Report for the Boston University National Emerging Infectious Diseases Laboratories (NEIDL)

Location	Date	Research agent	Description	Results	Action
Texas A&M University, College Station	April, 2006	<i>Coxiella burnetii</i>	Previously undiagnosed exposures to <i>C. burnetii</i> are diagnosed in three laboratory workers by serologic testing (Centers for Disease Control and Prevention 2007, 2007). As many as ten workers might have been infected (further information is unavailable (Subcommittee on Oversight and Investigations 2007).	Responsible officials did not report these infections to federal authorities as required by federal law.	CDC issued a cease and desist order to TAMU on April 20, 2007 that was expanded on June 30 to include work with all Select Agents. Other serious violations were found during a site visit inspection in July 2007.
Texas A&M University, College Station, Texas	February, 2006	<i>Brucella melitensis</i>	A researcher contracted undiagnosed brucellosis during improper disinfection of aerosolization chamber. She later required prolonged administration of intravenous and oral antibiotics (Centers for Disease Control and Prevention 2007, 2007; Subcommittee on Oversight and Investigations 2007).	Responsible officials did not report this infection to federal authorities, as required by federal law, until April 11, 2007 in response to an inquiry from the Sunshine Project. (Texas A&M University 2007)	CDC issued a cease and desist order to TAMU on April 20, 2007 that was expanded on June 30 to include work with all Select Agents. Other serious violations were found during a site visit inspection in July 2007.
Walter Reed Army Institute of Research-Naval Medical Research Center, Silver Spring, Maryland	January 2, 2006	<i>Brucella abortus</i> , <i>B. melitensis</i> , <i>B. suis</i> , <i>Yersinia pestis</i>	A water supply line burst inside the laboratory causing a flood. Water samples were culture-negative (Subcommittee on Oversight and Investigations 2007).	APHIS/CDC form 3 (Report of Theft, Loss, or Release of Select Agents and Toxins) was filed.	No further information available.
Yeshiva University New York, New York	December 2005	<i>Mycobacterium tuberculosis</i>	Two lab workers converted to skin-test positive status, indicating an infection with <i>M. tuberculosis</i> . One of these worked in both the BSL-2 and BSL-3 labs, whereas the second worked only in the BSL-2 lab (Yeshiva University 2006).	Infections were sub-clinical. Prophylactic antibiotic treatment was administered.	All other workers were given TB skin tests. Neither of the two positive employees worked with the TB aerosolization animal chamber. No accidents had occurred in the labs.

Final Supplemental Risk Assessment Report for the Boston University National Emerging Infectious Diseases Laboratories (NEIDL)

Location	Date	Research agent	Description	Results	Action
Lawrence Livermore National Laboratory, Livermore, California	September, 2005	<i>Bacillus anthracis</i>	1,025 vials were shipped to a Palm Beach, Florida laboratory. Two of the vials were missing caps and a third vial had a loosened cap. A subsequent shipment to a second laboratory contained an incorrect number of vials (Van Derbeken 2007).	Two workers possibly were exposed to <i>Bacillus anthracis</i> .	The workers were prophylactically treated with antibiotics. LLNL was fined \$450,000 for the violations.
Public Health Research Institute, New Jersey Medical School, Newark	September, 2005	<i>Yersinia pestis</i>	Three mice experimentally infected with <i>Yersinia pestis</i> went missing from a biocontainment lab (ProMED mail 2005).	No one was infected by the mice. If they had escaped there would have been no public threat according to spokesmen.	An investigation by the CDC and the FBI ruled out theft and concluded that lab error, mouse cannibalism and unauthorized removal all are possibilities.
Medical University of Ohio	September 30, 2005	<i>Coccidioides immitis</i>	A student potentially was exposed to infectious aerosols from a broken vial inside a centrifuge (Subcommittee on Oversight and Investigations 2007; Medical University of Ohio 2004 and 2005,).	Medical evaluation was provided.	The BSL-3 facility director, who was in charge of the <i>C. immitis</i> research, resigned as Director and was replaced as Animal and Biosafety Protocol Principal Investigator and as advisor to the student (see 2004 <i>C. immitis</i> incident elsewhere in table).
University of Chicago Chicago, Illinois	July/August 2005	<i>Bacillus anthracis</i> (Subcommittee on Oversight and Investigations 2007)	Percutaneous trauma from an instrument (presumably a hypodermic syringe) that had been used on an infected animal. (University of Chicago IBC 2005)	Possible infection with select agent.	Medical personnel administered antibiotic prophylaxis. Laboratory procedures were reviewed and revised as needed.

Final Supplemental Risk Assessment Report for the Boston University National Emerging Infectious Diseases Laboratories (NEIDL)

Location	Date	Research agent	Description	Results	Action
Walter Reed Army Institute of Research-Naval Medical Research Center, Silver Spring, Maryland	May 2, 2005	<i>Yersinia pestis</i>	A laboratory worker sliced through two pair of gloves while handling a rat carcass infected with <i>Y. pestis</i> (Subcommittee on Oversight and Investigations 2007).	The worker was sent to a medical emergency room, which released her and asked her to return for a follow-up visit.	No further information available.
Walter Reed Army Institute of Research-Naval Medical Research Center, Silver Spring, Maryland	April 27, 2005	<i>Yersinia pestis</i>	A laboratory worker potentially was exposed by a culture plate that was dropped outside of the biological safety cabinet (Subcommittee on Oversight and Investigations 2007).	APHIS/CDC form 3 (Report of Theft, Loss, or Release of Select Agents and Toxins) was filed.	No further information available.
The University of North Carolina at Chapel Hill	March 19, 2005	<i>Mycobacterium tuberculosis</i> (recombinant)	An exhaust fan servicing two BSC and the general laboratory space failed. Audible alarms on the cabinets and air pressure monitors had been turned off (The University of North Carolina at Chapel Hill Institutional Biosafety Committee 2005).	Loss of primary and secondary biocontainment occurred.	A review of all BSL-3 laboratories was scheduled to identify renovation needs to ensure compliance with current design standards.
University of Iowa, Iowa City	March 11, 2005	<i>Francisella novicida</i>	Investigators conducted research on the bacterium without obtaining IBC approval (NIH 2010).	No further information available.	No further information available.
Medical University of Ohio, Ohio	December 8, 2004	<i>Coccidioides immitis</i>	An infection, possibly laboratory-acquired, was diagnosed. However, the employee previously resided in an endemic area and previously had worked with <i>C. immitis</i> in another laboratory. Therefore, it could not be proved when and how the infection began (Subcommittee	The infected employee was provided with medical treatment and re-assigned to other duties.	Safety policies were revised, video surveillance was installed, serologic monitoring of staff was reviewed (see 2005 <i>C. immitis</i> incident elsewhere in this table).

Final Supplemental Risk Assessment Report for the Boston University National Emerging Infectious Diseases Laboratories (NEIDL)

Location	Date	Research agent	Description	Results	Action
			on Oversight and Investigations 2007).		
Cincinnati, Ohio	October, 2004	Non-Contemporary Human Influenza (H2N2)	H2N2 from the 1957-1958 flu pandemic was accidentally distributed to 2,750 labs in the U.S., along with 3,747 labs in 18 different countries, by the College of American Pathologists (CAP). The error was discovered in March by a participating lab in Canada. This virus requires Enhanced BSL-3 biocontainment precautions (ProMED mail 2005; World Health Organization 2005; Center for Infectious Disease Research and Policy 2005).	CAP was requested by the U.S. government to notify all participating labs to destroy the virus, to investigate, and to report to national health authorities any respiratory infection in lab workers.	CAP sent out notifications on April 8 and 12, 2004. No infections were reported as of April 12, 2005.
University of North Carolina at Chapel Hill	September 14, 2004	Venezuelan equine encephalitis virus.	A laboratory worker was found to have a high rise in anti-VEE virus titer. No occupational exposure was confirmed (Subcommittee on Oversight and Investigations 2007).	APHIS/CDC form 3 (Report of Theft, Loss, or Release of Select Agents and Toxins) was filed.	No further information available
University of Illinois at Chicago	September, 2004	Not specified (redacted by IBC)	Both doors of the double door biocontainment entryway were propped open by laboratory staff while experiments were in progress (University of Illinois at Chicago 2003-2006).	Infectious materials were not being handled at the time.	Principal Investigator was counseled and warned. Staff was re-trained and tested.

Final Supplemental Risk Assessment Report for the Boston University National Emerging Infectious Diseases Laboratories (NEIDL)

Location	Date	Research agent	Description	Results	Action
National Institutes of Health Bethesda, Maryland	July/August, 2004	Various	A waste treatment tank steam valve failed, resulting in severe damage to the maximum biocontainment (BSL-4) laboratory that was being used as a BSL-3 lab at the time (SARS virus research). The NIH Occupational Safety and Health Branch previously had been informed about problems with the valve, but elected to defer repairs (National Institutes of Health 2004).	No exposures resulted.	The building was closed for repairs and renovation.
Oakland, California	June 11, 2004	<i>Bacillus anthracis</i>	Children's Hospital and Research Center Southern Research Institute sent live, rather than dead, anthrax samples to researchers in Oakland. The problem was detected after 49 of the 50 research mice quickly died after inoculation with the samples (Centers for Disease Control and Prevention 2005; Miller 2004).	Seven scientists were exposed, but not infected.	No human infections were reported.
Boston University, Massachusetts	May and September, 2004	<i>Francisella tularensis</i>	Researchers were working under BSL-2 biocontainment protocol with what was believed to be a non-infectious vaccine strain of the bacterium. Later, it was determined the bacterial culture also contained the infectious wild-type strain that requires BSL-3 biocontainment precautions. Investigation was unable to determine the cause for the mixed culture. (Anonymous 2005; Barry 2005; Lawler 2005; Dalton 2005).	Two researchers became infected with <i>Francisella tularensis</i> in May and were not correctly diagnosed until a third scientist became infected with the bacterium in September.	An investigation revealed that researchers had failed to follow proper BSL-2 biocontainment protocol, and that the University failed to identify work-related illness in laboratory staff and failed to immediately report suspicious work-related illness to local and state health departments. Biosafety policies and SOPs were revised accordingly. The

			newly acquired aerosolization chamber for experimental infection of animals (Washington Department of Labor and Industries 2004).	employed in such cases.	researchers were not fully familiar with proper operation of the device.
Columbus, Ohio	March 1, 2003	West Nile virus (WNV)	An improperly packaged shipment containing dry ice burst. The package was carrying frozen infected bird tissue ^b (New York Times 2003).	Workers at a Federal Express shipping building were potentially exposed to WNV.	Authorities characterized the risk of infection as low.
University of New Mexico, Albuquerque	2003	Redacted by IBC; likely was <i>Francisella tularensis</i>	Puncture of thumb with hypodermic needle harboring spores to be used in mouse infections (University of New Mexico IBC 2003) (Subcommittee on Oversight and Investigations 2007).	Worker received prophylactic treatment; no infection resulted.	It was proposed that alternative methods for mouse inoculation be considered.
Texas Tech University , Lubbock, Texas	January 2003	<i>Yersinia pestis</i>	30 vials of the bacterium were reported missing by the principal investigator (Leung 2003).	It was not possible to determine what became of the vials.	The investigator was dismissed from the University due to related matters.
United States	October, 2002	West Nile virus (WNV)	A microbiologist working under BSL-3 conditions suffered a finger puncture from a hypodermic needle harboring WNV being harvested from infected mouse brain (Centers for Disease Control and Prevention 2002).	The wound was cleansed and bandaged. Serologic testing showed evidence of acute WNV infection. Mild symptoms developed and resolved.	CDC determined that applicable handling and biocontainment protocols were followed.
United States	August, 2002	West Nile virus (WNV)	A microbiologist, working under BSL-2 conditions using a Class II BSC, lacerated a thumb with a scalpel during necropsy of a bird infected with WNV (Centers for Disease Control and Prevention 2002).	The superficial wound was cleansed and bandaged. Symptoms began 4 days post injury; medical attention was sought 7 days after injury. Infection was self-limiting and was confirmed by serologic	CDC recommends BSL-3 biocontainment measures for WNV. However, CDC does accept BSL-2 biocontainment facilities that incorporate certain elements of BSL-3 biocontainment measures.

Final Supplemental Risk Assessment Report for the Boston University National Emerging Infectious Diseases Laboratories (NEIDL)

Location	Date	Research agent	Description	Results	Action
				testing.	
U.S. Army Medical Research Institute of Infectious Diseases, Fort Detrick, Frederick, Maryland	April 20, 2002 April 1, 2002	<i>Bacillus anthracis</i>	A researcher tested positive for exposure to anthrax spores, which were also released into a locker room and adjacent hallway. U.S. Army officials reported evidence of a second accidental release of anthrax spores (Perez 2010).	No one was infected in either incident.	The first incident involved a virulent strain. Test samples connected with the second incident tested positive for the attenuated (vaccine) strain.
U.S. Army Medical Research Institute of Infectious Diseases, Fort Detrick, Frederick, Maryland	April 8, 2002	<i>Bacillus anthracis</i>	A researcher was infected by handling culture flasks that had leaked. Flasks were loosely capped and caps covered by paper, according to protocol. Bacteria had splashed onto the paper, dried, and become airborne upon handling (Rusnak, Boudreau, et al. 2004).	The exposed worker, previously vaccinated, was given a booster injection.	SOP was modified to require use of respiratory protection and filter-lined tightly screwed caps were adopted.
Texas (not otherwise specified)	March 2002	<i>Bacillus anthracis</i>	A lab worker used an incorrect disinfectant; failed to wear disposable gloves; and failed to cover a pre-existing skin defect (facial cut from shaving) (Centers for Disease Control and Prevention 2002).	Cutaneous anthrax resulted following skin exposure to a contaminated surface.	Patient was successfully treated using antibiotics. CDC reviewed proper biosafety measures with laboratory personnel.
Rocky Mountain Laboratory, Hamilton, Montana	April 2001	<i>Yersinia pestis</i>	A culture container of the bacterium fell off of the shaker during the night. Multiple laboratory workers potentially were exposed to the bacterium when discovered the next morning (Anonymous 2003; Johnson 2009).	The spill was decontaminated. No infections occurred.	No further information is available.

Final Supplemental Risk Assessment Report for the Boston University National Emerging Infectious Diseases Laboratories (NEIDL)

Location	Date	Research agent	Description	Results	Action
U.S. Army Medical Research Institute of Infectious Diseases, Fort Detrick, Frederick, Maryland	March 2000	<i>Burkholderia mallei</i>	A research microbiologist routinely failed to wear disposable gloves, and became infected. A primary care physician prescribed antibiotics without knowledge of the specific etiology (Srinivasan et al. 2001; Centers for Disease and Prevention 2000).	The patient improved but relapsed to a life-threatening condition. Culture revealed specific etiology and appropriate antibiotics resulted in cure.	A review of laboratory procedures was conducted but no further information is available.
Rocky Mountain Laboratories, Hamilton, Montana	2000	<i>Mycobacterium tuberculosis</i>	PPD skin test conversion was noted for a laboratory technician (Johnson 2009).	Source of infection suspected to be from samples sent by outside laboratories. Samples were to have been inactivated prior to receipt, but validation was uncertain.	Policies and SOPs for sampling handling were revised to assume that samples could be infectious. HVAC systems were upgraded. Air flow alarms were added to BSCs. Aerosol-containment centrifuge was added.
Rocky Mountain Laboratories, Hamilton, Montana	1998	<i>Chlamydia trachomatis</i>	Researcher was diagnosed with a lung infection soon after working with the pathogen (Johnson 2009).	Policies and SOPs for safe handling of the pathogen were found to be inadequate.	New requirements for PPE (respiratory protection), use of a BSC to open centrifuge rotors/buckets, and correct use of BSC were instituted.
Rocky Mountain Laboratories, Hamilton, Montana	1996	<i>Mycobacterium tuberculosis</i>	PPD skin test conversion was noted for a laboratory technician. Source of infection was uncertain (Johnson 2009).	No disease ensued.	Equipment and procedures were revised, including addition of aerosol-containment rotor, upgraded respiratory protective equipment, semiannual chest xrays.
Yale University, New Haven, Connecticut	November 6, 1995	Japanese encephalitis virus	Researchers failed to obtain IBC approval for their work. This was reported to NIH under reporting requirements of the NIH Guidelines for	No further information was available.	No further information was available.

			determine, by skin tests results, the frequency of probable laboratory-acquired tuberculosis.	laboratory-acquired infections (Kao et al. 1997).	recommendations for regular skin testing of laboratory employees, were re-emphasized.
Royal Oak, Michigan	May-September 1988	<i>Brucella melitensis</i>	A laboratory worker thawed a frozen vial of bacterial suspension and inoculated a plate culture on the open bench top instead of within a BSC (Staszkiwicz et al. 1991)	Eight laboratory workers became infected, one being asymptomatic. The outbreak was most consistent with airborne spread.	The 7 symptomatic workers were given antibiotic therapy. One relapsed and required alternative therapy. Enhancements to laboratory SOPs were recommended by the Department of Epidemiology and the Infectious Diseases Division.

Notes:

a Some incidents reported here pertain to BSL-2 facilities, either because they involved facilities at Boston University (and therefore are relevant to this RA) or because they involved Select Agent pathogens that can be handled using either BSL-2 or BSL-3 biocontainment precautions, depending on particular circumstances of the work involved.

b West Nile virus biocontainment recommendations are BSL-3 for dissection of field-collected dead birds. This incident is included here because of public concern surrounding transportation of samples to and from BSL-3 and BSL-4 biocontainment facilities.

c Sabia virus, currently a BSL-4 virus, was not assigned to a biosafety level at the time of the described incident.

D.2 Part II. The Johnson Reports

D.2.1 Biosafety at National Institute of Allergy and Infectious Disease: 1982–2003, Karl M. Johnson, M.D., October 15, 2003

The NIH and CDC first promulgated National Guidelines for safe work with a broad range of infectious organisms in 1980. Four levels of physical containment and work practices were designated for agents with different virulence for humans and relative risk of infection from aerosols induced by laboratory manipulation. BSL-3 is reserved for organisms that cause serious disease and that are known to be infectious via the respiratory route. Examples include *Mycobacterium tuberculosis* and West Nile virus. For such agents, all procedures must be carried out in biosafety cabinets (BSCs) fitted with high-efficiency filters (HEPA). Centrifuges require sealed rotors so that aerosols that ensue if a tube breaks during spinning runs will be contained until the rotor is opened under the BSC. Air in such laboratories is maintained at negative pressure relative to hallways and cannot be blended with air to other laboratories and offices to prevent potential infection to others in the building. More and more, such laboratories also have HEPA filters on laboratory room exhaust.

In addition to agents known to be aerosol transmitted, microbiological science continues to confront newly discovered viruses and bacteria for which aerosol infectiousness is uncertain. The NIAID has adopted a policy for such organisms that stipulates BSL-3 equipment and practices in BSL-2 laboratories with negative pressure. Work with the Human Immunodeficiency Virus (HIV) in the early 1980s led to adoption of that strategy for HIV and its close animal virus relatives, a policy that continues. Similar standards were initiated for work with hepatitis viruses at request of senior investigators, largely because new agents that cause hepatitis continue to emerge and little is known in early years regarding their infectiousness as aerosols.

This review is limited to work done during the past two decades by scientists at intramural laboratories of NIAID on the Bethesda campus, at a neighboring facility in Rockville, Maryland, and at the institute's Rocky Mountain Laboratories in Hamilton, Montana. Senior scientists were interviewed to ascertain agents studied, the variety of research programs that evolved over two decades, animals employed, if any, laboratory space, daily number of

workers in the laboratories, and specific histories of laboratory accidents and consequences. Problems with function of facilities also were solicited and recorded.

Independent records of reported laboratory accidents that might expose workers to infection were reviewed. During the past 21 years, all such accidents were to be reported quickly to the NIH Occupational Medical Service (OMS) for epidemiologic and medical evaluation as well as immediate prophylactic treatment if indicated. Invasive wounds in course of laboratory work and clinical care of persons with chronic HIV infection are of continuing concern. The OMS is now able to provide antiviral therapy within two hours of an accident on a 7-day/24-hour basis when circumstances indicate the need for therapy.

Intake records of all accidents on the NIH campus were initially paper documents. Copies were forwarded to the Occupational Safety and Health Branch (OSHB) in the Director's office for to follow up circumstances of an accident and for remedial action when indicated. In addition to such immediate reaction to accidents and facility emergencies, the OSHB has developed standardized protocols for periodic review of all laboratories for compliance with NIH safety practices. Laboratories at BSL-3 level are reviewed at 6-month intervals; all others are reviewed annually. For the past decade, all records are computerized and electronic copies go from OMS to OSHB instantly. Records for this 21-year interval were cross-checked for details by staff of both offices, together with specific scientist memory, in constructing the biosafety record for NIAID since 1982. Records for the Rocky Mountain Laboratories were reviewed with biosafety and scientific staff at that facility.

The detailed report is organized by Laboratory within the NIAID Division of Intramural Research. Agents, research agendas, containment levels, animal use, location and space for laboratories are presented in tabular form, together with histories of laboratory accidents and of facility problems that have affected work in those laboratories.

By any measure, the safety record at intramural NIAID laboratories, where work is done with the institute's most pathogenic agents, is outstanding. No agent has escaped from any laboratory to cause infection in adjacent civilian communities. Indeed, this record stretches to almost 70

years at RML where several agents now on the national Select List have been studied for decades. If one takes the number of 8-hour person days estimated by senior research staff during direct conversations and translates these into 2,000 person hours per year in exposure to microbial organisms, impressive numbers emerge as shown in the following table.

Personnel hours worked and outcomes of accidental exposures to infectious agents: intramural NIAID 1982–2003

Hours at risk			
	BENCH	Animal	Total
BSL-3	553,000	81,500	634,500
BSL-2/3 P	2,235,500	360,200	2,555,200
Total	2,788,500	441,700	3,189,700

Outcomes of accidental exposures			
	Clinical infections	Silent infections	Other exposures, no infections
BSL-3	1	2	9*
BSL-2/3 P	0	2	15
Total	1	4	24

* One HIV invasive accident treated with anti-retroviral drugs. No infection ensued.

One clinical infection without sequelae and four silent infections in more than 3 million hours of exposure is a remarkable record, especially when continuous exposure of personnel to fluids containing HIV virus over many years is a significant part of that record. Indeed, only a single instance was considered worthy of immediate prophylaxis for that agent and no infection occurred.

Biosafety in NIAID laboratories demands, and receives, constant vigilance. I recommend, however, better documentation of communication between the OSHB and NIH Division of Engineering Services. I was unable to find very many records of specific facility problems and their outcomes. It might be well to have a brief computerized form for registry of each event that requires action, together with follow-up reports that find their way to OSHB.

Another concern is design and function of air handling systems for BSL-3 laboratories. In both Building 10 and the new Building 50, BSC IIB cabinets directly ventilated externally are an essential part of the overall exhaust system that always must be greater than the input air. If room negative pressure diminishes, the BSCs also shut down, a poor condition if aerosols are being generated in course of the work. Much better would be to have IIA BSCs as workstations. These would continue to capture aerosols regardless of overall room negativity. Hoods would not have to run continuously and room failure would not also release aerosols into the laboratory. The Uninterrupted Power Supply installed in Building 50 was a prudent decision. I hope that these questions will be/have been considered in the current renovation of Twinbrook III as BSL-3 laboratory. Finally, it was a pleasure to receive frank, careful responses from all the scientists I approached. They willingly turned from their particular microbial environments to candidly discuss the history of their work from a safety perspective.

D.2.2 Biosafety at BSL-4, More than 20 Years Experience at Three Major Facilities, Karl M. Johnson, M.D., October 15, 2003

What Is BSL-4, And How Did We Get There?

Special containment for work with infectious microbes in the United States originated during World War II in response to intelligence that the German army had a program for development of biological, in addition to chemical weapons that had been used during the first World conflict. Temporary facilities were established in a suburb of Frederick, Maryland, later to become the permanent Fort Detrick. During the 1950s and 1960s several agents, most notably the bacteria that cause plague and anthrax and the rickettsial organism that causes so-called Q fever, were produced in large quantities and in forms with properties that make highly infectious tiny particles in the air. The term used was, and is, *weaponized*.

Infections among those working with these and other microbes were a recurrent problem. Under the inspired leadership of the late Dr. Arnold G. Wedum, recognized today throughout the world as the *Father of Biosafety*, Fort Detrick borrowed technology from the nuclear industry to prevent such infections, especially those induced by small aerosols that arose during the course of routine laboratory manipulations. Stainless steel cabinets (termed Class III) were constructed and assembled in continuous airtight lines. Each had at least one pair of sealed glove ports to

1 allow manipulation of hazardous materials in a sealed-off environment. Incubators,
2 microscopes, and doors leading directly to autoclaves and to animal cabinets were integral to
3 the cabinet line. The cabinets had a constant supply of filtered air and filtered exhaust fans to
4 remove any particles generated during the work sessions. Air pressure in cabinet lines was
5 negative to the laboratory room and the exhaust was filtered. The room itself also was negative
6 to the rest of the building, and exhaust air was filtered before release to the environment. Thus
7 workers, others in the building, and the outside community, were all protected against aerosol
8 infection from agents otherwise intended for battle.

9
10 During these same two decades, new organisms with serious human pathogenicity were
11 discovered in nature on several continents. Most of these, all of which were viruses, caused a
12 syndrome (with variations) known as acute viral hemorrhagic fever (VHF). There was no
13 specific treatment or vaccine available for any of them, except for the classical virus that causes
14 yellow fever. That disease is now recognized as the prototype of VHF. Even more disturbing
15 was the fact that aerosols were infectious for laboratory staff for most of these agents. Virology
16 at Fort Detrick quickly entered the Class III cabinet habitat.

17
18 The recognition of Marburg virus in 1967 propelled the CDC into this arena. That agency was
19 asked to help with field studies designed to uncover the African reservoir for the virus, and it
20 was decided that diagnostic reagents were needed. Visions of travelers returning from parts of
21 the globe endemic for HF agents became a chronic concern. A small Class III cabinet
22 laboratory was established in 1970 at the CDC. It had about 70 linear feet of cabinet line and a
23 staff of two persons who tested samples from wild animals for infection and made diagnostic
24 reagents for Marburg and other viruses of concern.

25
26 One year previously (1969), President Richard Nixon unilaterally terminated the national
27 program of offensive biowarfare at Fort Detrick. Most of the buildings were given over to the
28 National Cancer Institute. But the Army now expanded its defensive program. A new facility
29 was constructed that became the principal laboratory of the U. S. Army Medical Research
30 Institute for Infectious Diseases (USAMRIID). It opened in early 1971 with a mission to
31 develop technology for detection and identification of potential biowarfare agents, to

1 understand pathogenesis of the new VHF agents, to search for specific antiviral therapies, and
2 to develop vaccines.

3
4 Another VHF agent, Lassa virus, appeared in Nigeria in 1969. When Marburg virus attacked
5 two young Australians traveling in southern Africa in 1975, CDC Director David Sencer
6 decided that it was time to reinforce the nascent Special Pathogens Branch. A surplus large
7 trailer was obtained from NIH and outfitted as a new laboratory for work with VHF agents. It
8 had a Class III cabinet line. Space previously used as offices was redesigned as the first
9 completely suited laboratory and animal room. Workers wore special positive pressured suits
10 that could be hooked up to hoses from the ceiling that provided clean breathing air. Suits came
11 in several sizes and each worker was now able to have gloves that truly fit their hands. All work
12 was to be done in movable Class II laminar flow biosafety cabinets (BSC) that pulled air across
13 the work surface then filtered it, with about half recirculated in the box and the rest released
14 into the laboratory. Similar filtered enclosures were employed to house infected animals.
15 Laboratory exhaust air was twice filtered before release to the environment, all solid wastes
16 were autoclaved in double-door machines installed through a laboratory wall, and all liquid
17 wastes were pressure cooked at high temperature before cool down and released to sanitary
18 sewers. Workers leaving the laboratory stood in a chemical shower to decontaminate the *space*
19 suits before doffing scrub suits and showering before leaving the facility. Various alarms and
20 redundant systems were installed to ensure that power, continuous negative pressure, and
21 breathing air were always available in emergency. Needles and scalpels were used as
22 infrequently as possible and plastic ware replaced glass for almost all procedures.

23
24 The new CDC laboratory was opened at the end of 1978. Laboratories using positive pressure
25 suits also were ready at USAMRIID within months. These configurations allowed convenient
26 installation and maintenance of new instruments and other equipment that was being developed
27 for molecular work on viruses. The principles of biocontainment were (1) capture each small
28 particulate aerosol immediately where it is generated, (2) ensure that workers have functional
29 hands, life support, minimum exposure to invasive accidents, and ready access to the tools
30 required for research, and (3) make sure that systems for prevention of escape of aerosolized

1 viruses to the environment are redundant. The BSC cabinets were the primary containment, the
2 exhaust-filtered laboratories were the secondary, and even these were redundant.

3
4 By 1976, some leading molecular microbiologists became worried that new technology could
5 potentially create novel organisms that might conceivably become Andromeda strains. The
6 Director of the NIH ordered new guidelines for standards of microbiological safety for diverse
7 agents with known properties of human pathogenicity and modes of transmission, as well as for
8 newly discovered agents. The first edition of the NIH/CDC guidelines was published in 1980.
9 Most work could be done in ordinary laboratories at BioSafety Level 2 (BSL-2). Others that
10 cause more serious illness in humans, and/or for which no treatment is available, were assigned
11 to BSL-3. All work was to be done in Class II biosafety cabinets. Room air was to be under
12 negative pressure relative to hallways with no recirculation to other space in the building.

13
14 BSL-4 was reserved for VHF agents, certain tick-borne encephalitis viruses, and a simian
15 herpesvirus for which human infection is almost universally fatal. At the time, this meant
16 USAMRIID and CDC Special Pathogens, but authorities in South Africa were progressively
17 concerned about VHF on their continent. Ebola virus, an even more virulent relative of
18 Marburg, had been discovered in 1976. Rift Valley fever virus had caused its first-ever
19 epidemic that included hemorrhagic fever. Crimean-Congo virus was a new concern. To meet
20 these challenges, a BSL-4 laboratory, modeled on the Detrick and Atlanta prototypes, was
21 constructed outside Johannesburg and commissioned in 1980. It had both suit and cabinet-line
22 laboratories.

23
24 These three laboratories were virtually *the* sites of BSL-4 viral work during the past 22-30
25 years. With experience over time, most investigators chose to work primarily in the positive-
26 pressure suit environment. Indeed, at the end of the 1980s, CDC moved into new large
27 laboratories that were almost devoid of Class III cabinet lines. Moreover, the Johannesburg
28 laboratory, now part of the National Institute for Communicable Diseases (NICD), recently
29 removed its Class III cabinets to expand positive-pressure suit space. Only the British BSL-4
30 laboratories continue to depend on Class III cabinet line configurations. All recently constructed
31 Level 4 facilities in other countries, as well as those proposed for ours, are positive-pressure suit

1 labs. Accordingly, this review will not include biosafety at the Porton Down facility. We are
2 concerned principally with the track record of, and a risk analysis for, BSL-4 positive-pressure
3 suit laboratories.

4
5 That record is exemplary. Most individuals who begin work in BSL-4 suites are already
6 experienced microbiologists. Specific training for use of the positive-pressure suits and for safe
7 execution of all procedures is standard practice at all of the laboratories. In context of current
8 international concern regarding potential use of some of these viruses as weapons of terror,
9 access to the facilities and to individual laboratories is carefully controlled. At two of the
10 facilities in the United States individual security clearance is required to qualify for work at the
11 BSL-4 level. The viruses under study do not escape, neither by accident nor by covert design.
12 Reviews of individual facilities are summarized below.

13 14 **D.2.2.1 USAMRIID — 1972-2003**

15 **Persons Interviewed:**

16 Drs. Peter Jahrling, Chief Civilian Scientist; Gerald Eddy, retired Chief, Virology Division.

17 18 **Research Program:**

19 Pathogenesis of viral infections in animal models, including clinical and anatomical pathology.
20 Quantitative susceptibility of animals to aerosol infection by VHF pathogens. Development of
21 diagnostic assays and air sampling detectors. Molecular anatomy and genetics of agents. Drug
22 screening program in search of antiviral compounds. Development of live attenuated,
23 inactivated, and recombinant vaccines.

24 **Agents Studied:**

25 Machupo, Junin, Guanarito, Sabia, and Lassa arenaviruses; Marburg and Ebola; Rift Valley fever
26 and Crimean-Congo hemorrhagic fever viruses; Tick-Borne encephalitis virus. Yersinia pestis
27 and Bacillus anthracis.

Animals Used:

Mice, hamsters, guinea pigs, non-human primates, wild rodents, lambs,

Site:

Two buildings, Fort Detrick, Maryland. Total BSL-4 space: about 6500 sf. One third is animal space and suit/cabinet ratio of lab space is about 2:1.

Time Devoted in BSL-4 Space:

Approximately 343,980 hours. (6.5 persons/8 hour day x 1680 hours/year x 31.5 years).

Laboratory Accidents and Outcomes:

During early years when work was completely in cabinets, invasive accidents resulted in treatment with human plasma containing specific antibodies to virus in question, as well as confinement in an isolation suite in one building that was also set up as an intensive care facility in event that a worker became ill after accidental exposure to an agent. Two invasive accidents were of most concern:

November 1979. Accidental finger puncture with needle on a syringe loaded with Lassa virus. Ribavirin and immune plasma were given. (This was an experimental therapy for monkeys under development at the Institute.) No illness or serological evidence for infection occurred.

December 1982. During autopsy, a bone fragment of a monkey infected with Junin virus punctured a finger. Immune plasma was used and no clinical or subclinical infection ensued.

D.2.2.2 CDC SPECIAL PATHOGENS

Persons Interviewed: Senior Scientists and Author

Research Program:

Development of diagnostic methods and reagents for diagnosis of all BSL-4 agents. Pathogenesis of viral infections in animal models, including natural wild reservoirs. Molecular anatomy and genetics of VHF agents. Limited vaccine development work. Response to VHF epidemics in natural settings. Diagnosis, clinical pathology and virology, discovery of new agents.

Agents Studied:

Five arenaviruses, Marburg, Ebola, Crimean-Congo HF virus, Rift Valley fever virus, Nipah and Hendra viruses, Russian spring summer encephalitis and Tick-Borne encephalitis viruses, Omsk and Kyasanur Forest disease viruses, Hantavirus (animal work only).

Animals Employed:

Mice, hamsters, guinea pigs, non-human primates, rats, five wild rodent species for rodent-borne agents.

Sites:

Building A: 1970-78. About 70 linear feet of Cabinet line.

Building B: 1979-1989. About 900 sf with 30 ft cabinet line, 300 sf positive-pressure suit lab and 200 sf of positive-pressure suit animal space.

Building C: 1990-2003. About 5000 sf of which approximately 30% is animal space. Laboratory is entirely positive-pressure suit operated.

Time Devoted in BSL-4 Space:

120,560 hours.

Laboratory Accidents and Outcomes:

Animal bite; Hantavirus infected rodent, no infection.

Animal bite; animals being inoculated with Hantavirus. Pre-inoculation bite from rat.

Needle stick to worker prior to setting up an inoculum with mouse-adapted Ebola virus. No infection.

Autoclave door interlock failed and a load not autoclaved was opened, but not handled. No infections resulted.

Multiple events over the years of outer gloves or suits developing tears or holes detected during work. Such incidents are evaluated and followed up. No treatments were ever used and no infections resulted.

Facility/System Failures: None of note that caused interruption of work.

**D.2.2.3 National Institute for Communicable Diseases, Johannesburg, South
Africa, 1980-2003**

Person Interviewed:

Dr. Robert Swanepoel, BSL-4 Laboratory Director

Research Program:

Diagnostic reagents and support for all HF outbreaks in Africa and neighboring regions when requested; pathogenesis of infections in animals, especially candidate wild reservoir species; clinical virology; molecular biology of selected hemorrhagic fever viruses; field investigations of natural history of disease outbreaks; and seroepidemiology of infections in humans and animals.

Agents Studied:

Marburg and Ebola viruses, Rift Valley fever virus, Crimean-Congo HF virus, ten hantaviruses.

Animals Employed:

Mice, guinea pigs, rabbits, bats, tortoises, pigeons, snakes, roaches, spiders, frogs, millipedes, snails, 20 species of wild rodents, hares, hedgehogs, guinea fowl, chickens, etc. Much animal work was devoted to a search for wild reservoirs of Marburg and Ebola viruses.

Site:

Rietfontein, 4500 sf. Space divided into 721 sf positive-pressure suit lab and 222 sf similar animal holding room, plus cabinet lab of 999 sf (now defunct). Remaining 1443 sf devoted to change rooms, showers, and service corridors.

Time Devoted in BSL-4 Space:

Approximately 40,000 hours in nearly 23 years.

Laboratory Accidents and Outcomes:

Bat bite through double gloves. No infection.

Multiple other accidents. Those exposed are monitored closely for 21 days, during which time they are not permitted to leave town—as are all employees after their last day of work inside BSL-4 space. No infections recorded.

Facility/System Failures:

Only one that caused shutdown of operations. About 5 liters of highly concentrated Marburg virus was suddenly aerosolized when worker opened chamber to add a bit more fluid without closing the nitrogen pressure tank and bleeding off pressure. Laboratory was mopped for several hours with glutaraldehyde, and finally decontaminated with formaldehyde gas. No infection occurred in two *exposed* workers. There was no breach in BSL-4 containment, and no infections occurred in neighboring open-air monkey colonies on the campus. This was a maximum challenge to BSL-4 containment, and I am aware of no other event remotely comparable in terms of concentration and volume of a highly lethal virus.

D.2.3 Summary

No clinical infections occurred at three institutions during work with BSL-4 agents, mostly hemorrhagic fever viruses during the past 31 years. Almost half a million hours of laboratory (and field) exposure have been recorded, the majority of which was time spent in positive pressure suits. Nor have there been major defects or incidents in operation of the physical facilities. No escape of any agent with clinical consequences for neighboring communities occurred.

Invasive injuries were infrequent, eloquent testimony to the awareness of the dangers and the daily care observed by workers who volunteer for such duty. One laboratory inadvertently carried out a maximum aerosol challenge to BSL-4 containment with a highly pathogenic hemorrhagic fever virus. Virus did not escape the laboratory, nor was a worker infected.

The zero numerator of infections in these three laboratories and the huge denominator of exposure hours make it impossible to provide a number for ‘risk of infection’ to either laboratory workers or outside communities. Nevertheless, that number must be small. When the value of diagnosis, treatment, and control of deadly outbreaks of hemorrhagic fever over the past three

decades is added to this equation, risk/benefit clearly comes out in favor of continued operation of BSL-4 laboratories.

Indeed, considering new challenges posed to the world community by these agents, it is fair to conclude that more such facilities are needed. Better therapeutic agents are desperately needed. High priority also must go to the development of vaccines that can protect laboratory and hospital personnel in countries where natural epidemics occur, as well as first responders to intentional aerosol attack on any community.

D.2.4 Biosafety at BSL-4, Experience at Five Facilities, Karl M. Johnson, M.D., 15 May, 2009

This report contains information from an earlier version produced in October 2003 as part of the final EIS for the not yet commissioned NIH Integrated Research Facility at Rocky Mountain Laboratory, Hamilton, Montana. It adds additional experience at two of the laboratories reviewed initially, and includes new data from two smaller facilities in the United States. Summarized below are updated reviews of two national facilities since my initial report of July 2003. The third original laboratory (Johannesburg) has been closed for rehabilitation since 2003, so information on that facility is limited to the initial 2003 report. New data are included from laboratories at the University of Texas Medical Branch in Galveston, Texas, and the Southwest Foundation for Biological Research in San Antonio, Texas that began BSL-4 work in the present decade.

D.2.4.1 USAMRIID — 1972-2003 and July 2003-March 2009

Persons Interviewed:

Drs. Peter Jahrling, Chief Civilian Scientist, and Gerald Eddy, retired Chief, Virology Division. Col. Mark Kortepeter, MD, Deputy Commander for the recent interval.

Research Program:

Pathogenesis of viral infections in animal models, including clinical and anatomical pathology. Quantitative susceptibility of animals to aerosol infection by VHF pathogens. Development of diagnostic assays and air sampling detectors. Molecular anatomy and genetics of agents. Drug

1 screening program in search of anti-viral compounds. Development of live attenuated,
2 inactivated, and recombinant vaccines.

3
4 **Agents Studied:**

5 Machupo, Junin, Guanarito, Sabia, and Lassa arenaviruses; Marburg and Ebola; Rift Valley fever
6 (now at BSL-3 with worker vaccination) and Crimean-Congo hemorrhagic fever viruses; Tick-
7 Borne encephalitis virus; hantaviruses in animals; SARS coronavirus (animal work).

8
9 **Animals Employed:**

10 Mice, hamsters, guinea pigs, rabbits, non-human primates, wild rodents, lambs,

11
12 **Site:**

13 Two buildings, Fort Detrick, Maryland. Only one building since 1999. Total BSL-4 space: about
14 6500 sf, increasing to ~8,400 sf since 2003. One third is animal space and suit/cabinet ratio of
15 lab space is about 1:1.

16
17 **Total Hours Devoted 1972-2009: 462,168 in 36.25 yrs.**

18 Approximately 343,980 hours to July, 2003 (31.5 years).

19 Approximately 118,188 hours from July, 2003, almost 6 yrs.

20
21 **Laboratory Accidents and Outcomes:**

22 During early years when work was performed completely in cabinets, invasive accidents resulted
23 in treatment with human plasma containing specific antibodies to virus in question, as well as
24 confinement in an isolation suite in one building that was also set up as an intensive care facility
25 in event that a worker became ill after accidental exposure to an agent. Two invasive accidents
26 were of most concern:

27
28 November 1979. Accidental finger puncture with needle on a syringe loaded with Lassa virus.
29 Ribavirin and immune plasma were given. (This was an experimental therapy for monkeys under
30 development at the Institute.) No illness or serological evidence for infection occurred.

December 1982. During autopsy, a bone fragment of a monkey infected with Junin virus punctured a finger. Immune plasma was used and no clinical or subclinical infection ensued.

2004. A needle stick occurred inoculation of mice with mouse-adapted Zaire Ebola virus. Exposure was considered probable and risk of infection low to moderate. Worker was isolated at facility for 21 days and did not incur either infection or clinical disease. I consider this event the most potentially serious to have occurred since the original report in 2003.

Six other accidents resulted in daily temperature checks for 21 days, and in three instances, baseline laboratory measurements, but not worker isolation. None led to virus infection or disease:

2005. Ebola and Marburg viruses. Sharp object punctured boot but did not break skin.

2006. Lassa virus. Handled slides not properly irradiated, but acetone fixed.

2007. Marburg virus. Laceration on tip of third finger from contact with animal cage.

2007. Marburg virus. Separation of BSL-4 filter from suit.

2008. Marburg virus. V-shaped rip in suit. Positive airflow inside suit prevents contact with room air.

2008. Lassa virus. Brass connector on suit fell apart.

D.2.4.2 CDC SPECIAL PATHOGENS---1979-2003 and July 2003–March 2009

Persons Interviewed:

Senior Scientists and Author, to 2003.

Dr. Pierre Rollin, Acting Chief Special Pathogens, from 2003.

Research Program:

Development of diagnostic methods and reagents for diagnosis of all BSL-4 agents. Pathogenesis of viral infections in animal models, including natural wild reservoirs. Molecular anatomy and genetics of VHF agents. Limited vaccine development work. Response to VHF epidemics in natural settings. Diagnosis, clinical pathology and virology, discovery of new agents.

Agents Studied:

Six arenaviruses, Marburg, Ebola, Crimean-Congo HF virus, Rift Valley fever virus, Nipah and Hendra viruses, Russian spring summer encephalitis and Tick-Borne encephalitis viruses, Omsk and Kyasanur Forest disease viruses, hantavirus animal work.

Animals Employed:

Mice, hamsters, guinea pigs, non-human primates, rats, five wild rodent species for rodent-borne agents.

Sites:

Building A: 1979-1989. About 900 sf with 30 ft cabinet line, 300 sf positive-pressure suit lab and 200 sf of positive-pressure suit animal space.

Building B: 1990-2009. About 5000 sf of which approximately 30% is animal space. Laboratory is entirely positive-pressure suit operated.

Total Hours Devoted 1979-2009: 153,560 in ~30 years

120,560 hours, to July 2003

33,000 hours since July 2003

Laboratory Accidents and Outcomes:

Animal bite; Hantavirus infected rodent, no infection.

Animal bite; animals being inoculated with Hantavirus. Pre-inoculation bite from rat.

Needle stick to worker prior to setting up an inoculum with mouse-adapted Ebola virus. No infection.

Autoclave door interlock failed and a load not autoclaved was opened, but not handled. No infections resulted.

Multiple events over the years of outer gloves or suits developing tears or holes detected during work. Such incidents are evaluated and followed up. No treatments were ever used and no infections resulted. No events since 2003 except several more glove or suit tears, and disconnects of air supply or filters to suits. No isolation of worker or evidence of infection occurred.

Facility/System Failures: None of note that caused interruption of work.

D.2.4.3 NATIONAL INSTITUTE FOR COMMUNICABLE DISEASES, JOHANNESBURG, SOUTH AFRICA, 1980 -2003

Person Interviewed:

Dr. Robert Swanepoel, BSL-4 Laboratory Director

Research Program:

Diagnostic reagents and support for all HF outbreaks in Africa and neighboring regions when requested. Pathogenesis of infections in animals, especially candidate wild reservoir species, clinical virology. Molecular biology of selected hemorrhagic fever viruses. Field investigations of natural history of disease outbreaks. Seroepidemiology of infections in humans and animals.

Agents Studied:

Marburg and Ebola viruses, Rift Valley fever virus, Crimean-Congo HF virus, ten hantaviruses.

Animals Employed:

Mice, guinea pigs, rabbits, bats, tortoises, pigeons, snakes, roaches, spiders, frogs, millipedes, snails, 20 species of wild rodents, hares, hedgehogs, guinea fowl, chickens, etc. Much animal work was devoted to a search for wild reservoirs of Marburg and Ebola viruses.

Site: Laboratory opened in 1980.

Rietfontein, 4500 sf. Space divided into 721 sf positive-pressure suit lab and 222 sf similar animal holding room, plus cabinet lab of 999 sf (now defunct). Remaining 1443 sf devoted to change rooms, showers, and service corridors.

Total Hours Devoted 1980-2003: 40,000 in almost 23 years

Laboratory has been closed for major refitting since 2003.

Laboratory Accidents and Outcomes:

Bat bite through double gloves. No infection.

Multiple other accidents. Those exposed are monitored closely for 21 days, during which time they are not permitted to leave town—as are all employees after their last day of work inside BSL-4 space. No infections recorded.

Facility/System Failures:

Only one that caused shutdown of operations. About 5 liters of highly concentrated Marburg virus was suddenly aerosolized when worker opened chamber to add a bit more fluid without closing the nitrogen pressure tank and bleeding off pressure. Laboratory was mopped for several hours with glutaraldehyde, and finally decontaminated with formaldehyde gas. No infection occurred in two *exposed* workers. There was no breach in BSL-4 containment, and no infections occurred in neighboring open-air monkey colonies on the campus.

This was the maximum challenge to BSL-4 containment in the past 36+ years, and I am aware of no other event remotely comparable in terms of concentration and volume of a highly lethal virus released as infectious aerosol inside a BSL-4 laboratory. Pressure filtration to concentrate a BSL-4 agent has not been practiced since at any of the facilities covered in this report.

**D.2.4.4 SOUTHWEST FOUNDATION FOR BIOMEDICAL RESEARCH, SAN
ANTONIO, TEXAS, March 2000 - April 2009**

Persons Interviewed:

Dr. Jean Patterson, Chair, Dept. of Virology and Immunology

Dr. Ricardo Carrion Jr. Assistant scientist and BSL-4 lab manager

Research Program:

Pathogenesis of viral hemorrhagic fevers, especially in non-human primates. Development of animal models for studies of infection. Molecular analysis of viral infections and of natural and induced mutant viruses.

Agents Studied:

Marburg and Ebola viruses, Lassa virus and other pathogenic arenaviruses, CCHF virus, SARS virus, herpes B monkey virus.

Animals Employed:

Mice, hamsters, guinea pigs, rabbits, marmosets, cynomolgous monkeys.

Site: Opened in March 2000

Separate building on campus on outskirts of city. Approximately 1200sf suit space, which is one large room for both bench and animal work.

Total Hours Devoted: 11,650 in 9 years.

Laboratory Accidents and Outcomes:

One each glove and suit tear. Workers followed three weeks for fever. No infection.

Facility/System Failures:

Autoclave failure in 2004. Result was overnight flood of entire laboratory to depth of about one foot. Outer door held so no breach in containment occurred. Autoclaves never run after hours now and water supply is turned off before leaving lab each day.

D.2.4.5 UNIVERSITY OF TEXAS MEDICAL BRANCH, July 2004–April 2009

Persons Interviewed:

Ms. Dee Zimmerman, UTMB Biosafety Principal

Dr. Mike Holbrook, University BSL-4 Managing Scientist

Research Program:

Pathogenesis, experimental immunization, diagnostic development. Very active program for training and research among graduate students.

Agents Studied:

Ebola, Marburg, five arenaviruses, Nipah, Hendra, RSSE and Tick-Borne encephalitis, Rift Valley virus, CCHFV, Omsk, Kyasanur Forest Disease virus, Andes hantavirus, H5N1 influenza virus.

Animals Employed:

Mice, hamsters, wild small rodents, guinea pigs, non-human primates.

Site: Opened in July 2004

Small building attached to main Dept. Pathology facility on campus of medical school in residential Galveston, TX. Total 1900 sf, equally divided into bench and animal rooms.

Total Hours devoted: Approximately 25,000 in 5.5 years.

Laboratory Accidents and Outcomes: (All accidents and facility failures reported to CDC/SDAC and Community Liaison Committee).

January 2009. Scientist dropped plate containing Junin virus on floor. Spill was decontaminated and reported after proper procedures were performed. No virus escape, no personnel infection.

Facility/System Failures:

June 2005. Door from fumigation to buffer zone opened spontaneously about 2cm. The lab was shut down for annual maintenance at this time. Equipment and supplies had been surface decontaminated but not yet fumigated. Annual program was continued with full fumigation of all spaces and no untoward event occurred.

February 2008. Door from necropsy room into chemical shower inadvertently opened. Door had to be manually closed through chemical shower, breaking lab containment. Lab subsequently

1 completely decontaminated and repairs made to malfunctioning door closing device. No human
2 or environmental exposure.

4 **D.2.5 Summary**

5 This report summarizes almost 700,000 hours of worker exposure in BSL-4 laboratories operated
6 for a cumulated 103 facility years at five distinct sites in the United States and South Africa. Not
7 a single clinical infection occurred during this huge work experience over an interval of more
8 than 36 years, nor did any virulent BSL-4 virus escape to cause environmental injury anywhere.

9
10 Invasive injuries were infrequent, eloquent testimony to the awareness of the dangers and the
11 daily care observed by workers who volunteer for such duty. Nevertheless, such accidents and
12 potential exposures remain the greatest chronic cause of concern for all those managing such
13 research programs. But it is important to note that infections are almost certain to be recognized
14 even before actual clinical disease occurs and each organization herein cited has written plans
15 and dedicated clinical facilities and staff available for management of patients. This assures that
16 the environment and contiguous human community will not be impacted by any such event.

17
18 It also has been gratifying to learn that design, construction, and operation of each of these
19 facilities continue to demonstrate unquestioned competence of thought, and execution of sound
20 principles, use of robust materials, and careful, consistent management over a very long interval.
21 Accidents that release virus aerosols into laboratory space have been infrequent and generally of
22 small volume; but one inadvertent maximum aerosol challenge to BSL-4 containment with a
23 highly pathogenic hemorrhagic fever virus did occur several years ago. Virus did not escape the
24 laboratory, nor was a worker infected, further testimony to the soundness of design and
25 construction of both primary and secondary barriers to aerosol escape.

26
27 The zero numerator of infections among laboratorians and the huge denominator of exposure
28 hours make it impossible to provide a number for 'risk of infection' to either laboratory workers
29 or outside communities. Nevertheless, that number must be vanishingly small. When the value of
30 diagnosis, treatment, and control of deadly outbreaks of hemorrhagic fever over the past three

decades is added to this equation, risk/benefit clearly comes out in favor of continued operation of BSL-4 laboratories.

Indeed, considering new challenges posed to the world community by these agents, it is no surprise that several more BSL-4 facilities have been designed and/or constructed. Better therapeutic agents are desperately needed. High priority also must go to the development of vaccines that can protect laboratory and hospital personnel in countries where natural epidemics occur, as well as first responders to intentional aerosol attack on any community.

Karl M. Johnson, M.D.

E. Identification of Candidate Initiating Events

E.1 Methodology

This risk assessment (RA) selects several of the most common loss of biocontainment initiating events experienced at research laboratories and from those initiating events develops scenarios that account for National Emerging Infectious Disease Laboratory (NEIDL)-specific preventive and mitigative features. This appendix documents the process used to ensure that a broad range of potential initiating events were considered. Multiple sources were used to identify potential initiating events including prior analyses of the NEIDL, analyses of similar laboratories, and reports of incidents at similar facilities.

Prior analyses of the NEIDL reviewed to identify postulated events were the following:

- *Final Environmental Impact Statement, National Emerging Infectious Disease Laboratory, Boston, Massachusetts* (NEIDL FEIS) (NIH and DHHS 2005)
- *Draft Supplementary Risk Assessments and Site Suitability Analyses for the National Emerging Infectious Diseases Laboratory Boston University* (DSRASSA) (NIH 2007)

National Environmental Policy Act (NEPA) documents associated with the analysis of other biosafety laboratories were also reviewed. The review consisted of the following NEPA documents:

- *Final Revised EA for the Proposed Construction and Operation of a Biosafety Level 3 Facility at LLNL* (DOE 2008)
- *Final Environmental Impact Statement For the Galveston National Laboratory for Biodefense and Emerging Infectious Diseases Research Facility in Galveston, Texas* (NIH 2005a)
- *National Bio and Agro-Defense Facility Environmental Impact Statement* (DHS 2008)
- *Final Environmental Impact Statement, Construction and Operation of the New U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID) Facilities and Decommissioning and Demolition and/or Re-use of Existing USAMRIID Facilities at Fort Detrick, Maryland* (USAMRMC 2006)

- *Evaluation of the Health and Safety Risks of the New USAMRIID High Containment Facilities at Fort Detrick, Maryland* (National Research Council 2010)
- *Final Environmental Impact Statement (FEIS) on the Rocky Mountain Laboratories Integrated Research Facility in Hamilton, Montana* (NIH 2004)

Appendix D (Operating Experience at High Biocontainment Facilities) of this RA provides a listing of some of the relevant incidents that have occurred at other biosafety level (BSL)-3 and BSL-4 laboratories. Numerous other references associated with experiments related to potential laboratory incidents and reports of incidents at other laboratories were reviewed. Many of those incidents in the other sources are also included in Appendix D of this RA. The following documents also provided incidents and postulated accidents that were considered:

- *Subcommittee Hearings on SBIR: Advancing Medical Breakthroughs, Subcommittee On Investigations and Oversight Committee On Small Business United States House of Representatives One Hundred Tenth Congress Second Session* (House Hearing 2008)
- *Epidemiology of Laboratory-Associated Infections*, in *Biological Safety: Principles and Practices* (4th edition) (Harding and Byers 2006)
- *Microbial Aerosol Generation During Laboratory Accidents and Subsequent Risk Assessment* (Bennett and Parks 2006)
- *Risk of Occupationally Acquired Illnesses from Biological Threat Agents in Unvaccinated Laboratory Workers*, *Biosecurity and Bioterrorism: Biodefense Strategy, Practice, and Science*, Volume 2, Number 4, 2004 (Rusnak et al. 2004)
- *A Case of Ebola Virus Infection*, *British Medical Journal* (Emond 1977)
- NIH Office of Biotechnology Activities (OBA) Incident Reporting Template, NIH/NIAID (NIH 2010, NIH 2010a)
- *Fatal Laboratory-Acquired Infection with an Attenuated Yersinia pestis Strain - Chicago, Illinois, 2009*, Centers for Disease Control and Prevention, *Morbidity and Mortality Weekly Report*, February 25, 2011 (CDC 2011)
- *NIH Blue Ribbon Panel to Advise on the Risk Assessment for the BU National Emerging Infectious Disease Laboratories* (NIH 2009)
- *Mistakes Happen: Accidents and Security Breaches at Biocontainment Facilities*, The Council for Responsible Genetics. (CRG 2007).

- *Volume V: Anthrax at Sverdlovsk, 1979, U.S. Intelligence On The Deadliest Modern Outbreak* (Wampler and Blanton 2001)

In addition to a review of events identified from other sources, the NEIDL design and operating plans were reviewed to identify events that might be unique to NEIDL or that were not included in other sources.

E.2 Results

A review of the references listed in Section E.1 identified more than 300 incidents and postulated events, but some of them were not reported in sufficient detail to be of value for this analysis and were removed from further consideration. More than 300 incidents and postulated events were found to contain sufficient detail to be of value to this evaluation, and they are listed in Table E-1. Some events are reported in multiple references, but only one reference is listed for each entry. Some details of the scenario descriptions in the table are not fully reflective of NEIDL because of differences in biocontainment features. For example, some incidents occurred before modern biocontainment features and practices were implemented. Also, some incidents involved pathogens or toxins that might not be used in NEIDL. Differences in biocontainment features or pathogens do not mean an initiating event is not relevant for this analysis, only that the entire event sequences is not relevant. Because this review is focused solely on initiating events, incidents that differ from those possible at NEIDL were retained. Many of the incidents and postulated events have similar initiating events and were grouped accordingly. The last column of the table provides a general candidate grouping, and the grouping was carried forward for use in the initiating event selection process.

1

Table E-1. List of incidents and postulated events

#	Scenario description	Reference	Candidate event group
1	Two steer that had never been inoculated with FMDV were found to be infected. It was determined that FMDV probably came into the room through leaks in the walls, possibly in conjunction with a power failure that could have caused a difference in air pressure between the two rooms. Preventive maintenance of the rooms was conducted to prevent recurrence.	NEIDL RA Appendix D	Breach of containment (wall cracks or open doors)
2	Puncture of thumb through rubber glove while transferring Ebola from liver of infected guinea pig. Immediately removed glove and immersed thumb in hypochlorite solution. Became ill 6 days later.	Emond 1977	Puncture - needlestick
3	Foot and mouth disease virus escaped from the biocontainment facility. The suspected cause was construction work in progress. Cattle outside the laboratory facility were found to be infected with FMDV.	NEIDL RA Appendix D	Contamination outside laboratory
4	Accidental finger puncture with needle on a syringe loaded with Lassa virus. Ribavirin and immune plasma were given. (This was an experimental therapy for monkeys under development at the Institute.) No illness or serological evidence for infection occurred.	NEIDL RA Appendix D	Puncture - needlestick
5	Approximately 9 steer were found to have antibodies to type O FMDV, with no known reason for the unintentional exposure to FMDV. It was surmised that a laboratory worker accidentally could have transmitted the virus to the animals.	NEIDL RA Appendix D	Contamination inside laboratory
6	Four steer vaccinated with FMDV type O were found to be infected with Type A. The cause was not identified, but it was surmised that cross-contamination from another lab area was most likely.	NEIDL RA Appendix D	Contamination inside laboratory
7	During autopsy, a bone fragment of a monkey infected with Junin virus punctured a finger. Immune plasma was used, and no clinical or subclinical infection ensued.	NEIDL RA Appendix D	Puncture - during necropsy
8	Worker punctured finger on broken cover slip in HIV lab. No medical treatment. No infection occurred.	NIH 2004	Puncture - general
9	One heifer without previous inoculation or known exposure to FMDV was found to be infected with type O virus. Type O had been used in nearby rooms, and animals from those rooms had been euthanized and then transported through the corridor.	NEIDL RA Appendix D	Contamination inside laboratory
10	Main electrical power lines to one lab were knocked out by hurricane-force winds. Backup power was unavailable because of deferred repairs on an inoperable emergency transmission line. Disposal systems for virus-laden waste were inoperable for 32 hours, causing a backup of infectious sewage. No infections in animals were reported.	NEIDL RA Appendix D	Loss of power
11	A research virologist discovered a leaking vessel upon opening a sealed aerosol biocontainment centrifuge rotor. Improper PPE ^a was used, and the incident was not reported. Symptoms began 8 days afterward. Two days later, the infection was correctly diagnosed. Antiviral therapy cured the nearly fatal infection. No secondary infections were found.	NEIDL RA Appendix D	Centrifuge release

#	Scenario description	Reference	Candidate event group
12	Two people, working in separate ABSL-3 rooms, each became symptomatic and were diagnosed with influenza 1.5 days after collecting nasal specimens from experimentally infected pigs. Genetic analyses determined that the workers had become infected with the same virus used to infect the pigs. An investigation determined that an incorrect mask had been supplied to the workers for 1 day, and it is possible that error facilitated infection of personnel.	NEIDL RA Appendix D	Inadequate PPE use
13	A research microbiologist routinely failed to wear disposable gloves and became infected. A primary care physician prescribed antibiotics without knowledge of the specific etiology. The patient improved but relapsed to a life-threatening condition. Culture revealed specific etiology and appropriate antibiotics resulted in cure.	NEIDL RA Appendix D	Inadequate PPE use
14	An open container of <i>Y. pestis</i> fell off a shaker during the night. Several workers entered the lab next morning and the accident was immediately discovered. Surfaces were decontaminated and lab was closed until a new BSL-3 was available. No infections occurred.	NIH 2004	Spill/splash
15	PPD [purified protein derivative] skin test conversion. Employee treated with isoniazid. No clinical or radiological evidence for disease ensued. Employee worked in the Electronic Microscopy Branch (EMB) in Bldg 5. Work involved prep of samples submitted by outside collaborators in EM. Centrifugation done outside BSC. Although all samples supposedly were inactivated before receipt at RML, suspicion is that residual live bacteria were source of infection. Several modifications to equipment and procedures instituted: (1) A modern sealed centrifuge was installed, (2) bldg 5 air handling was upgraded, and alarms for BSC function were provided, (3) documented inactivation protocols and safety tests must now accompany materials received from outside sources, (4) all samples to be processed as though they still contain viable organisms.	NIH 2004	Pathogen not inactivated
16	Spores were found outside the laboratory.	NRC 2010	Contamination outside laboratory
17	A worker contracted glanders but did not disclose the type of work he was doing when he sought medical attention, which contributed to the delay in his diagnosis. He admitted to not wearing gloves. No other infections occurred.	NRC 2010	Inadequate PPE use
18	A lab worker used an incorrect disinfectant; failed to wear disposable gloves; and failed to cover a preexisting skin defect (facial cut from shaving). Cutaneous anthrax resulted following skin exposure to a contaminated surface. Patient was successfully treated using antibiotics	NEIDL RA Appendix D	Inadequate PPE use
19	A researcher tested positive for exposure to anthrax spores, which were also released into a locker room and adjacent hallway. No one was infected.	NEIDL RA Appendix D	Contamination inside laboratory

Final Supplementary Risk Assessment for the Boston University National Emerging Infectious Diseases Laboratories (NEIDL)

#	Scenario description	Reference	Candidate event group
20	A researcher was infected by handling culture flasks that had leaked. Flasks were loosely capped and caps covered by paper, according to protocol. Bacteria had splashed onto the paper, dried, and become airborne upon handling. The exposed worker, previously vaccinated, was given a booster injection. SOP was modified to require use of respiratory protection and filter-lined tightly screwed caps were adopted.	NEIDL RA Appendix D	Container leak/spill/open
21	U.S. Army officials reported evidence of a second accidental release of anthrax spores. No one was infected.	NEIDL RA Appendix D	Contamination inside laboratory
22	Researchers working with an infectious strain of <i>E. coli</i> did not use proper protection because they thought they were working with a harmless variety.	CRG 2007	Inadequate PPE use
23	A microbiologist, working under BSL-2 conditions using a Class II BSC, lacerated a thumb with a scalpel during necropsy of a bird infected with WNV. The superficial wound was cleansed and bandaged. Symptoms began 4 days later; medical attention was sought 7 days after injury. Infection was self-limiting and was confirmed by serologic testing.	NEIDL RA Appendix D	Puncture - during necropsy
24	A microbiologist working under BSL-3 conditions suffered a finger puncture from a hypodermic needle harboring WNV being harvested from infected mouse brain. The wound was cleansed and bandaged. Serologic testing showed evidence of acute WNV infection. Mild symptoms developed and resolved.	NEIDL RA Appendix D	Puncture - needlestick
25	Microbiologist contracted WNV after cutting finger with a scalpel used to perform a necropsy on a lab animal.	CRG 2007	Puncture - during necropsy
26	Puncture of thumb with hypodermic needle harboring spores to be used in mouse infections. Worker received prophylactic treatment; no infection resulted. It was proposed that alternative methods for mouse inoculation be considered.	NEIDL RA Appendix D	Puncture - needlestick
27	30 vials of the bacterium were reported missing by the principal investigator. It was not possible to determine the cause.	NEIDL RA Appendix D	Inadequate pathogen accountability
28	An improperly packaged shipment containing dry ice burst. The package was carrying frozen infected bird tissue. Workers at a FedEx shipping building were potentially exposed to WNV. Authorities characterized the risk of infection as low.	NEIDL RA Appendix D	Transportation mishap
29	Inventory discrepancy because of poor record keeping.	House Hearings 2008	Inadequate pathogen accountability
30	Inventory discrepancy because of poor record keeping.	House Hearings 2008	Inadequate pathogen accountability
31	Academic loss inventory discrepancy because of poor record keeping.	House Hearings 2008	Inadequate pathogen accountability
32	Loss in transit while importing select agents. Per FBI, the packages were discovered and incinerated in Belgium.	NEIDL RA Appendix D	Inadequate pathogen accountability
33	A graduate student working on a virulent recent New York strain of WNV became sick with fever and myalgia after making several passages of the new virus in Vero E6 cells also used to grow SARS-CoV. The student had minimal training and help from an institute technician. He was admitted to the hospital with a dry cough and signs of pulmonary inflammation. He was transferred to isolation and developed a moderately severe evolution of the disease. No secondary infections occurred. An investigation of the lab proved that the WNV was contaminated with the SARS-CoV.	NEIDL RA Appendix D	Contamination inside laboratory

#	Scenario description	Reference	Candidate event group
34	An investigation to assess security at Plum Island Animal Disease Center in the aftermath of the 2001 terrorist attacks is concluded. The report enumerated fundamental concerns that pathogens were not adequately secured from unauthorized access.	NEIDL RA Appendix D	Inadequate pathogen accountability
35	A 3-hour power failure undermined containment systems, leading workers to seal windows and doors with duct tape. All three backup generators failed.	CRG 2007	Loss of power
36	A researcher worked with <i>E. coli</i> outside a hood and failed to sufficiently sanitize the area afterward, thereby infecting a colleague.	CRG 2007	Contamination inside laboratory
37	A senior research scientist working with SARS in a Class III BSC cleaned up waste fluid that leaked from a tightly docked transfer chamber connected to the main cabinet. From the main cabinet, he sprayed alcohol into the chamber, waited 10 minutes, opened the chamber to spray more and finally physically cleaned it up. The next day he attended a SARS meeting in Singapore. Four days later, he noted fever and fatigue, which progressed into a dry cough and severe myalgia. He was hospitalized Dec. 16, and experienced moderately severe clinical illness. Contacts, especially plane passengers, were monitored or quarantined; no secondary infections occurred. An investigation of the lab revealed that SARS-CoV nucleic acid was on the handle of an alcohol bottle in the transfer chamber and on the light switch in the Class III cabinet.	NEIDL RA Appendix D	Contamination inside laboratory
38	Three researchers were infected with tuberculosis after the seal of a test chamber began leaking. They were not wearing respirators.	NEIDL RA Appendix D	Container leak/spill/open
39	A worker found three broken vials of the virus [Russian spring-summer encephalitis virus]. Wearing only a laboratory coat and gloves, the worker used tweezers to remove broken glass and then moved the materials to another container.	NEIDL RA Appendix D	Puncture - during necropsy
40	FMDV was accidentally transmitted to an animal clean room. Unintentional FMD infection occurred in animals in the nearby clean room as a result.	NEIDL RA Appendix D	Contamination inside laboratory
41	Autoclave failure in 2004. Result was overnight flooding of entire laboratory to depth of about one foot. Outer door held so no breach in containment occurred. Policy and SOP were amended to never allow autoclaves to be in operation after hours, and water supply is turned off before leaving lab each day. The clave door interlock failed, and a load not autoclaved was opened, but not handled. No infections resulted.	NEIDL RA Appendix D	Flooding inside laboratory
42	Unlikely exposure—vials labeled as RSSV, entity could not confirm viability.	House Hearings 2008	Inadequate pathogen accountability
43	A needle stick occurred during inoculation of mice. Exposure was considered probable and risk of infection low to moderate. Worker was isolated at facility for 21 days and did not incur either infection or clinical disease.	NEIDL RA Appendix D	Puncture - needlestick
44	Discrepancy in shipment—2 vials not shipped.	House Hearings 2008	Inadequate pathogen accountability
45	Discrepancy in shipment—shipped empty box.	House Hearings 2008	Inadequate pathogen accountability
46	Inventory discrepancy because of poor record keeping.	House Hearings 2008	Inadequate pathogen accountability

Final Supplementary Risk Assessment for the Boston University National Emerging Infectious Diseases Laboratories (NEIDL)

#	Scenario description	Reference	Candidate event group
47	A laboratory worker became feverish months after handling a culture of <i>Brucella</i> sp. Infection was confirmed in July by laboratory testing. It was determined that the employee had handled the culture without using proper biocontainment precautions. The employee eventually returned to work.	NEIDL RA Appendix D	Inadequate PPE use
48	Shipped inactivated toxin.	House Hearings 2008	Inadequate pathogen accountability
49	Researchers were working under BSL-2 biocontainment protocol with what was believed to be a noninfectious vaccine strain of the bacterium. Later, it was determined that the bacterial culture also contained the infectious wild-type strain that requires BSL-3 biocontainment precautions. The investigation was unable to determine the cause for the mixed culture. Two researchers became infected with <i>Francisella tularensis</i> in May and were not correctly diagnosed until a third scientist became infected with the bacterium in September. An investigation revealed that researchers had failed to follow proper BSL-2 biocontainment protocol and that the university failed to identify work-related illness in laboratory staff and failed to immediately report suspicious work-related illness to local and state health departments. Biosafety policies and SOPs were revised accordingly. The chief of Infectious Diseases was replaced.	NEIDL RA Appendix D	Inadequate pathogen accountability
50	Inventory discrepancy—individual failed to note that a vial had been destroyed.	House Hearings 2008	Inadequate pathogen accountability
51	No release occurred because the power outage occurred in the room after the laboratory workers performed necropsy of infected mice and culture tissue inside a BSC that never lost power.	House Hearings 2008	Loss of power
52	A researcher suffered an accidental finger stick with a hypodermic needle that contained the Zaire strain of Ebola virus. She was working with a guinea pig model of the infection. The researcher died several days later.	NEIDL RA Appendix D	Puncture - needlestick
53	Children's Hospital and Research Center Southern Research Institute sent live, rather than dead, anthrax samples to researchers in Oakland. The problem was detected after 49 of the 50 research mice quickly died after inoculation with the samples. Seven scientists were exposed but not infected.	NEIDL RA Appendix D	Inadequate pathogen accountability
54	Two cattle not involved in live virus research were observed with clinical signs of FMD. The FMDV was type O, but not the same type O strain involved in the July 19 incident. No specific explanation for the unintended infections was found. Following that and the July 19 incidents, new animal care protocols were instituted to restrict access to all animal rooms. Restrictions included clothing exchange, mandatory exit showers, and decontamination of all laboratory samples removed from the animal rooms.	NEIDL RA Appendix D	Inadequate pathogen accountability
55	A waste treatment tank steam valve failed, resulting in severe damage to the maximum biocontainment laboratory that was being used as a BSL-3 lab at the time (SARS virus research). The NIH Occupational Safety and Health Branch previously had been informed about problems with the valve but elected to defer repairs. No exposures resulted.	NEIDL RA Appendix D	Flooding inside laboratory
56	A laboratory worker became ill after working with a diagnostic culture that was later identified as a select agent.	House Hearings 2008	Inadequate pathogen accountability

#	Scenario description	Reference	Candidate event group
57	Both doors of the double-door biocontainment entryway were propped open by laboratory staff while experiments were in progress. Infectious materials were not being handled at the time.	NEIDL RA Appendix D	Breach of containment (wall cracks or open doors)
58	Unlikely exposure to biohazardous waste that contained sealed culture plates containing select agent.	House Hearings 2008	Contaminated waste
59	H2N2 from the 1957-1958 flu pandemic was accidentally distributed to 2,750 labs in the United States, along with 3,747 labs in 18 countries. The error was discovered in March by a participating lab in Canada. Sent out notifications on April 8 and 12, 2004. No infections were reported as of April 12, 2005.	NEIDL RA Appendix D	Inadequate pathogen accountability
60	Discrepancy in shipment—1 vial not shipped.	House Hearings 2008	Inadequate pathogen accountability
61	Discrepancy in shipment—1 vial not shipped.	House Hearings 2008	Inadequate pathogen accountability
62	Three laboratory workers became ill after working with the wild-type select agent instead of what they believed as the excluded select agent.	NEIDL RA Appendix D	Inadequate pathogen accountability
63	Discrepancy in shipment—1 vial not shipped.	House Hearings 2008	Inadequate pathogen accountability
64	A sharp object punctured a boot but did not break the skin.	NEIDL RA Appendix D	Puncture - general
65	Potential exposure—individuals were possibly exposed when culture fluid was discovered in the bottom of a centrifuge.	House Hearings 2008	Centrifuge release
66	Discrepancy in shipment—1 vial not shipped.	House Hearings 2008	Inadequate pathogen accountability
67	A fan servicing two BSCs and the general laboratory space failed. Audible alarms on the cabinets and air pressure monitors had been turned off. Loss of primary and secondary biocontainment occurred.	NEIDL RA Appendix D	HVAC ^b failure
68	Discrepancy in shipment—1 vial not shipped.	House Hearings 2008	Inadequate pathogen accountability
69	Discrepancy in shipment—3 vials not shipped.	House Hearings 2008	Inadequate pathogen accountability
70	Potential exposure—the BSC fan was turned off while work was being performed in the BSC, and a nasal swab confirmed exposure to an excluded strain.	House Hearings 2008	HVAC failure
71	A laboratory worker potentially was exposed by a culture plate that was dropped outside the BSC.	NEIDL RA Appendix D	Container leak/spill/open
72	A laboratory worker sliced through two pairs of gloves while handling a rat carcass infected with <i>Y. pestis</i> . The worker was sent to a medical emergency room, which released her and asked her to return for a follow-up visit.	NEIDL RA Appendix D	Puncture - during necropsy
73	Unlikely exposure—infected lung tissue spattered on disposable lab gown of a laboratory worker vaccinated against the select agent.	House Hearings 2008	Spill/splash
74	Discrepancy in shipment—1 vial not shipped.	House Hearings 2008	Inadequate pathogen accountability

#	Scenario description	Reference	Candidate event group
75	The door from a fumigation area to a buffer zone was opened spontaneously approximately 2cm. The lab was shut down for annual maintenance at the time. Equipment and supplies had been surface decontaminated but not yet fumigated. The annual maintenance program was continued with full fumigation of all spaces and no untoward event occurred.	NEIDL RA Appendix D	Breach of containment (wall cracks or open doors)
76	Percutaneous trauma from an instrument (presumably a hypodermic syringe) that had been used on an infected animal. Possible infection with select agent. Medical personnel administered antibiotic prophylaxis.	NEIDL RA Appendix D	Puncture - needlestick
77	Inventory discrepancy—entity could not account for three infected mice. It was determined that the mice were cannibalized by other mice in the cage or buried under the bedding and autoclaved by mistake by the animal care staff.	House Hearings 2008	Inadequate pathogen accountability
78	1,025 vials were shipped to a Palm Beach, Florida, laboratory. Two of the vials were missing caps, and a third vial had a loosened cap. A subsequent shipment to a second laboratory contained an incorrect number of vials. Two workers possibly were exposed to <i>Bacillus anthracis</i> . The workers were prophylactically treated with antibiotics	NEIDL RA Appendix D	Container leak/spill/open
79	Three mice experimentally infected with <i>Yersinia pestis</i> went missing from a biocontainment lab.	NEIDL RA Appendix D	Inadequate animal control
80	Potential exposure—two laboratory workers opened a package that contained leaking tubes on open bench.	House Hearings 2008	Container leak/spill/open
81	A student potentially was exposed to infectious aerosols from a broken vial inside a centrifuge. Medical evaluation was provided.	NEIDL RA Appendix D	Centrifuge release
82	Discrepancy in shipment—1 vial not shipped.	House Hearings 2008	Inadequate pathogen accountability
83	Discrepancy in shipment—1 vial not shipped.	House Hearings 2008	Inadequate pathogen accountability
84	Inventory discrepancy—Individual failed to note that a container with a select agent had been destroyed.	House Hearings 2008	Inadequate pathogen accountability
85	Inventory discrepancy—inventory reported as missing because of poor record keeping.	House Hearings 2008	Inadequate pathogen accountability
86	Inventory discrepancy—individual failed to note isolates that had been destroyed.	House Hearings 2008	Inadequate pathogen accountability
87	Potential exposure—laboratory workers opened a package that contained an unknown liquid.	House Hearings 2008	Inadequate PPE use
88	Discrepancy in shipment—incorrect number of vials was shipped by sender.	House Hearings 2008	Inadequate pathogen accountability
89	Handled slides not properly irradiated, but acetone fixed.	NEIDL RA Appendix D	Pathogen used with inappropriate biocontainment
90	Unlikely exposure—water supply broke inside lab causing a flood. Water samples were negative.	NEIDL RA Appendix D	Flooding inside laboratory

#	Scenario description	Reference	Candidate event group
91	A researcher contracted brucellosis during improper disinfection of aerosolization chamber. She later required prolonged administration of intravenous and oral antibiotics. Responsible officials did not report the infection to federal authorities, as required by federal law, until April 11, 2007, in response to an inquiry from the Sunshine Project. CDC issued a cease and desist order to TAMU on April 20, 2007, that was expanded on June 30 to include work with all select agents. Other serious violations were found during a site visit inspection in July 2007.	NEIDL RA Appendix D	Pathogen not inactivated
92	Unlikely exposure—entity confirmed no exposure to select agent when a plate containing a select agent dropped to the floor (the plate landed upside down).	House Hearings 2008	Container leak/spill/open
93	Potential exposure to select agent when a laboratory worker failed to turn on an autoclave.	House Hearings 2008	Pathogen not inactivated
94	Inventory discrepancy—inventory reported as missing because of poor record keeping.	House Hearings 2008	Inadequate pathogen accountability
95	Potential exposure—laboratory worker working with diagnostic sample on bench top.	House Hearings 2008	Pathogen used with inappropriate biocontainment
96	Potential exposure of five individuals when a broken vial containing a select agent was discovered in a centrifuge.	House Hearings 2008	Centrifuge release
97	Potential exposure—a laboratory worker working with diagnostic sample on bench top.	House Hearings 2008	Pathogen used with inappropriate biocontainment
98	A centrifuge secondary container lid broke during centrifugation of virus, causing the rotor to become unbalanced. The researcher noted loss of volume in one viral tube and, suspecting viral leakage, undertook decontamination of the centrifuge, centrifuge tube, work area, adjacent equipment and himself.	NEIDL RA Appendix D	Centrifuge release
99	Potential exposure—nine individuals worked with the bacterium without using BSL-3 biocontainment precautions. APHIS/CDC form 3 (Report of Theft, Loss, or Release of Select Agents and Toxins) was filed.	NEIDL RA Appendix D	Inadequate PPE use
100	A laboratory worker potentially was exposed when opening an autoclave bag containing the bacterium. The bag had not been decontaminated.	NEIDL RA Appendix D	Pathogen not inactivated
101	Potential exposure to two people when the cap of a liquid culture containing the bacterium came off in a shaking incubator.	NEIDL RA Appendix D	Container leak/spill/open
102	Laboratory workers potentially were exposed to the bacterium when a tube of liquid culture in a shaking incubator appeared to be cracked.	NEIDL RA Appendix D	Container leak/spill/open
103	Inventory discrepancy—during inventory reconciliation, entity determined that the vial was never filled.	House Hearings 2008	Inadequate pathogen accountability
104	Potential exposure—employee cut arm with box cutter in a room in which select agent work is performed.	House Hearings 2008	Puncture - general
105	Potential exposure—laboratory worker working with diagnostic sample on bench top.	House Hearings 2008	Pathogen used with inappropriate biocontainment
106	Potential exposure—lab worker was bitten by an infected guinea pig.	House Hearings 2008	Animal bite/scratch
107	An employee was bitten on the hand by an infected monkey. The skin appeared to be broken in two or three places.	NEIDL RA Appendix D	Animal bite/scratch

#	Scenario description	Reference	Candidate event group
108	Potential exposure—three laboratory workers exposed while sniffing plates that contained select agents.	House Hearings 2008	Inadequate PPE use
109	Two culture plates of the bacterium were dropped on the floor; the lid came off one of the plates. Concluded by CDC to have been an unlikely exposure.	NEIDL RA Appendix D	Container leak/spill/open
110	Viable select agent (<i>B. anthracis</i>) was taken from BSL-3 biocontainment to BSL-2 biocontainment.	NEIDL RA Appendix D	Pathogen used with inappropriate biocontainment
111	Unlikely exposure when a laboratory worker dropped two culture plates containing a select agent (lid intact or plate face down).	House Hearings 2008	Container leak/spill/open
112	Unlikely exposure when notebook was removed from a lab where work was performed on a select agent. The room had been decontaminated with vaporized hydrogen peroxide before removal.	House Hearings 2008	Contamination inside laboratory
113	Potential release due to leakage problem with collection tank that might have contained a select agent.	House Hearings 2008	Liquid waste leak
114	The center reported leaks of contaminated waste three times in November and December. One worker cut his finger while preparing a pipe for repairs. The worker potentially was exposed to <i>B. suis</i> . APHIS/CDC form 3 (Report of Theft, Loss, or Release of Select Agents and Toxins) was filed.	NEIDL RA Appendix D	Liquid waste leak
115	An inventory discrepancy was noted in the number of mice held for incineration after completing an experiment. Entity determined that the employee left a dead mouse inside a cage and that it was autoclaved and destroyed with the bedding.	House Hearings 2008	Inadequate animal control
116	Inventory discrepancy—an infected mouse was discovered missing. Entity determined that mouse was likely autoclaved with bedding material and disposed of.	House Hearings 2008	Inadequate animal control
117	Laceration on tip of third finger from contact with animal cage.	NEIDL RA Appendix D	Puncture - general
118	Separation of BSL-4 filter from suit.	NEIDL RA Appendix D	PPE failure (excluding PAPR ^c)
119	Potential exposure—an employee was bitten by a pig infected with <i>B. suis</i> . The worker potentially was exposed to <i>Brucella</i> sp.	NEIDL RA Appendix D	Animal bite/scratch
120	An experimentally infected monkey scratched the hand of a laboratory worker. The skin was broken, potentially infecting the worker. The worker received medical treatment including antibiotic therapy.	NEIDL RA Appendix D	Animal bite/scratch
121	Potential exposure from needlestick with a syringe that had been used on mice inoculated with the bacterium.	NEIDL RA Appendix D	Puncture - needlestick
122	Personnel entered BSL-3 biocontainment area without wearing required PPE.	NEIDL RA Appendix D	Inadequate PPE use
123	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules.	NEIDL RA Appendix D	Container leak/spill/open
124	Potential exposure—laboratory worker working with a diagnostic sample on bench top.	House Hearings 2008	Pathogen used with inappropriate biocontainment
125	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules.	NEIDL RA Appendix D	Container leak/spill/open

#	Scenario description	Reference	Candidate event group
126	Tube leakage occurred inside a centrifuge used for concentration of <i>B. anthracis</i> cells. Four people apparently were exposed to <i>B. anthracis</i> . Prophylaxis was refused. No infections resulted. Procedures were modified to require that centrifuge buckets be opened only within a BSC and inspected and decontaminated after each use.	NEIDL RA Appendix D	Centrifuge release
127	Potential exposure—dirty mouse cage dropped inside BSL-3 suite.	NEIDL RA Appendix D	Container leak/spill/open
128	A potential exposure due to a leaking autoclave bag was reported.	NEIDL RA Appendix D	Container leak/spill/open
129	An employee potentially was exposed while working with the bacterium without using BSL-3 biocontainment precautions.	NEIDL RA Appendix D	Inadequate PPE use
130	A package shipped via commercial carrier was lost in transit.	NEIDL RA Appendix D	Transportation mishap
131	Potential exposure when notebooks were removed from a lab where work was performed on a select agent.	House Hearings 2008	Contamination inside laboratory
132	Unlikely exposure—airflow found to be reversed for BSL-3 lab. During the period of reversed airflow, the laboratory was unoccupied.	House Hearings 2008	HVAC failure
133	Potential exposure—an employee was scratched by a broken rib during necropsy.	NEIDL RA Appendix D	Puncture - general
134	A lightning strike knocked out electricity to BSL-3 and unoccupied BSL-4 biocontainment areas. Circuit breakers that should have remained engaged were tripped. Backup generators failed to start. Negative directional airflow was not maintained. A battery-powered system provided power to lights and doors for 15–20 minutes.	NEIDL RA Appendix D	Loss of power
135	Potential exposure when notebooks were removed from a lab where work was performed on a select agent.	House Hearings 2008	Contamination inside laboratory
136	Potential exposure—environmental surveillance indicated presence of the bacterium on a freezer handle, light switch, and shoes in the hot side of the change room.	NEIDL RA Appendix D	Contamination inside laboratory
137	Potential exposure—needlestick with a syringe containing a select agent during necropsy.	NEIDL RA Appendix D	Puncture - needlestick
138	Loss—possible loss of a select agent.	House Hearings 2008	Inadequate pathogen accountability
139	Potential exposure—needlestick with a syringe containing a select agent.	House Hearings 2008	Puncture - needlestick
140	Potential exposure—an employee dropped a culture vessel of the bacterium, splashing it onto a lab coat, pants, and shoes.	NEIDL RA Appendix D	Container leak/spill/open
141	A needle stick with a syringe containing the virus was reported.	NEIDL RA Appendix D	Puncture - needlestick
142	An employee was bitten by a ferret inoculated with a virus.	NEIDL RA Appendix D	Animal bite/scratch
143	Potential exposure—an employee was bitten by a rat that had been inoculated with bacterium.	NEIDL RA Appendix D	Animal bite/scratch
144	Potential exposure—employee stabbed by broken capillary tube that might have been used for PCR testing for <i>B. anthracis</i> .	House Hearings 2008	Puncture - general
145	A needle stick with syringe containing the bacterium was reported.	NEIDL RA Appendix D	Puncture - needlestick
146	Three vials discovered missing during inspection of entity.	House Hearings 2008	Inadequate pathogen accountability

#	Scenario description	Reference	Candidate event group
147	An outbreak of foot and mouth disease was confirmed at a farm in Surrey, United Kingdom. It was concluded that the virus likely originated from the nearby Pirbright Research and manufacturing site, because of construction activities surrounding a leaking drainage pipe. A subsequent outbreak on September 12, 2007, was shown by genetic analysis to be unrelated to the Pirbright facilities.	NEIDL RA Appendix D	Contamination outside laboratory
148	A needlestick with syringe containing a virus was reported.	NEIDL RA Appendix D	Puncture - needlestick
149	Potential exposure to a select agent when a laboratory worker failed to turn on an autoclave.	House Hearings 2008	Pathogen not inactivated
150	A graduate student accidentally broke a flask containing <i>B. anthracis</i> cells.	NEIDL RA Appendix D	Container leak/spill/open
151	An employee potentially was exposed by being stuck by a broken scalpel blade.	NEIDL RA Appendix D	Puncture - general
152	V-shaped rip in suit. Positive airflow inside the suit prevented contact with room air.	NEIDL RA Appendix D	PPE failure (excluding PAPR)
153	Brass connector on a suit fell apart.	NEIDL RA Appendix D	PPE failure (excluding PAPR)
154	Door from necropsy room into chemical shower inadvertently opened. The door had to be manually closed through the chemical shower, breaking lab containment. The lab was then completely decontaminated and repairs made to the malfunctioning door-closing device. No human or environmental exposure occurred.	NEIDL RA Appendix D	Breach of containment (wall cracks or open doors)
155	A parenteral (injection) exposure was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules.	NEIDL RA Appendix D	Puncture - needlestick
156	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules.	NEIDL RA Appendix D	Container leak/spill/open
157	Inventory discrepancy because of poor record keeping.	House Hearings 2008	Inadequate pathogen accountability
158	A parenteral (injection) exposure was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules.	NEIDL RA Appendix D	Puncture - needlestick
159	A bird caused a Georgia Power transformer to fail, knocking out electricity to BSL-3 biocontainment areas. Backup generators failed to start, leaving the labs without main electrical power for 75 minutes. CDC personnel did not attempt to override and start the backup generators. Negative directional airflow was not maintained. No exposures or infections were reported. Backup failure was determined to be due to removal of two generators from service for upgrades. Their absence caused a power fluctuation when main power was lost, resulting in shutdown of the entire backup generator system.	NEIDL RA Appendix D	Loss of power
160	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules.	NEIDL RA Appendix D	Container leak/spill/open
161	A parenteral (injection) exposure was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules.	NEIDL RA Appendix D	Puncture - needlestick
162	Inventory discrepancy—entity determined that the vial was left unfilled from an initial spore stock preparation.	House Hearings 2008	Inadequate pathogen accountability

#	Scenario description	Reference	Candidate event group
163	An animal care technician was bitten by a macaque that was part of a vaccine study of tuberculosis.	NEIDL RA Appendix D	Animal bite/scratch
164	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules.	NEIDL RA Appendix D	Container leak/spill/open
165	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules.	NEIDL RA Appendix D	Container leak/spill/open
166	ULPA [ultra low penetration air] filters used in manufacturing aerosol biocontainment enclosures for flow cytometers were found to be faulty. Eight of 10 filters from 3 different lots tested at one site (Yale University, Jan. 22, 2009) failed to meet performance specifications. Seven of nine units tested at a second site (Duke University, Jan 26, 2009) failed to meet performance criteria.	NEIDL RA Appendix D	HVAC failure
167	Scientist dropped a plate containing the Junin virus on the floor. The spill was decontaminated and reported after proper procedures were performed. No virus escape, no personnel infection.	NEIDL RA Appendix D	Container leak/spill/open
168	An employee found four vials of material that were not in the institution's inventory. A complete inventory was performed resulting in more than 9,000 vials being discovered and reported.	NRC 2010	Inadequate pathogen accountability
169	A mouse escaped during weighing operations and ran up a worker's arm. Located the mouse more than 10 minutes later on left shoulder upon donning PPE. No bites or scratches were noticed. The mouse was determined to not be shedding virus (previously infected with MPXV).	NIH 2011b	Inadequate animal control
170	A laboratory researcher wearing protective gloves experienced a needlestick from a syringe suspected to contain the Ebola virus. The researcher was quarantined in Hamburg University Hospital for observation. Treatment included use of the experimental Feldmann vaccine. The worker did not become ill. No further information concerning potential seroconversion.	NEIDL RA Appendix D	Puncture - needlestick
171	Five technicians potentially were exposed to <i>B. anthracis</i> as a result of a protocol violation. Cultivated <i>B. anthracis</i> cells routinely are killed in the BSL-3 area and, after confirmation of death, are moved to the BSL-2 area. In this incident, the cells were moved to the BSL-2 area before confirmatory tests were completed. Test results later showed that the cells had not been killed. Cell suspensions had been handled within a BSC in the BSL-2 area, but as a precaution, all workers were given prophylactic antibiotic treatment.	NEIDL RA Appendix D	Pathogen used with inappropriate biocontainment
172	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules.	NEIDL RA Appendix D	Container leak/spill/open
173	Scientist working with weakened strain of <i>Y. Pestis</i> that was considered harmless to humans died of the plague. Subsequent investigation yielded that the scientist had hemosiderosis, which causes an excessive buildup of iron in the body.	CDC 2011	Inadequate PPE use
174	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules.	NEIDL RA Appendix D	Container leak/spill/open
175	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules.	NEIDL RA Appendix D	Container leak/spill/open

#	Scenario description	Reference	Candidate event group
176	A microbiology researcher at BU sought medical attention for laboratory-acquired bacteremia and meningitis. Molecular typing determined the infecting strain was the same strain he had been working with. Work with <i>N. meningitis</i> is conducted at BSL-2 using BSL-3 precautions (respiratory protection provided by Class II BSC). Intravenous antibiotics were administered, and the researcher recovered fully. University experts determined the researcher did not consistently wear appropriate PPE and did not consistently follow appropriate safe microbiological practices. It was surmised that the researcher touched his gloved hand to his face while working with the bacterium [Ad Hoc Committee, 2010 #16418]. All laboratory members repeated laboratory safety retraining and organism-specific retraining.	NEIDL RA Appendix D	Inadequate PPE use
177	A parenteral (injection) exposure was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules.	NEIDL RA Appendix D	Puncture - needlestick
178	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules.	NEIDL RA Appendix D	Container leak/spill/open
179	A parenteral (injection) exposure was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules.	NEIDL RA Appendix D	Puncture - needlestick
180	Mouse dander was found outside a mouse cage that was to be completely sealed to contain potentially infectious bioaerosols associated with infected mice. Seven researches were given antibiotic treatment as a precaution. Work in the BSL-3 lab was halted pending an evaluation.	NEIDL RA Appendix D	Contamination inside laboratory
181	A parenteral (injection) exposure was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules.	NEIDL RA Appendix D	Puncture - needlestick
182	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules.	NEIDL RA Appendix D	Container leak/spill/open
183	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules.	NEIDL RA Appendix D	Container leak/spill/open
184	The FBI closed its case files on the 2001 theft and deliberate release of <i>B. anthracis</i> spores, concluding that a USAMRIID scientist had acted alone. At least 22 people were infected and 5 were killed.	NEIDL RA Appendix D	Malevolent act
185	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules.	NEIDL RA Appendix D	Container leak/spill/open
186	A parenteral (injection) exposure was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules.	NEIDL RA Appendix D	Puncture - needlestick
187	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules.	NEIDL RA Appendix D	Container leak/spill/open
188	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules.	NEIDL RA Appendix D	Container leak/spill/open

#	Scenario description	Reference	Candidate event group
189	Worker observed an ear-tagged mouse while working in BSL-2 laboratory. The mouse had escaped from BSL-3 biocontainment. Worker caught the mouse and secured it in a flask. The mouse was euthanized inside a BSC. No injuries or illnesses were reported.	NIH 2011a	Inadequate animal control
190	Power failure of a PAPR unit occurred, apparently as a result of its on/off switch unknowingly being pressed against the hard surface of a chair back. Power loss was noticed after a few seconds; power was restored by pressing the on/off switch. Respiratory protection was not provided by the PAPR for a short time. Incident details would suggest no exposure occurred. The worker was evaluated by proper authorities. The manufacture was notified of the deficiency in equipment design. SOP was modified to require placement of PAPR motor unit to the side of the belt when using a chair.	NEIDL RA Appendix D	PAPR failure (addressed separately from other PPE)
191	The intake HEPA filter fell off the PAPR unit during use and could have been loose for a prolonged period. The worker reattached the filter and continued working. Respiratory protection was not provided by the PAPR for a short time. There is no mention of whether gloves were changed before handling the filter. Oseltamivir prophylaxis was initiated. Respiratory specimens collected at 24, 36, and 72 hours were negative (PCR). SOPs were modified to include verification of PAPR HEPA filter before entry into biocontainment areas.	NEIDL RA Appendix D	PAPR failure (addressed separately from other PPE)
192	Exhaust ventilation failed several times in 1980s. Staff was not immunized against <i>C. burnetti</i> , so repeated ventilation problems caused sealing of animal room from the laboratory area in 1988. Animal studies were dropped for several years. No infections occurred.	NIH 2004	HVAC failure
193	Two researchers contracted a virus in laboratories became infected after using defective gloves. Exposed through cuts on hands.	CRG 2007	PPE failure (excluding PAPR)
194	Over two dozen agents went missing at USAMRIID. Agents subject to removal without authorization.	CRG 2007	Inadequate pathogen accountability
195	LAIs at USAMRIID. Chikungunya was needlestick; vaccinia was cutaneous.	NRC 2010	Puncture - needlestick
196	Research fellow hospitalized for pneumonia in left lung. <i>C. trachomatis</i> isolated and specific sero-conversion was documented. Uneventful recovery with antibiotic therapy. Researcher did sonication of cultured organism in Class II BSC 2 days before onset of illness. Three large-scale purifications of organisms done during 3-week period before illness. The specific source of infection remained indeterminate. All procedures were reviewed with staff. Particle masks were adopted for all aerosol-generating procedures and for 30 minutes after completion of those. Centrifuge rotors were to be opened only in BSC, and both the instrument and rotors were to be examined for leaks after each run. Alcohol-soaked sponges were required to surround the sonication tube, and all worker faces were to stay outside the glass front of the BSC. No further infections have occurred since.	NIH 2004	Centrifuge release
197	A spill was reported to NIH under reporting requirements of the NIH Guidelines for Research Involving Recombinant DNA Molecules.	NEIDL RA Appendix D	Container leak/spill/open

#	Scenario description	Reference	Candidate event group
198	An experimentally infected mouse died and later could not be accounted for. Laboratory personnel suggested the dead mouse was overlooked, was in the cage during cage sterilization, and was discarded with the sterilized bedding.	NEIDL RA Appendix D	Inadequate animal control
199	A ferret experimentally infected with H5N1 virus bit a technician on the thumb. The worker was placed on home quarantine for 5 days and directed to wear a mask to protect others.	NEIDL RA Appendix D	Animal bite/scratch
200	Centrifuge was in the room, not in a BSC. A worker was working with one liter of <i>Coxiella burnetii</i> slurry. The worker placed 165 mL of slurry into each of six 250-mL polypropylene centrifuge tubes and failed to insert O-rings or tighten the screw-on centrifuge caps.	DOE 2008	Centrifuge release
201	A scientist working with Ebola virus in the maximum containment laboratory setting sustained a percutaneous (through broken skin) exposure to the virus but did not recognize the exposure and thus did not report it.	NIH 2007	Puncture - general
202	During the necropsy of an NHP [non-human primate] infected with the recombinant monkeypox, the virologist sustained an unrecognized percutaneous exposure due to a breach in the integrity of his glove.	NIH 2007	Puncture - general
203	A male virologist-physician removed what he believed to be a BSL-2 arenavirus (Tacaribe) from the laboratory freezer on a Monday morning and expanded the virus in a cell culture system. On Thursday, high-speed centrifugation of cell culture fluids in the laboratory resulted in some spillage through a crack in the seal of a centrifuge bottle. Two other workers were present in the lab but were remote from the centrifuge. The virologist notified his coworkers of the spill and he cleaned it up. Co-worker 1 chose to leave the lab and go on a coffee break, while co-worker 2 remained at the bench remote from the centrifuge during cleanup. The spill was not considered significant by any worker and was not reported.	NIH 2007	Centrifuge release
204	A lab chief who was studying the pathogenesis of the RVFV causing the epidemic in east Africa asked a post-doctoral fellow to package a vial of virus for transportation to a colleague's lab across the country. In doing so, the post-doc placed a small amount of dry ice in the infectious agent shipping container and sealed the container preparing it for courier pickup. The courier placed the package in the back of a step van and proceeded to drive down the street (Albany Street, Tyng Road, or Camp Sargent Road) toward a main road when he hit a pot hole. The jarring of the package caused the over-pressurized shipping container to explode frightening the driver who crashed the van into a utility pole by the road. RVFV was released into the interior of the van. Local emergency responders handle the incident; the driver, while shaken up and experiencing a mild concussion, was not otherwise injured.	NIH 2007	Transportation mishap
205	A 250-mL flask containing 50 mL of the spore suspension was dropped from a height of 0.75 m on the floor.	Bennet and Parks 2006	Container leak/spill/open
206	A universal bottle containing 15 mL of the standard spore suspension was slowly spilled from a height of 0.9 m to simulate the effect of a spill on a bench running on to the laboratory floor.	Bennet and Parks 2006	Container leak/spill/open
207	Dropped three 50-mL bottles, each containing 15 mL of culture. Three bottles in a rack were dropped 1 m to the floor.	Bennet and Parks 2006	Container leak/spill/open

#	Scenario description	Reference	Candidate event group
208	A peristaltic pump was primed from a 50-mL reservoir of the spore suspension. The outlet tubing was then blocked and both the pump and samplers were operated. The increase in back-pressure caused a connector in the outlet tubing to become detached and the suspension was sprayed at the wall of the room.	Bennet and Parks 2006	Spill/splash
209	Four fungal plates with extensive growth of <i>Penicillium</i> sp. and heavy surface growth of spores were dropped on the laboratory floor.	Bennet and Parks 2006	Container leak/spill/open
210	An outdated Sorvall GSA rotor had its 'O' ring seal removed and had 10 mL of a 5E9 spore suspension gently pipetted into the rotor chamber. The rotor was accelerated to 4,000 rev/min in a RC5B centrifuge, braked, and the centrifuge lid opened while the air samplers were operated.	Bennet and Parks 2006	Centrifuge release
211	A set of sealed rectangular centrifuge buckets with screw-down lids was tested to find out if they generated microbial aerosols. It was found that the buckets were contained when the bucket seal was in place and applied with silicone grease supplied by the manufacturer. However, aerosols were generated when the seal was not in place. In experiment 9a, the bucket contained two overfilled Falcon centrifuge tubes containing a 9E9 spore/mL suspension and in experiment 9b a 50-mL spill of the same suspension was rolled around inside the bucket so that some of the fluid would rest on the inside walls of the lid before centrifugation.	Bennet and Parks 2006	Centrifuge release
212	Four plates contained 3-day-old colonies of <i>B. atrophaeus</i> , which were slightly dry, were dropped on the laboratory floor.	Bennet and Parks 2006	Container leak/spill/open
213	A 1-liter flask containing 200 mL of a 9E8 spore/mL suspension was placed on the rack of a Gallenkamp chest-shaking incubator in a totally unsecured position. The shaker was then operated at 100 rev/min, and the samplers were switched on. The flask smashed almost immediately, and the shaker lid was opened 30 seconds after the broken glass pieces had settled.	Bennet and Parks 2006	Centrifuge release
214	A spill of 18 mL of <i>B. atrophaeus</i> spore suspension was created by spilling the contents of a universal container from about 0.8 m. This is a similar scenario to experiment 4, which consisted of a 15-mL spill. The tests were carried out with a 9.1E5 (a), 9.1E6 (b), 9.1E7 (c) and 9.1E8 (d) spore/mL suspension.	Bennet and Parks 2006	Container leak/spill/open
215	A GSA rotor was overfilled with 10 mL of spore suspension as in experiment 8. The centrifuge was accelerated up to 4,700 rev/min within a minute, braked, and the lid opened while the samplers were operated for a 10-minute period. This experiment was carried out with the four different suspensions used in experiment 12.	Bennet and Parks 2006	Centrifuge release
216	Procedure violation creates sharps (scissors, scalpels, sharp lab surfaces, other glass items including reagent bottles, vials, blood tubes, capillary tubes, microscope slides).	Tetra Tech 2009	Puncture - during necropsy
217	Equipment malfunction creates sharps (scissors, scalpels, sharp lab surfaces, other glass items including reagent bottles, vials, blood tubes, capillary tubes, microscope slides).	Tetra Tech 2009	Puncture - during necropsy
218	Procedure violation results in ingestion from inadvertent contact between mucous membranes and contaminated surfaces or hands.	Tetra Tech 2009	Hand to mouth/eyes/nose contamination
219	A laboratory equipment malfunction results in ingestion from inadvertent contact between mucous membranes and contaminated surfaces or hands.	Tetra Tech 2009	Hand to mouth/eyes/nose contamination

#	Scenario description	Reference	Candidate event group
220	Procedure violation results in aerosol production and inhalation (centrifuge, grinding, homogenizing, blending, vigorous shaking or mixing, sonic disruption, cell separator, etc.).	Tetra Tech 2009	Centrifuge release
221	Equipment malfunction results in aerosol production and inhalation (centrifuge, grinding, homogenizing, blending, vigorous shaking or mixing, sonic disruption, cell separator, etc.).	Tetra Tech 2009	Centrifuge release
222	Procedure violation results in aerosol production and inhalation from opening pressurized containers.	Tetra Tech 2009	Centrifuge release
223	Laboratory equipment malfunction results in aerosol production and inhalation from opening pressurized containers.	Tetra Tech 2009	Container leak/spill/open
224	Animal handling procedure violation results in bites, scratches.	Tetra Tech 2009	Animal bite/scratch
225	Animal handling equipment malfunction results in bites, scratches.	Tetra Tech 2009	Animal bite/scratch
226	Animal handling procedure violation results in needlesticks.	Tetra Tech 2009	Puncture - needlestick
227	Animal handling equipment malfunction results in needlesticks.	Tetra Tech 2009	Puncture - during necropsy
228	Animal handling procedure violation results in ingestion from inadvertent contact between mucous membranes and contaminated surfaces or hands.	Tetra Tech 2009	Hand to mouth/eyes/nose contamination
229	Animal handling equipment malfunction results in ingestion from inadvertent contact between mucous membranes and contaminated surfaces or hands.	Tetra Tech 2009	Hand to mouth/eyes/nose contamination
230	Animal handling procedure violation results in aerosol production and inhalation (inoculating animals intranasally, harvesting infected tissue from animals).	Tetra Tech 2009	Animal-related aerosol
231	Animal handling equipment malfunction results in aerosol production and inhalation (inoculating animals intranasal, harvesting infected tissue from animals).	Tetra Tech 2009	Animal-related aerosol
232	Animal handling or insectary procedure violation or equipment malfunction results in escaped animal or arthropod.	Tetra Tech 2009	Animal escape or pathogen release to environment
233	Procedure violation results in incomplete sterilization/ disinfection of solid waste.	Tetra Tech 2009	Contaminated waste
234	Procedure violation results in incomplete sterilization/ disinfection of solid waste.	Tetra Tech 2009	Contaminated waste
235	Procedure violation results in incomplete sterilization/disinfection of liquid waste	Tetra Tech 2009	Contaminated waste
236	Equipment malfunction results in incomplete sterilization/ disinfection of liquid waste; this also includes inadvertent sewage vessel blowdown or overpressure event.	Tetra Tech 2009	Contaminated waste
237	Thermal treatment tanks for accumulated liquid waste fail before treatment in a seismic event; untreated liquid waste enters public system.	Tetra Tech 2009	NPH ^d - earthquake
238	Loss of power and failure of emergency backup causes loss of negative pressure in potentially contaminated areas.	Tetra Tech 2009	Loss of power
239	Severe low-pressure front (hurricane) causes reversal of air flow.	Tetra Tech 2009	NPH - strong wind
240	Incomplete chemical disinfection of HEPA filter plenum during maintenance results in pathogen leak.	Tetra Tech 2009	Pathogen not inactivated

#	Scenario description	Reference	Candidate event group
241	Equipment malfunction during HEPA filter change out during maintenance results in pathogen leak.	Tetra Tech 2009	HVAC failure
242	Seismic event causes loss of power and failure of HEPA filter plenums.	Tetra Tech 2009	NPH - earthquake
243	Loss of power and failure of emergency backup causes loss of negativity in BSL-4 spaces and door seals fail.	Tetra Tech 2009	Loss of power
244	Laboratory supply and exhaust registers both in the ceiling produces incomplete room ventilation and stagnant areas in laboratory; contamination of PPE and LAI results.	Tetra Tech 2009	HVAC failure
245	Re-entrainment of facility exhaust into intake plenum for office spaces and other unfiltered spaces.	Tetra Tech 2009	NPH - strong wind
246	Facility ventilation dP [differential pressure] control based on supply-side parameters fails to react to exhaust damper closing or their failure to open after being closed; this causes facility pressurization and possible loss of containment.	Tetra Tech 2009	HVAC failure
247	Suit breach from crush, pinch, puncture (air-lock doors, quick disconnects, movement of equipment, suit puncture or tear).	Tetra Tech 2009	PPE failure (excluding PAPR)
248	Suit breach from procedural error—inadequate pre-use inspection fails to locate breach in suit.	Tetra Tech 2009	PPE failure (excluding PAPR)
249	Personnel error leads to suit breach from heat/cold, dehydration from physical exertion and dry air supply, hypothermia and hot surfaces from autoclaves and other surfaces, hypoxia (air flow restriction).	Tetra Tech 2009	PPE failure (excluding PAPR)
250	Personnel error leads to suit breach from physical and sensory isolation, claustrophobia.	Tetra Tech 2009	PPE failure (excluding PAPR)
251	Procedure violation during specimen transport inside facility results in spill (slip, trip, fall, drop, jostle, jar, impact).	Tetra Tech 2009	Container leak/spill/open
252	Equipment malfunction during specimen transport/storage inside facility results in spill (slip, trip, fall, drop, jostle, jar, impact) poor or inadequate packaging/transport system, or failure of storage environment.	Tetra Tech 2009	Container leak/spill/open
253	Procedure violation during specimen transport inside facility results in spill (slip, trip, fall, drop, jostle, jar, impact).	Tetra Tech 2009	Container leak/spill/open
254	Equipment malfunction during specimen transport/storage inside facility results in spill (slip, trip, fall, drop, jostle, jar, impact) poor or inadequate packaging/transport system, or failure of storage environment.	Tetra Tech 2009	Container leak/spill/open
255	Procedure violation during specimen transport inside facility results in spill (slip, trip, fall, drop, jostle, jar, impact).	Tetra Tech 2009	Container leak/spill/open
256	Equipment malfunction during specimen transport/storage inside facility results in spill (slip, trip, fall, drop, jostle, jar, impact) poor or inadequate packaging/transport system, or failure of storage environment.	Tetra Tech 2009	Container leak/spill/open
257	Internal flooding from failure of process piping, fire suppression piping, or similar system.	Tetra Tech 2009	Flooding inside laboratory
258	Procedure violation when handling, processing, sterilizing mixed rad/bio-waste/equipment (solid or liquid) resulting in incomplete pathogen destruction.	Tetra Tech 2009	Pathogen not inactivated
259	Equipment malfunction when handling, processing, sterilizing mixed rad/bio waste/equipment (solid or liquid) resulting in incomplete pathogen destruction.	Tetra Tech 2009	Pathogen not inactivated

#	Scenario description	Reference	Candidate event group
260	Procedure violation using radioactive materials creates mechanism for contamination, aerosol generation, ingestion, inoculation.	Tetra Tech 2009	Pathogen not inactivated
261	Procedure violation during necropsy results in LAI because of cut/puncture, ingestion, or inhalation.	Tetra Tech 2009	Puncture - during necropsy
262	Equipment malfunction during necropsy results in LAI because of cut/puncture, ingestion, or inhalation.	Tetra Tech 2009	Puncture - during necropsy
263	Deflagration of natural gas or other flammable process gas leak causing BSC failure, laboratory, or main structure failure fire might result; personnel contamination, room contamination, ventilation system leakage around, through HEPA.	Tetra Tech 2009	Deflagration
264	Overpressure from blockage in steam line leading to autoclave failure or process steam line failure, personnel contamination, room contamination, ventilation system leakage around, through HEPA filters, environmental contamination.	Tetra Tech 2009	Contamination inside laboratory
265	Deflagration of formaldehyde or other flammable agent during laboratory disinfection or sanitization, personnel contamination, room contamination, structural failure, loss of containment, ventilation system leakage around, through HEPA filters.	Tetra Tech 2009	Deflagration
266	Deflagration of unanticipated chemical reaction leading to BSC failure, personnel contamination, room contamination, ventilation system leakage around, through HEPA filters.	Tetra Tech 2009	Deflagration
267	Deflagration/explosion and fire external to the facility involving the supply of diesel, fuel oil, gasoline leading to facility breach, personnel contamination, room contamination, possible environmental contamination.	Tetra Tech 2009	Deflagration
268	Fire from deflagration of natural gas or other flammable process gas leak causing BSC failure, personnel contamination, room contamination, ventilation system leakage around, through HEPA filters.	Tetra Tech 2009	Fire
269	Deflagration of anticipated or unanticipated chemical reaction leading to BSC failure, personnel contamination, room contamination, possible ventilation system leakage around, through HEPA filters.	Tetra Tech 2009	Deflagration
270	Fire from flammable process liquids causing BSC failure, personnel contamination, room contamination, possible ventilation system leakage around, through HEPA filters.	Tetra Tech 2009	Fire
271	Fire from buildup of combustibles (poor combustible control in laboratories) causing BSC failure, personnel contamination, room contamination, possible ventilation system leakage around, through HEPA filters.	Tetra Tech 2009	Fire
272	Fire from fuel accumulation external to the facility; supply of diesel, fuel oil, gasoline burns leading to facility breach, personnel contamination, room contamination, possible environmental contamination.	Tetra Tech 2009	Fire
273	Helicopter or small airplane crash into facility (DOE-STD-3014 scenario) causes structure failure; significant environmental and public contamination.	Tetra Tech 2009	Aircraft crash
274	Wildfire breaches facility boundary and reaches fuel accumulation external to the facility; supply of diesel, fuel oil, gasoline burns leading to facility breach, personnel contamination, room contamination, possible environmental contamination.	Tetra Tech 2009	NPH - other

292	Loss of power from lightning or other source causes loss of negativity; environmental and public contamination.	Tetra Tech 2009	Loss of power

#	Scenario description	Reference	Candidate event group
293	A potential release of a biological agent in the form of a liquid aerosol resulting from a BSL-4 laboratory accident. For the purposes of this MCE analysis, the highest volume used in centrifugation would be six completely filled 250-mL (8.45-fluid-ounce) bottles of cell culture supernatant that contains 108 plaque-forming units (PFUs) per milliliter, for a total of 1.5×10^{11} PFUs. Assuming that all six bottles break, a viral aerosol would be created within the rotor. It is also assumed that the rotor gasket fails to contain any aerosol generated.	USAMRMC 2006	Centrifuge release
294	Escape of an infected animal, terrorist acts, and external acts.	USAMRMC 2006	Inadequate animal control
295	An MCE analysis was developed for potential release of a biological agent in the form of a liquid aerosol resulting from work in BSL-3 facilities. The MCE scenario for a BSL-3 laboratory accident occurs during the processing of a 1-liter (0.26-gallon) slurry. In this scenario, a laboratory worker fails to use rubber O-rings to seal the centrifuge tubes and fails to properly tighten the safety centrifuge caps designed to prevent leakage into the centrifuge compartment that houses the rotor. All six tubes spill slurry into the rotor cups, and some of the slurry leaks into the rotor compartment, which is not sealed against the release of organisms in a small-particle aerosol.	USAMRMC 2006	Centrifuge release
296	A researcher is handling a 15-cc conical tube containing a powder-like preparation of purified <i>B. anthracis</i> containing 1×10^{10} spores. The cap fits loosely. The researcher accidentally drops the tube on the bare, stainless steel surface of the properly operating BSC.	NIH 2005	Container leak/spill/open

304	Procedural errors resulting in inadvertent infection (e.g., mislabeled tubes).	NIH 2009	Inadequate pathogen accountability
305	Malevolent actions.	NIH 2009	Malevolent act
306	Suicide bomber/airplane attack/truck with explosives/fire.	NIH 2009	Malevolent act
307	Disgruntled or deranged lab worker spreads agents in community.	NIH 2009	Malevolent act
308	Three researchers became skin-test positive for tuberculosis after using a newly acquired aerosolization chamber for experimental infection of animals.	NEIDL RA Appendix D	Centrifuge release
309	Malfunction of the HVAC system pulled potentially contaminated air out of the BSL-3 biocontainment area and into a clean hallway. Nine workers were tested for possible exposure to the bacterium, and no infections were diagnosed. The HVAC system was brought back into compliance. Duct tape was used to seal the door and remained in place as of June 2008.	NEIDL RA Appendix D	HVAC failure

#	Scenario description	Reference	Candidate event group
310	Researchers were working under BSL-2 biocontainment protocol with what was believed to be a non-infectious vaccine strain of the bacterium. Later, it was determined the bacterial culture also contained the infectious wild-type strain that requires BSL-3 biocontainment precautions. Investigation was unable to determine the cause for the mixed culture. Two researchers became infected with <i>F. tularensis</i> in May and were not correctly diagnosed until a third scientist became infected with the bacterium in September. An investigation revealed that researchers had failed to follow proper BSL-2 biocontainment protocol and that the university failed to identify work-related illness in laboratory staff and failed to immediately report suspicious work-related illness to local and state health departments. Biosafety policies and SOPs were revised accordingly.	NEIDL RA Appendix D	Pathogen used with inappropriate biocontainment
311	Bat bite through double gloves. No infection occurred.	NEIDL RA Appendix D	Animal bite/scratch
312	Highly concentrated virus was suddenly aerosolized when worker opened chamber to add a bit more fluid without closing the nitrogen pressure tank and bleeding off pressure. Laboratory was mopped for several hours with glutaraldehyde, and finally decontaminated with formaldehyde gas. No infection occurred in two exposed workers. There was no breach in BSL-4 containment, and no infections occurred in neighboring open-air monkey colonies on the campus.	NEIDL RA Appendix D	Container leak/spill/open
313	One each glove and suit tear. Workers followed for 3 weeks for fever. No infection occurred.	NEIDL RA Appendix D	PPE failure (excluding PAPR)
314	Animal bite; animals being inoculated with Hantavirus. Pre-inoculation bite from rat.	NEIDL RA Appendix D	Animal bite/scratch
315	Needlestick to worker before setting up an inoculum with mouse-adapted Ebola virus. No infection occurred.	NEIDL RA Appendix D	Puncture - needlestick
316	Autoclave door interlock failed, and a load not autoclaved was opened but not handled. No infections resulted.	NEIDL RA Appendix D	Pathogen not inactivated
317	Multiple events over the years of outer gloves or suits developing tears or holes or disconnects of air supply to suits detected during work. Incidents were investigated and followed up. No treatments ever used and no infections resulted.	NEIDL RA Appendix D	PPE failure (excluding PAPR)
318	A laboratory worker thawed a frozen vial of bacterial suspension and inoculated a plate culture on the open bench top instead of within a BSC. Eight laboratory workers became infected, one being asymptomatic. The outbreak was most consistent with airborne spread. The seven symptomatic workers were given antibiotic therapy. One relapsed and required alternative therapy. Enhancements to laboratory SOPs were recommended by the Department of Epidemiology and the Infectious Diseases Division.	NEIDL RA Appendix D	Container leak/spill/open
319	Earthquake up to design basis.	DOE 2008	NPH - earthquake

Notes:

- a. PPE = personal protective equipment
- b. HVAC = heating, ventilating, and air conditioning system
- c. PAPR = powered air-purifying respirator
- d. NPH = natural phenomena hazards

1 As explained previously, the incidents and postulated events identified in Table E-1 were
2 combined into groups of similar initiators, which are identified in the last column of Table E-1.
3 Table E-2 lists the initiating event groups. The candidate initiating events groups were carried
4 forward for further consideration.

Table E-2. Candidate initiating event groups

#	Candidate event group
1	Aircraft crash
2	Animal bite/scratch
3	Animal escape or pathogen release to environment
4	Animal-related infectious aerosol
5	Breach of containment (wall cracks or open doors)
6	Centrifuge release
7	Container leak/spill/open
8	Contaminated waste (e.g., not inactivated)
9	Contamination inside laboratory
10	Contamination outside laboratory
11	Deflagration
12	Fire
13	Flooding inside laboratory
14	Fomite/vector
15	Hand to mouth/eyes/nose contamination
16	HVAC ^a system failure
17	Inadequate animal control
18	Inadequate pathogen accountability
19	Inadequate PPE ^b use
20	Liquid waste leak
21	Loss of power
22	Malevolent act
23	NPH ^c —earthquake
24	NPH—tornado and strong wind
25	NPH—other (flood, snow, etc.)
26	PAPR ^d failure (addressed separately from other PPE)
27	Pathogen not inactivated
28	Pathogen used with inappropriate biocontainment
29	PPE failure (excluding PAPR ^c)
30	Puncture—during necropsy
21	Puncture—needlestick
32	Puncture—general
33	Spill/splash
34	Transportation mishap

Notes:

a. HVAC = heating, ventilating, and air conditioning system

b. PPE = personal protective equipment

c. NPH = Natural phenomena hazards

d. PAPR = Powered air-purifying respirator

F. Event Sequence Analysis

F.1 Introduction

F.1.1 Overview

This appendix to the *Risk Assessment (RA) of the National Emerging Infectious Diseases Laboratories (NEIDL) at Boston University Medical Center (BUMC)* provides the analyses of potential loss of biocontainment events selected in Appendix E for analysis. The frequency and exposure categories presented in Appendix E are also used in this appendix. There are several additional analyses that must be performed as inputs to the potential loss of biocontainment analyses. The input analyses provided in this appendix are as follows:

- *Biocontainment features*—The frequency and consequence of a potential loss of biocontainment event is dependent on the biocontainment features. A brief description of the biocontainment features is provided.
- *Inventory*—The pathogen and animal inventories are a required input for all loss of biocontainment analyses.
- *Airborne dispersion analysis*—An analysis of the airborne dispersion is required for all potential aerosol release events (i.e., an earthquake).
- *Population estimates*—Population estimates are required to determine the population consequences for all potential aerosol release events (i.e., an earthquake).

The potential events resulting in a potential loss of biocontainment addressed in this appendix are as follows:

- *Earthquake*—An earthquake was selected as the maximum reasonably foreseeable¹ (MRF) event, defined here as the event that results in the largest release from the facility.
- *Aircraft crash*—The aircraft crash was expected to pose less risk than the earthquake, so this analysis confirms that expectation.
- *Centrifuge release*—The centrifuge release event provides representative results for numerous other events, as explained in Appendix E. Biosafety level (BSL) 3 or BSL-4 laboratory centrifuge release events are analyzed.

¹ The term *reasonably foreseeable* extends to events that may have catastrophic consequences, even if their probability of occurrence is low, provided that the analysis of the impacts is supported by credible scientific evidence, is not based on pure conjecture, and is within the rule of reason (DOE 2002).

- *Needlestick*—The needlestick event provides representative results for numerous other events, as explained in Appendix E. BSL-3 and BSL-4 centrifuge release events are analyzed.
- *Malevolent acts*—Malevolent act scenarios are identified in Chapter 6 are assigned a probability and a determination was made as to whether a release of a pathogen could be reasonably expected to occur if the adversary was successful in accomplishing their mission. The consequences of malevolent acts are also compared to the consequences of accidental loss of biocontainment events, consistent with the recommendations of the DOE NEPA Guidance (DOE 2002).

F.1.2 General Guidance

This RA complies with the National Environmental Policy Act (NEPA) requirements governing disclosure of incomplete and unavailable information (Title 40 of the *Code of Federal Regulations* [CFR] section 1502.22). Consistent with these requirements, this appendix identifies the limitations of the data used, discusses the options and significance of assumptions made, and provides a basis for use of these assumptions and data. The results presented herein reflect the uncertainty in both the data and the models used for this evaluation.

NEPA guidance provided by the U.S. Department of Energy (DOE), *Recommendations for Analyzing Accidents under the National Environmental Policy Act* (DOE 2002, referred to as the DOE NEPA Guidance) was also used as guidance for this analysis. That guidance was selected because it is the most relevant and detailed guidance available for this type of analysis. The National Research Council of the National Academies reviewed the DOE NEPA Guidance and concluded the following (National Research Council 2010, page 15):

U.S. Department of Energy's (DOE) recommendations for the preparation of EISs contain some of the most detailed explanations and guidelines for discussing human health impacts in an EIS. Although DOE's recommendations for analyzing human health effects are limited to exposure to radiation and chemicals, they also are relevant to pathogen exposures.

A key element of the DOE NEPA Guidance for the accident analyses is the application of a *sliding scale*. This sliding scale allows for adjustment of the level of detail of an accident analysis in accordance with the frequency and consequences of the accident, and the level of information available. While realism is important, the DOE NEPA Guidance also supports use of *bounding* (i.e., analyses that are based on conservative assumptions that envelope potential factors) when its use is consistent with the sliding scale approach. Bounding approaches can have several potential benefits including streamlining the analysis

and potentially being more defensible than more rigorous approaches because they are unlikely to underestimate potential accident consequences (DOE 2002).

F.1.3 Historic Incident Data

Operational incidents have occurred at BSL-3 and BSL-4 facilities (see Appendix D) and the data provide insights into the types of incidents that might occur at NEIDL. Appendix D includes the recent Center for Disease Control and Prevention (CDC) report of 395 “potential release events” and 7 laboratories associated infections (LAIs) from 2003 to 2009 nationwide at laboratories working with select agents (NRC 2011).

The operating experience was used to identify potential initiating events, develop scenarios, and estimate the scenario frequencies. While the operational data were useful, there are a number of limitations of the data that limit its usefulness, especially quantitatively. The incident data cannot be used to estimate the frequency for various events for multiple reasons including the following:

- Biocontainment features and protocols have been improving over time and the historic data do not fully reflect the features in place at the NEIDL.
- Incidents are underreported because of fear of reprisal and the stigma associated with such events (Harding and Byers 2006), with approximately half going unreported (Rosenstock 2000).
- The source of exposure for the majority of laboratory related illness (82 percent) is not known (Harding and Byers 2006). As a result, any derived estimate of the true number of such incidents is uncertain and could be underestimated.
- The number of operational hours associated with the reported incidents is not known.
- The incidents are often not described in sufficient detail to determine the full chain of events. For example, the description “loss of containment” could refer to spills, centrifuge releases, or other types of events.

Therefore, reports of historic incidents were used as an input to identifying candidate events, developing scenarios, and estimating frequency categories in a qualitative manner.

F.1.4 Frequency Categories

The likelihood of events can be described and calculated in several ways. Table F.1-1 compares several equivalent ways of describing (using numbers and measures) the likelihood of events.

1

Table F.1-1 Measures of likelihood.

Average Return Period ^a (years)	Average Frequency ^b (per year)	Probability / Chance of Occurrence in Facility Lifetime ^c (in 50 years)	
1	1	Virtually 100%	Virtually 100-in-100
10	0.1	99%	99-in-100
100	0.01	39%	1-in-2.5
1,000	0.001	4.9%	1-in-21
10,000	0.0001	0.5%	1-in-200
100,000	0.00001	0.05%	1-in-2000
1,000,000	0.000001	0.005%	1-in-20,000
10,000,000	0.0000001	0.0005%	1-in-200,000

^a **Average return period in years:** This is the average time, in years, before the event would be expected to occur. If the event was to occur multiple times, this would be the average time between occurrences. This way of describing events is often used in characterizing flood levels; for example, a “1000-year flood” is a water level that is estimated to occur with a 1,000-year average return period or “once per 1,000 years”.

^b **Average frequency per year:** This is the average number of occurrences of the event per year.

^c **Probability / chance of occurrence in facility lifetime (50 years):** This is the chance that the event would occur at least once in a given 50-year period.

2 The operational data from research laboratories like the NIEDL (see Appendix D) are not adequate for
3 development of quantitative frequency estimates (e.g., mean rate plus uncertainties) for the events
4 analyzed, so alternate approaches were used. A technique commonly used when quantitative estimates of
5 frequency are not possible is the use of categories (i.e., ranges of values), which is used by the U.S.
6 Environmental Protection Agency (EPA), U.S. Department of Energy (DOE), and National Aeronautics
7 and Space Administration (NASA). (EPA 1987, NASA 2005, NASA 2009, DOE 1994) Each event
8 sequence is assigned to a frequency category based the initiating event, and the number and nature of
9 concurrent failures of preventive and mitigative features. The assignment of frequency categories often
10 relies on comparison with events in other industries and use of judgment. For this analysis, when it was
11 not clear which of two frequency categories should be assigned, the higher frequency category was used
12 to avoid underestimating the risk. Table F.1-2 identifies the frequency categories (i.e., A, B, C, and D)
13 used in this RA and provides a verbal description and average return period for each category.

Table F.1-2 Frequency categories

Category	Verbal description	Average return period (1 in “this many” years)
A	An event sequence was assigned to this category if its likelihood is sufficiently high to assume that it will occur during the operational lifetime of the NEIDL (i.e., during 50 years of operation).	1 to 100 years
B	An event sequence was assigned to this category if one or more of the events in this category could occur during the NEIDL’s operating life, but any specific event sequence in the group is not expected to occur.	100 to 10,000 years
C	An event sequence was assigned to this category if collectively none of the events in this category is expected to occur during the operating life of the facility, but the events in this category are still reasonably foreseeable.	10,000 to 1 million years
D	An event sequence was assigned to this category if it does not meet the criteria for <i>reasonably foreseeable</i> . An event sequence is categorized as category D if it is impossible or highly improbable (i.e., beyond reasonably foreseeable).	>1 million years

F.1.5 Exposure Categories

The exposure categories were defined in terms of the number of people potentially exposed to a pathogen by an event sequence. The number of people potentially exposed can vary depending on the type of event and the operational parameters at the time of the event. For example, the number of people in a room can vary from event to event depending on the activities involved. In addition, some events, such as a needle stick, might affect only one person, while another event such as an aerosolized pathogen release could affect multiple people in the room. Therefore, the exposure categories were generally defined as a range in the number of people potentially exposed. Table F.1-3 defines the exposure categories for each potentially exposed group because the total population and potential for exposure is different for each group.

Table F.1-3. Exposure categories

Exposure category	Laboratory workers	Facility workers	Members of the public (number of people within the radius)
NONE	0	0	≤ 30 m
LOW	A single individual (1)	A few individuals on the same floor (≤10)	> 30 m to ≤ 300 m
MODERATE	Most individuals in the room (1 to 4)	Most individuals on the floor (≤ 87 for BSL-3 and ≤ 30 for BSL-4)	> 300 m to ≤ 3 km
HIGH	An atypical number of individuals (>4) ^a	Most individuals in the building (≤ 300)	> 3 km

^a Although the possibility exists, it is not expected that activities will involve more than four workers in a room (BUMC 2009e).

F.2 BIOCONTAINMENT FEATURES

Biosafety in Microbiological and Biomedical Laboratories (CDC and NIH 2007), referred to as BMBL, defines *containment* (the term biocontainment will be used here) as

safe methods, facilities and equipment for managing infectious materials in the laboratory environment where they are being handled or maintained. The purpose of containment is to reduce or eliminate exposure of laboratory workers, other persons, and the outside environment to potentially hazardous agents.

A number of biocontainment features associated with the NEIDL can be grouped as administrative controls (which include laboratory practices and techniques), safety equipment, and the facility design and construction. BMBL (CDC and NIH 2007) and the *BUMC Biosafety Manual* (BUMC 2011) identify and include discussions of the various biocontainment features for each BSL. The biocontainment features that play a key role in these analyses are the following:

Administrative Controls:

1. Procedures
2. Training

Safety Equipment:

3. Container
4. Storage systems
5. Powered air-purifying respirator (PAPR)
6. Positive-pressure suit
7. Centrifuge rotor or buckets/cups
8. Centrifuge chamber
9. Biological safety cabinet (BSC)
10. Personal protective equipment (PPE) (Note: This does not include respiratory protection such as a respirator and a positive-pressure suit, which are addressed separately)

Facility Design and Construction:

11. Heating, ventilation, and air conditioning (HVAC) system
12. Sealed walls, floors, and ceilings
13. Alarms

The following paragraphs describe the NEIDL biocontainment features associated with the analyses in this appendix. Chapter 2 (Facility and Site Description) and Appendix A (Facility Design and Operations) also provide descriptions of these as well as other NEIDL biocontainment features.

1. *Procedures*—The BUMC Biosafety Manual (BUMC 2011) (Appendix W) provides requirements for development of NEIDL standard operating procedures (SOPs). The BUMC Biosafety Manual and the required NEIDL-specific SOPs minimize the potential for loss of biocontainment and direct the laboratory worker's responses in case of a potential loss of biocontainment. Requirements for safe storage and use of pathogens are a key part of the procedures. Section 2.1.4 of Chapter 2 provides additional details on administrative controls.
2. *Training*—The training requirements for NEIDL laboratory workers are outlined in the BUMC Biosafety Manual Appendix F for BSL-3 and Appendix G for BSL-4. The training program educates employees about the hazards to which they might be exposed and instructs them on the proper protocols to be used for safe operation of the NEIDL. Section 2.1.4 of Chapter 2 provides additional details on administrative controls.
3. *Container*—Pathogens must be stored using double containment. Both the inner and outer containers must be durable and leak-proof (BUMC 2011). Proper storage of pathogens is governed by the Occupational Safety and Health Administration and Commonwealth of Massachusetts regulations (105 CMR 480.000) (BUMC 2011). Containers provide the first (i.e., inner-most) biocontainment barrier.
4. *Storage systems*—Pathogens will be placed in freezers, refrigerators, and other storage systems when not in use, which provides another biocontainment barrier. Frozen samples are far less susceptible to airborne release than unfrozen samples, though the containers may potentially be more susceptible to failure.
5. *PAPR*—Laboratory workers are required to use a hooded, PAPR for all BSL-3 activities. The airborne protection factor (APF) for the PAPR used in NEIDL is 1,000 (BUMC 2010; NIH 2010).
6. *Positive-pressure suit*—In BSL-4, a one-piece totally encapsulating, positive-pressure personnel suit supplied with HEPA-filtered external air is required for all activities, including centrifugation (BUMC 2011).
7. *Centrifuge rotor or buckets/cups*—There are two types of rotors (i.e., fixed angle and swinging bucket) that hold the individual sample containers in the centrifuge. Both fixed-angle rotors and swinging buckets used in the NEIDL BSL-3 and BSL-4 laboratories will have aerosol-tight (i.e., O-ring seals), thereby providing a containment barrier to potential aerosol releases during centrifugation. The rotors or buckets will be prepared for and opened after centrifugation in

- 1 BSCs, which includes loading the containers, balancing the rotor or buckets, disinfecting
2 surfaces, and installing the rotor or bucket lids (BUMC 2011, BUMC 2009a).)
- 3 8. *Centrifuge chamber*—The centrifuge has an enclosure that surrounds the rotor during
4 centrifugation. The chamber includes a door interlocked with the control system that prevents
5 operation unless the door is closed and prevents opening of the door until the rotor has stopped
6 spinning. The chamber door on all centrifuges can reduce potential aerosol release to some extent
7 (BUMC 2009a).
- 8 9. *BSC*—Rotor loading and unloading operations must be performed only inside a BSC (BUMC
9 2011). The directional air flow of the BSC ensures that any aerosol released when a rotor or
10 bucket is opened is confined by the BSC and filtered by its HEPA filtration. A discussion of
11 BSCs is presented in Appendix A of BMBL and Appendix C of the BUMC Biosafety Manual.
- 12 10. *PPE*—The specific PPE used for centrifuge operation is dependent on the pathogen, and
13 concentrations involved, but will always include protective clothing, eye protection (the respirator
14 could serve this function), and double gloves (BUMC 2009a). PPE are removed prior to exiting
15 the BSL-3 or BSL-4 laboratories to avoid carrying contamination out of the laboratory. While
16 respirators are considered to PPE, they are addressed separately because of their significance for
17 reducing the inhalation hazard and the pathogen-specific requirement to use them.
- 18 11. *HVAC*—The HVAC system provides mitigative protection to laboratory workers, facility
19 workers, and the public from potential airborne releases. The HVAC features providing that
20 protection include the following (BUMC 2011, 2009b; CDC and NIH 2007; NIH 2008):
- 21 • Single-pass airflow that does not recycle potentially contaminated air.
 - 22 • Directional air flow control for BSL-3 and differential pressure control for BSL-4 to ensure
23 that airborne contamination flows from areas of least biohazard to areas of greatest
24 potential biohazard.
 - 25 • A minimum of eight air exchanges per hour for BSL-2, BSL-3, and BSL-4 laboratories,
26 which reduces the concentration of the entrained aerosol over time.
 - 27 • HEPA filtration on the inlet for the BSL-4 HVAC system.
 - 28 • Exhaust air is filtered before being discharged up the stack. The BSL-3 air is filtered
29 through a single HEPA filter, and the BSL-4 air is filtered through two HEPA filters in
30 series.
 - 31 • Backflow prevention on the air supply inlet to prevent release in case of a loss of airflow.
32 BSL-4 dampers are air-tight bubble-dampers and the BSL-3 dampers are low-leakage
33 dampers.
 - 34 • Redundant exhaust fans that provide adequate airflow in case of a loss of fan.

- Isolation dampers (airtight dampers for BSL-3 and low-leakage dampers for BSL-3) automatically controlled in case of a loss of directional airflow for BSL-3 or pressure differential for BSL-4.
- Emergency generators and battery-backed power supplies in case of a loss of off-site power.

12. *Sealed walls, floors, and ceilings*—The NEIDL BSL-3 and BSL-4 laboratories are designed and constructed to minimize the potential airborne releases from potentially contaminated areas even in case of a total loss of HVAC airflow. The BSL-3 and BSL-4 areas have sealed floors, ceilings, and walls, including sealed wall penetrations. Access to the laboratories is controlled via interlocked doors that prevent both doors from being opened simultaneously. Airtight doors isolate areas of greatest biohazard in BSL-4 laboratories. Pressure tests in the NEIDL’s BSL-4 laboratory show that half of the negative pressure differential will be maintained for 20 minutes in case of a loss of active HVAC. Those features greatly reduce the potential spread of airborne contamination to other areas of the NEIDL or outside the building (BUMC 2011, 2009c; CDC and NIH 2007; NIH 2008).

13. *NEIDL structure*—The NEIDL structure has been designed to withstand severe natural phenomena such as earthquakes. Attachment D of this appendix provides a brief summary of NEIDL structural design features important to this analysis.

14. *Alarm and communications systems*—The NEIDL has alarm and communications systems that alert workers to potentially dangerous systems, such as HVAC upsets.

Biocontainment features can be preventive, mitigative, or a combination of both. Preventive features are structures, systems, or components that prevent the loss of biocontainment, such as an aerosol-tight container. Mitigative features are structures, systems, or components that reduce the consequences given that a loss of biocontainment does occur, such as respiratory protection. The role of each of the individual biocontainment features is specific to each event sequence.

F.3 NEIDL INVENTORY

F.3.1 Introduction

F.3.1.1 Inventory Types

A key factor affecting the consequences associated with potential accidents involving loss of biocontainment at the NEIDL is the pathogen inventory (i.e., quantity, concentration, and form of the pathogen). For example, greater concentrations of pathogens in liquid suspension may result in greater

airborne concentrations for aerosol release events. The inventory is also important because it defines part of the NEIDL operating conditions covered by the RA. Animals (arthropods and mammals) that could be experimentally infected also are important for events that can involve the escape of one or more animals.

NEIDL will contain pathogens in master, seed, and working stock inventories as well as infected animals. In general, a pathogen sample received at NEIDL is used to generate a master stock, which is promptly converted to the seed stock, which in turn is used to generate the working stock as needed. There can be multiple strains of a given pathogen in NEIDL, and each strain would have its own master stock, seed stock, working stock, and infected animal inventories. Those inventory stocks are defined as follows:

Master stock—Upon receipt of a new pathogen sample and after appropriate testing, a master stock is cultured. The master stock has a close and well-documented link to the original sample received at the laboratory and is the source of the seed stock. The identity, purity, and stability of the master stock is verified before being converted to the seed stock. If seed stock inventories become depleted, a new master stock inventory can be cultured from the remaining seed stock, which was potentially derived directly from the original master stock. Generation or regeneration of a seed stock is an infrequent occurrence and is expected to occur about once every one to five years for a pathogen.

Seed stock—The seed stock is created by dividing the master stock into small vials (generally 1 to 2 milliliters [mL]), which are frozen until they used. As the name implies, the seed stock is used to grow the working inventories used in the research activities.

Working stock—When work with a pathogen is to be undertaken, a vial of the seed stock is thawed and used to start a new culture of the pathogen. Working stocks are the cultures used in daily research.

Infected animal—Activities at the NEIDL will include animals (mammals and arthropods) infected with various pathogens as part of the research.

F.3.1.2 Concentration Units of Measure

Various methods are used to quantify the concentration of bacteria and viruses in a liquid suspension. As a result of the differences between those methods, there are different units of measure for the concentration. For bacteria, the most common unit of measure is the colony forming unit (CFU) per milliliter; for viruses, there are multiple different units of measure. The measurement and units of

measure are dependent on the method used to quantitate the virus. Below are the units used to quantify the concentration in this RA.

Colony forming unit (CFU)—A measure of viable cells in which a colony represents growth from either a single cell, or an aggregate of cells, derived from a single progenitor cell. CFU is used to describe the number of viable bacterial cells per unit of measure, e.g., per mL of liquid (Hung et al. 2005).

Fluorescent focus unit (FFU)—The fluorescent-focus assay is a modification of the plaque assay that uses a fluorescent stain to detect virus microscopically and permit quantitation. The FFU assay is useful in detecting viruses that do not destroy host cells (Flint et al. 2009).

Median cell culture infective dose (CCID₅₀)—The minimum concentration of virus particles needed to produce, in a given cell line culture under specified conditions, a detectable cytopathic effect in 50 percent of exposed cell cultures (Flint et al. 2009).

Median mouse infective dose (MID₅₀)—The minimum concentration of virus required to cause infection in 50 percent of exposed mice (Flint et al. 2009).

Median mouse intracerebral lethal dose (MICLD₅₀)—The minimum concentration of virus required to cause death in 50 percent of mice exposed by intracerebral injection (Flint et al. 2009).

Median tissue culture infective dose (TCID₅₀)—The terms *cell culture* and *tissue culture* tend to be used synonymously (Spector et al. 2002). See the median cell culture infective dose (CCID₅₀).

Plaque forming unit (PFU)—A measure, determined by the technique known as plaque assay, of the quantity of individual and aggregated virus particles that are infectious for a given cell line culture under specified conditions. This measure is expressed as the number of plaques formed per unit volume (liquid) (Flint et al. 2009).

F.3.2 Methodology

The scope of this calculation package is as follows:

- The inventory is provided for the 13 BSL-3 and BSL4 pathogens ultimately evaluated in the RA. The 13 pathogens were selected on the basis of independent review and consideration of

recommendations from the National Institutes of Health (NIH) Blue Ribbon Panel (BRP) and the National Research Council teleconference (NIH 2009). No additional pathogens are considered.

- Estimates are provided for the master, seed, and working stock inventories.
- The experimentally infected animals (mammals and arthropods) likely to be associated with each of the 13 pathogens are identified.
- The inventories presented herein are the culmination of the following activities and sources of information:
 - Discussions and correspondence with representatives of the BUMC provided their expected inventories of the research programs.
 - Literature reviews and surveys of program leaders and senior scientists at other BSL-4 biocontainment facilities were performed.
 - A joint NIH and Tetra Tech review of the collected information was performed at the March 5, 2010, NIH-Tetra Tech Working Group meeting.
 - Subsequent detailed discussions with NEIDL leaders and reviews of available NEIDL operating procedures were used as a final step in resolving specific questions related to operations that affect pathogen inventories.
 - BUMC provided their expected master and working stock volumes (BUMC 2011a).

Those inputs were important factors, but the ultimate basis for the maximum inventory estimates is the NIH and Tetra Tech review and approval process, which is documented by this report.

F.3.3 Results

The seed stock, master stock, working stock, and infected animal inventories are presented below.

F.3.3.1 Master Stock Inventory

Master stock inventories for a given pathogen are present for only a few days while they are being cultured and until they are converted to the seed stock inventory. A new master stock for a given pathogen is likely to be generated no more than once every one to five years. As a result, master stock inventories will be present less than 1 percent of the time throughout the facility operating lifetime because they are used to produce the seed stock. It is possible that research will be conducted on multiple strains of a pathogen, so multiple master stocks could be generated for a pathogen. The maximum NEIDL master stock volumes and concentrations for the facility are presented in Table F.3-1.

Table F.3-1 NEIDL master stock maximum volumes and concentrations

Pathogen ^a	BSL	Maximum volume (mL)	Maximum concentration (/mL) ^b
<i>B. anthracis</i> ^{c d}	2/3	100 ^{c d}	2.4×10^8 CFU ^{c d}
<i>F. tularensis</i> ^c	3	100 ^c	2×10^9 CFU ^c
<i>Y. pestis</i> ^c	3	100 ^c	2×10^7 CFU ^c
1918H1N1V	3	500	1×10^8 PFU
SARS-CoV	3	500	1×10^7 PFU
RVFV	3	500	1×10^8 PFU or 1×10^9 CCID ₅₀ and MICLD ₅₀ ^e
ANDV	3/4 ^f	500	1×10^6 CCID ₅₀
EBOV	4	500	5×10^7 CCID ₅₀
MARV	4	500	1×10^7 CCID ₅₀
LASV	4	500	1×10^7 TCID ₅₀ and FFU (PFU)
JUNV	4	500	1×10^7 PFU
TBEV-FE	4	500	1×10^8 MID ₅₀
NIPV	4	500	2×10^7 PFU and TCID ₅₀

- a. *Bacillus anthracis* (*B. anthracis*); *Francisella tularensis* (*F. tularensis*); *Yersinia pestis* (*Y. pestis*); 1918 H1N1 influenza virus (1918H1N1V); SARS-associated coronavirus (SARS-CoV); Rift Valley fever virus (RVFV); Andes virus (ANDV); Ebola virus (EBOV); Marburg virus (MARV); Lassa virus (LASV); Junin virus (JUNV); tick-borne encephalitis virus, Far Eastern sub-type, formerly known as tick-borne encephalitis complex (Russian spring-summer encephalitis virus) (TBEV-FE); and Nipah virus (NIPV).
- b. Suspension concentrations are given in terms of colony forming units (CFU) per milliliter for bacteria and plaque forming units (PFU), median tissue culture infective dose (TCID₅₀), fluorescent focus units (FFU), median cell culture infective dose (CCID₅₀), median mouse infective dose (MID₅₀), or median mouse intracerebral lethal dose (MICLD₅₀) per milliliter for viruses. Section F.3.1.2 provides background information on the methods and units associated with the concentration measurements.
- c. Bacteria will be grown on solid medium plates, which will then be harvested and converted to a liquid suspension for use in either aerosol or subcutaneous animal inoculation. The liquid suspension form is reported here rather than the solid medium form because of the solid medium form has a greatly reduced airborne release potential.
- d. In spore form in suspension.
- e. Two values are reported for RVFV with different units. The CCID₅₀ and MICLD₅₀ units are an order of magnitude greater because this measurement is more sensitive.
- f. BSL-4 is required when infecting rodent species permissive (susceptible to) for chronic infection.

F.3.3.2 Seed Stock Inventory

There could be multiple 1- to 2-mL vials of each pathogen, and multiple strains of each pathogen, in storage. It is difficult to predict which pathogen species and strains could be present in NEIDL at any time, so generally it should be conservatively assumed that all strains of all pathogen species could be present at all times. The total number of vials of any pathogen is not known but could be 100 or more for each pathogen strain. However, the seed stock is not considered a significant contributor to risk because of the following factors:

- The seed stock is in a frozen form, which is highly resistant to release, especially to aerosol release, and is only thawed before use. Redundancies in the off-site power supply feeds and the

on-site emergency diesel generators minimizing the potential for a loss of power to the freezers (BUMC 2009d, BUMC 2009b). Additionally, the seed stock can remain frozen in the freezers for many hours without power, thereby, allowing time for corrective action.

- Except when being used to produce a working stock, the seed stock is secured in freezers, which protect the individual vials from physical damage and provide an additional barrier to release.
- The volume of each vial is a very small fraction of the total pathogen inventory (e.g., about 1 percent of the working stock volume) and the presence of many vials of a seed stock becoming thawed and breached concurrently is unlikely.

The maximum NEIDL seed stock concentration estimates are presented in Table F.3-2.

Table F.3-2. NEIDL maximum seed stock concentrations

Pathogen ^a	BSL	Maximum concentration (/mL) ^b
<i>B. anthracis</i>	2/3	2.4×10^8 CFU
<i>F. tularensis</i>	3	2×10^9 CFU
<i>Y. pestis</i>	3	2×10^7 CFU
1918H1N1V	3	1×10^8 PFU
SARS-CoV	3	1×10^7 PFU
RVFV	3	1×10^8 PFU or 1×10^9 CCID ₅₀ and MICLD ₅₀ ^c
ANDV	3/4 ^d	1×10^6 CCID ₅₀
EBOV	4	5×10^7 CCID ₅₀
MARV	4	1×10^7 CCID ₅₀
LASV	4	1×10^7 TCID ₅₀ and FFU (PFU)
JUNV	4	1×10^7 PFU
TBEV-FE	4	1×10^8 MID ₅₀
NIPV	4	2×10^7 PFU and TCID ₅₀

a. *Bacillus anthracis* (*B. anthracis*); *Francisella tularensis* (*F. tularensis*); *Yersinia pestis* (*Y. pestis*); 1918 H1N1 influenza virus (1918H1N1V); SARS-associated coronavirus (SARS-CoV); Rift Valley fever virus (RVFV); Andes virus (ANDV); Ebola virus (EBOV); Marburg virus (MARV); Lassa virus (LASV); Junin virus (JUNV); tick-borne encephalitis virus, Far Eastern sub-type, formerly known as tick-borne encephalitis complex (Russian spring-summer encephalitis virus) (TBEV-FE); and Nipah virus (NIPV).

b. Suspension concentrations are given in terms of colony forming units (CFU) per milliliter for bacteria and plaque forming units (PFU), median tissue culture infective dose (TCID₅₀), fluorescent focus units (FFU), median cell culture infective dose (CCID₅₀), median mouse infective dose (MID₅₀), or median mouse intracerebral lethal dose (MICLD₅₀) per milliliter for viruses. Section F.3.1.2 provides background information on the methods and units associated with the concentration measurements.

c. Two values are reported for RVFV with different units. The CCID₅₀ and MICLD₅₀ units are an order of magnitude greater because this measurement is more sensitive.

d. BSL-4 is required when infecting rodent species permissive for (susceptible to) chronic infection.

F.3.3.3 Working Stock

The facility working stocks are the inventories used in the daily research experiments. The working stock inventories are a primary focus of the RA because they are in use more frequently than the master stock and are in a liquid suspension, a more releasable form than the frozen seed stock. The working stocks will frequently be in a liquid suspension form; however, virus suspensions may be frozen on occasion and bacteria may be grown on solid media (e.g., agar). For this RA, it is conservatively assumed that the working stocks are always in liquid suspension form because this form has a greater release potential than frozen or solid forms. The working stock concentration used in the RA is the maximum concentration based upon the methodology described in Section F.3.2.

Virus working stock volumes will vary depending on the type of experiments being performed and the quantity of viruses required to carryout those experiments. For bacteria, this RA is based on the assumption that the maximum working stock volumes are present at all times. For viruses, the working stock volumes are considerably greater than the volumes for bacteria. This RA is based on the assumption that for viruses, the typical working stock volume of 150 mL is present at all times. The typical virus working stock volume will be 150 mL; however, some experiments will not require 150 mL and some will require more, with a maximum of 500 mL (BUMC 2011a). The assumption that a 150-mL liquid suspension working stock volume is present for each of the viruses at all times is appropriate and conservative even for the limited instances when the volume may be up to 3-1/3 times larger for the following reasons:

- Active research is likely to be conducted on only a fraction of the viruses at any given time. Therefore, assuming there is a working stock for each virus at all times overstates the overall volume.
- The instances when a working stock exceeds 150 mL are roughly offset by the times when the working stock is less than 150 mL; therefore, the average volume is about 150 mL.
- A liquid suspension working stock for a given actively researched virus will not be present in the laboratory in a vulnerable form (i.e., not frozen and not secured in storage such as a refrigerator) at all times throughout the year. Working stocks will not be present during preparation and clean-up phases of the research. In addition, the working stocks will be frozen or secured in storage such as a refrigerator during large portions of the research period. If a liquid working stock is only out of storage during all normal work hours, it would be at risk for only ¼ of the year.
- The inventory is based on the maximum concentration, which is a large conservative bias, and this conservatism compensates for the occasions when the volume may exceed 150 mL. The

concentration can vary by one or more orders of magnitude while the maximum volume is only a factor of 3-1/3 larger than the typical volume.

The typical working stock volumes and maximum concentrations used for the NEIDL RA for all 13 pathogens being evaluated are presented in Table F.3-3.

Table F.3-3 NEIDL facility working stock typical volumes and concentrations

Pathogen ^a	BSL	Typical volume (mL)	Maximum concentration (/mL) ^b
<i>B. anthracis</i> ^{c d}	2/3	50 ^{c d}	2.4×10^8 CFU ^{c d}
<i>F. tularensis</i> ^c	3	1 ^c	2×10^9 CFU ^c
<i>Y. pestis</i> ^c	3	5 ^c	2×10^7 CFU ^c
1918H1N1V	3	150	1×10^8 PFU
SARS-CoV	3	150	1×10^7 PFU
RVFV	3	150	1×10^8 PFU or 1×10^9 CCID ₅₀ and MICLD ₅₀ ^e
ANDV	3/4 ^f	150	1×10^6 CCID ₅₀
EBOV	4	150	5×10^7 CCID ₅₀
MARV	4	150	1×10^7 CCID ₅₀
LASV	4	150	1×10^7 TCID ₅₀ and FFU (PFU)
JUNV	4	150	1×10^7 PFU
TBEV-FE	4	150	1×10^8 MID ₅₀
NIPV	4	150	2×10^7 PFU and TCID ₅₀

a. *Bacillus anthracis* (*B. anthracis*); *Francisella tularensis* (*F. tularensis*); *Yersinia pestis* (*Y. pestis*); 1918 H1N1 influenza virus (1918H1N1V); SARS-associated coronavirus (SARS-CoV); Rift Valley fever virus (RVFV); Andes virus (ANDV); Ebola virus (EBOV); Marburg virus (MARV); Lassa virus (LASV); Junin virus (JUNV); tick-borne encephalitis virus, Far Eastern sub-type, formerly known as tick-borne encephalitis complex (Russian spring-summer encephalitis virus) (TBEV-FE); and Nipah virus (NIPV).

b. Suspension concentrations are given in terms of colony forming units (CFU) per milliliter for bacteria and plaque forming units (PFU), median tissue culture infective dose (TCID₅₀), fluorescent focus units (FFU), median cell culture infective dose (CCID₅₀), median mouse infective dose (MID₅₀), or median mouse intracerebral lethal dose (MICLD₅₀) per milliliter for viruses. Section F.3.1.2 provides background information on the methods and units associated with the concentration measurements.

c. Bacteria will be grown on solid medium plates, which will then be harvested and converted to a liquid suspension for use in either aerosol or subcutaneous animal inoculation. The liquid suspension form is reported here rather than the solid medium form because of the solid medium form has a greatly reduced airborne release potential.

d. In spore form in suspension.

e. Two values are reported for RVFV with different units. The CCID₅₀ and MICLD₅₀ units are an order of magnitude greater because this measurement is more sensitive.

f. BSL-4 is required when infecting rodent species permissive (susceptible to) for chronic infection.

It is possible that research will be conducted on multiple strains of a given pathogen at the same time in the same laboratory suite. Based on discussions with BUMC personnel, it is expected that no more than two strains of a given pathogen are likely to be used in a laboratory suite at a given time. However, there are multiple Research Cores housed in BSL-3 or BSL-4 spaces, and concurrent research projects and activities collectively involving multiple pathogens are likely.

F.3.3.4 Infected Animals

The NEIDL will also contain various experimentally infected animals (arthropods and mammals) at any given time. There are multiple ways in which infected animals can expose people including (1) exposure to animals and bedding dust during handling operations, (2) direct exposure of workers and the public by escaped animals, and (3) establishing reservoirs (i.e., domestic and wild animals that are a potential source of infection) after escape. Table F.3-4 identifies the pathogens that could be associated with each type of mammal and arthropod.

Table F.3-4. Animal-pathogen pairing

Pathogen ^a	BSL	Non-human primates	Rodent ^b	Mosquito	Tick

a. *Bacillus anthracis* (*B. anthracis*); *Francisella tularensis* (*F. tularensis*); *Yersinia pestis* (*Y. pestis*); 1918 H1N1 influenza virus (1918H1N1V); SARS-associated coronavirus (SARS-CoV); Rift Valley fever virus (RVFV); Andes virus (ANDV); Ebola virus (EBOV); Marburg virus (MARV); Lassa virus (LASV); Junín virus (JUNV); tick-borne encephalitis virus, Far Eastern sub-type, formerly known as tick-borne encephalitis complex (Russian spring-summer encephalitis virus) (TBEV-FE); and Nipah virus (NIPV).

b. Includes suckling or weanling mice.

c. BSL-4 is required when infecting rodent species permissive (susceptible to) for chronic infection.

F.3.3.5 Variability and Uncertainty

There are numerous variabilities and uncertainties that apply to the results presented in Sections F.3.1 through F.3.4. Table F.3-5 provides a discussion and an estimate of the potential effect of each of the key variabilities and uncertainties.

1

Table F.3-5. Summary of key variabilities and uncertainties.

Variability/ uncertainty	Discussion	Potential effect ^a
Pathogens evaluated	It is possible that not all 13 pathogens evaluated will be used in NEIDL. Consideration of pathogens that might not be used in NEIDL is a conservatism (i.e., overestimate of risk), but the magnitude of the conservatism is unknown. The largest potential conservatism would be if the most affecting pathogens were not ever used in NEIDL.	Conservatism, unknown magnitude
	It is possible that pathogens other than the 13 evaluated might be used in NEIDL. Other pathogens could have their own specific characteristics, but the pathogens considered are expected to cover the range of attributes likely to be associated with other pathogens that might be used. To the extent that the 13 pathogens envelope other potential pathogens, research on additional pathogens will not increase risk. If another pathogen is used that exceeds the range/combination of attributes associated with the 13 pathogens, it is possible that this evaluation is non-conservative (i.e., underestimates risk), but the magnitude of the non-conservatism is unknown.	Likely accurate, but potential non-conservatism, unknown magnitude
	At any given moment, research will be conducted on only a fraction of the 13 pathogens. Therefore, some events that are not dependent on laboratory activities (e.g., an earthquake) could overpredict risk.	Conservatism, unknown magnitude
Master stock total volume	The master stock maximum volume estimates might overstate the volumes for actually used for some pathogens. In general, the volumes are expected to be conservative estimates, and actual volumes will be somewhat less.	Likely conservatism, unknown magnitude
Master stock maximum concentration	The master stock concentrations are expected to be maximum values that are not exceeded, but it is possible that those values will be exceeded by a culture inadvertently grown to higher concentrations. If the estimated master stocks concentrations are exceeded, the extent of exposure could increase proportionally to that increase. Because the master stocks are present for only a small fraction of the time, this potential non-conservatism is considered a small risk factor.	Likely conservatism but potential non-conservatism, unknown magnitude
Seed stock total volume	The volume of the seed stock is expected to be 1 to 2 mL per vial and there could be 100 or more vials. A precise estimate of the number of vials is not provided because the frozen seed stock is not considered a large factor in the risk assessment because <ul style="list-style-type: none"> The samples are in a frozen form, which is highly resistant to airborne dispersion, The samples are stored in freezers, which makes them much less vulnerable to airborne release, and The volume of each vial is a very small fraction of the total pathogen inventory (e.g., often about 1% of the working stock) and a breach of many vials concurrently is unlikely. 	Non-conservatism, but expected to be negligible
Seed stock maximum concentration	The seed stock concentrations are expected to be maximum values, but it is possible that those values will be exceeded or that they overestimate the actual concentrations. However, as explained for the <i>Seed stock total volume</i> row above, the risks associated with the seed stock are small so the impact on the overall risk is small.	Possible non-conservatism, but expected to be negligible
Working stock volume	The maximum working stock volume used for some activities could be larger than the typical volume (up to 500 mL versus 150 mL). As explained in Section F.3.3.3, the typical volumes reflect most activities and the occasions when larger volumes are used are counteracted by the times when smaller volumes are used and the conservatism in the concentration.	Possible non-conservatism, but expected to represent most activities

Variability/ uncertainty	Discussion	Potential effect ^a
Working stock maximum concentration	The working stock concentrations are expected to be maximum values, but it is possible that those values will be exceeded by a culture inadvertently grown to higher concentrations. If the estimated working stocks' concentrations are exceeded, the extent of exposure could increase proportionally to this increase.	Likely conservatism but potential non-conservatism, unknown magnitude
Animal-pathogen pairings: nonhuman primates and rodents	Because all pathogens are selected for each mammal, this is a conservative estimate that cannot be exceeded for the pathogens selected.	Conservatism, unknown magnitude
	It is possible that mammals other than those listed in Table F.3-3 could be used in NEIDL. The risk associated with additional mammals might or might not increase the risk.	Possible non-conservatism, unknown magnitude
Animal-pathogen pairings: mosquito and tick	There is only one pathogen likely to be associated with mosquitoes and one pathogen likely to be associated with ticks. Use of another of the 13 pathogen with either arthropod is possible and this might or might not increase risks.	Possible non-conservatism, unknown magnitude
	It is possible that arthropods (mosquitoes or ticks) other than those listed in Table F.3-3 could be used in NEIDL. Vector-specific SOPs would be required if new vectors are added.	Possible non-conservatism, unknown magnitude

a. This is a qualitative indication of the direction and magnitude of the conservative or non-conservative effect of this factor on risk.

As shown in Table F.3-5, numerous variabilities and uncertainties could affect the results. Some of those potential factors are conservative (i.e., tend to over-estimate frequency or consequence) and some are non-conservative (i.e., tend to under-estimate frequency or consequence). The magnitude of each conservatism and non-conservatism is not known, but the inventories are considered conservative overall because they reflect the maximum expected volumes and concentrations and are appropriate for use in the RA.

F.4 POPULATION ESTIMATES

F.4.1 Introduction

The RA includes consideration of impacts on the general population as a result of postulated airborne pathogen releases. General population estimates for each of the three sites being evaluated (i.e., the urban, suburban, and rural sites) are a necessary input for the population impact assessments. This section describes the methodology and results associated with the development of general population estimates at the three sites. The urban, suburban, and rural sites being evaluated in the RA are described in Appendix B. This analysis addresses only the general population and does not distinguish the medically vulnerable subpopulations or the environmental justice subpopulations, which are addressed in Appendix I and in Appendix M and Chapter 10 of the RA, respectively.

F.4.2 Methodology

This analysis provides estimates of the population surrounding each of the three sites, including both residents and nonresidents. This RA is intended to address known conditions and not to speculate about potential future changes; however, it is important to ensure that foreseeable future population changes do not invalidate the conclusions of this RA. Therefore, following sections address the current resident, current nonresident, and future populations.

F.4.2.1 Current Resident Population

Population estimates for NEPA analyses are typically based on U.S. Census Bureau data, which are residential population values. As explained in Section F.1.2, this analysis follows NEPA guidance. Because of their configuration, Census data are not in a format that is readily usable for population impact analyses, so a computer code was developed by the U.S. Census Bureau to convert the data into an appropriate format. For the calculation, the Census data associated with the three sites were converted to the appropriate format and adjusted to reflect population changes since the last census. This section describes the data set, computer code, and adjustments used to develop the resident population estimates for the three sites.

F.4.2.2 Population Data Set

Census data are collected by the U.S. Census Bureau on a decennial (10-year) basis. Census data are collected and reported on both a county level and a block level. The 2000 Census data set includes almost 8 million census-blocks, one for each block in the continental United States at the time, and more than 3,000 counties (Nuclear Regulatory Commission 2003a). Block-level data are used as the starting point for the analysis because the finer resolution is necessary to obtaining accurate population estimates in close proximity to each site. The 2010 census data have been collected but the block-level data were not available for use at the time of analysis, (i.e., January 2011) so the 2000 census data are used as the starting point for this RA. Use of the 2000 census data as the starting point is adequate because (1) 2010 Massachusetts population is only 3.1 percent larger than the 2000 population, and (2) the 2000 census data are updated to reflect more recent data (i.e., greater of 2009 or 2010 populations).

F.4.2.3 Computer Code

In 1973 the U.S. Census Bureau developed a computer code to calculate population estimates surrounding a site. After release of the 2000 Census data, the U.S. Nuclear Regulatory Commission tasked Sandia National Laboratories with developing an updated version of the U.S. Census Bureau computer code to make it compatible with the new (i.e., 2000) data set and allow it to run on modern personal computer

operating systems. The resulting new software, SECPOP 2000 (Nuclear Regulatory Commission 2003a), was used for this RA.

The SECPOP 2000 code was used to place the block-level census data into a radial (or polar) grid with sixteen 22.5°-sectors similar to the one shown in Figure F.4-1. The radial grid configuration is used because it is consistent with the configuration used by airborne dispersion computer codes, which are another essential input for the general population impact assessment.

SECPop 2000 provides the

population in tabular form by sector

for each annular ring. For this analysis, each radial ring is 0.1 km (0.6 mile) wide, and the grid extends to a radius of 1 km. While a radius of 1 km captures the majority of the impacts, the expected number of infections would be somewhat higher if the calculation were performed for a larger radius. There are two competing factors associated with exposures at greater distance, namely, (1) a decrease in the exposure level as the distance increases and (2) a tendency for the number of people per segment to increase at greater radii because the area of each segment increases as the distance from the center increases. The maximum radius of 1 km was selected for several reasons:

- The 1-km radius is consistent with U.S. Nuclear Regulatory Commission recommendations for the NEPA environmental justice evaluation of proposed actions in cities (Nuclear Regulatory Commission 2003).
- The highest density of nonresidents surrounding the urban site is located within 0.5 km of NEIDL and is included in the 1-km radius.
- No high-population resident communities are just beyond the 1-km radius that would significantly affect the results.
- The average exposure levels are extremely low at 1 km and would be even lower for greater distances. The MRF (total collapse) earthquake analysis (see Section F.8.3) estimates the average exposure level to be less than one one-thousandth (1/1,000) of a unit for all but one pathogen and

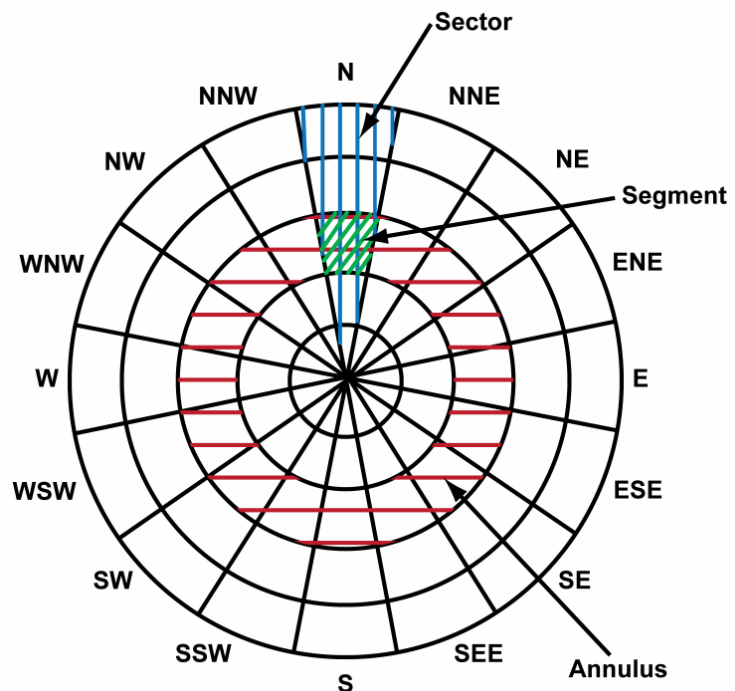

Figure F.4-1. Radial Grid.

less than one one-hundredth (1/100) of a unit for all pathogens at 1 km. The calculated exposures at even greater distances would result in even lower exposure levels.

F.4.2.4 Updating of Data

The U.S. Census Bureau Population Estimate Program (PEP) produces estimates of the population for each year after the last published decennial census (i.e., 2000). The PEP estimates are provided at a county level and are based on July 1 of each year. The PEP estimates include the percentage changes from the prior decennial census. The PEP county-level population changes were used to update the 2000 block-level population data to July 2009. Subsequent to the analysis, the 2010 PEP adjustments became available. Table F.4-1 presents the 2009 and 2010 PEP adjustment factors for the counties in which the urban, suburban, and rural sites are located. The analysis was not revised to reflect the 2010 adjustments because the 2009 adjustments are the same or larger for all three sites, which tends to slightly overstate the potential impacts.

Table F.4-1. 2009 and 2010 county population adjustment factors

Site	County	2000 to 2009 adjustment	2000 to 2010 adjustment
Urban	Suffolk, MA	+9.2%	+4.7%
Suburban	Middlesex, MA	+2.6%	+2.6%
Rural	Hillsborough, NH	+6.6%	+5.2%

Source: Census Bureau 2011

F.4.2.5 Averaging

The resident population at the three sites varies from segment to segment within an annular ring. In addition to that direction-dependence of the population, the wind frequency and conditions are direction-dependent. Because both the population and the wind frequency and conditions are direction dependent and are inputs to the population exposure calculations, the approach used to address the direction aspects of the population and wind data is important.

The population exposure calculations can be performed in either a direction-dependent or a direction-independent manner. This analysis was performed using a direction-independent approach (i.e., the population is based on the average population for the 16 segments in each ring) to minimize the effect of the uncertainties associated with both the wind and population estimates. The population estimates are uncertain because of the population movement throughout the day (e.g., residents going to work or stores), which the resident population data set does not take into account. There is also uncertainty

associated with the airborne dispersion calculations because they are based on data from the nearest weather towers, but those towers are as much as 29 km (18 miles) from the corresponding site (see Section F.5). The local weather conditions can be significantly different from the nearest tower conditions, especially with rolling terrain such as the terrain surrounding the rural site. The direction-independent approach is used for this analysis because it minimizes the effects of that uncertainty by averaging the all segment populations in an annular ring. Scoping calculations were performed to consider that effect, and the direction-independent results were found to be about 10 to 20 percent higher than the direction-dependent results for all sites. Therefore, the average population in each annular ring is used for this analysis to reduce the chance that impacts are underestimated.

F.4.2.6 Current Nonresident Population

The Census data include all people residing in the area including student and jail residents; however, the resident population data do not include people frequently near the site but residing elsewhere. Students, staff, patients, and occupants of vehicles are examples of nonresidents near the sites. The following subsections address the methodology for estimating those subpopulations.

F.4.2.7 Students, Staff, and Patients

The student, staff, and patient population estimates were developed for each site by identifying the relevant facilities within 1 km, estimating the number of people at each facility, estimating the fraction of the time they are present, their distance from the site. The average number of people outdoors or inside buildings for each annular ring at each site was estimated using the following methodology:

1. *Number of people*—The total population within 1 km of each was estimated by first identifying the major facilities in the vicinity of each site and then estimating the number of people present at the facilities. The number of people frequenting the facilities was obtained by a combination of reports by the organizations and phone interviews. In general, an influx of employees into an area is largely offset by residents that leave for work in other areas, so this analysis focused on large, nonresident population groups. If estimates could not be obtained for all sectors, estimates for the sectors with the greatest population were used as the basis for other sectors.
2. *Fraction of the time present*—The population estimates are used for analysis of earthquake-caused releases and an earthquake has an equal likelihood of occurring at any time of the year, so it is appropriate to prorate the nonresident population by the fraction of the year each nonresident is present. The fraction of the year that the people are near the sites was estimated on the basis of the nature of the activities near the site. For example, a typical work year was used as a basis for employees, and a typical school year was used for students.

3. *Distance from the site*—The annular ring in which the facilities are located were identified to allocate the population to the appropriate annular ring. When groups were generally beyond 0.5 km, they are assumed to be uniformly distributed throughout the 1-km area. This is a conservative assumption that compensates for potential omissions in the analysis because exposure levels tend to be greater at inner annular rings. When a group is generally closer than 0.5 km but distributed throughout that area, they were assumed to be uniformly distributed throughout the 0.5 km.
4. *Annular ring allocation*—The average population was then allocated to each annular ring surrounding the site. In most cases, the population can be assumed to be uniformly distributed within multiple annular rings, so the population is allocated on the basis of the area of each segment in the rings.

F.4.2.8 Vehicle Occupants

The average number of vehicle occupants traveling within 1 km of each site was also estimated. The average population for each annular ring was based on the number of vehicles in the area, the occupancy rate of the vehicles, and the location of the vehicles relative to the site. The methodology used to estimate this vehicle occupant population was as follows:

- *Vehicle population*—The average vehicle population within 1 km of the site was based on available data. Traffic count data are not available for many, but not all, roadways at each site. The Department of Transportation in Massachusetts and New Hampshire provide traffic count data for many roadways near the sites (MDOT 2011; NHDOT 2011). Those data are provided on 24-hour basis averaged over the year. Vehicle counts are not available for all roadways and two approaches were used in cases where data were not available: (1) estimates of other roadways expected to have similar or greater traffic counts were used as a basis for estimates, and (2) when estimates can be developed for the busiest sectors, this estimate can be used as the basis for the other sectors. The average number of vehicles in a kilometer of roadway can be determined using an assumed traffic speed.
- *Occupancy*—The number of people in a vehicle depends on the vehicle type and the community. The national average occupancy ranges from 1.12 for trucks to 2.35 for vans, with an average of 1.59 for cars (DOE 2010). A value of 2 occupants per vehicle is used for this analysis.
- *Annular ring allocation*—The location of each roadway needs to be considered to allocate the population to each annular ring. A uniform distribution of vehicle occupants throughout the 1-km radius was assumed for this analysis. Use of the uniform distribution assumption is conservative because the vehicle density is low nearest each of the sites, thereby overestimating the vehicle occupants where the exposure levels would be greatest.

F.4.2.9 Future Population Changes

Two potential future changes to the current populations were considered, namely, (1) general growth or decline in the population of the area, and (2) changes in the population that are a direct result of a new laboratory being built.

General population changes—The U.S. Census Bureau has projected that the 2000-to-2030 general population growth will be 10.4 percent for Massachusetts and 33.2 percent for New Hampshire (Census Bureau 2011a), but it does not provide projections at a finer level of resolution (i.e., at a county or block level). Table F.4-2 shows the adjustment that would result if the 2009 populations were increased to the Massachusetts and New Hampshire 2030 projections.

Table F.4-2. Adjustment for 2009 to 2030

Site	2009 to 2030 Adjustment
Urban	1.2%
Suburban	7.8%
Rural	26.6%

Note: The adjustment from 2000 to 2030 is 10.4 percent Massachusetts and 33.2 percent for New Hampshire.
Source: Census Bureau 2011a

The Table F.4-2 adjustments from 2009 to 2030 were not used and would not alter the conclusions of the RA for the following reasons:

- The 2030 projections are statewide averages that do not reflect actual site differences. Therefore, use of these statewide projections would reflect artificial values and would not reflect real differences among the sites. For example, the suburban and rural sites are only about 65 km (40 miles) apart, yet the 2030 projections would result in an 18.8 percent difference in population growth rate.
- The 2030 adjustments are minor. On the basis of the results presented in Section F.4.3.3, the adjustments would increase the average population per sector from 5.8 to 7.3 for the rural site, from 51 to 55 for the suburban site, and from 2,201 to 2,215 for the urban site. Those small changes would not affect the conclusions of this RA.

Effect of a new laboratory—There would be an increase in both the resident and nonresident populations in the areas surrounding the suburban and rural sites if a new laboratory were built there. No discernable changes are expected for the urban site because the facility is already built, and there is a high population

base that is not associated with laboratory. To assess the impact of that population increase on the suburban and rural sites, it is necessary to know both the extent of the increase and the location of this new population.

The population increase at the suburban and rural sites could theoretically be large relative to the current populations, but it is difficult to predict the actual extent of the increase. The population increase would be dependent on such unknowable factors as the number of people who would decide to live near the new laboratory versus those choosing to commute from other towns or cities, the number of other research facilities that might choose to locate near the new laboratory, and the extent of the support infrastructure that would be built around the facility. Projections of those increases are not available and attempts to do so would be speculative; however, the population at the sites would certainly remain only a small fraction of the density near the urban site.

While it is difficult to project the extent of the population increase, it is possible to provide some insight into the location of that growth. The building sites for the suburban and rural sites are owned by Boston University (BU) and are relatively large, so BU can control development near the laboratories. The suburban and rural sites are described as follows:

- The suburban site, formerly the BU Corporate Education Center, is a 210-acre (0.85-km²) forested site overlooking a private pond (see Chapter 2). The property includes wetlands and a historic site that serve as a buffer zone to limit resident and nonresident populations growth near the new laboratory.
- The rural site, the BU Sargent Center for Outdoor Education, consists of 700 acres (2.8 km²) of open fields and forested land (see Chapter 2). The buffer zone allows BU to prevent resident and nonresident populations from building close to the new laboratory. The site for the new laboratory is near the center of the site, so if development of the site is not permitted, residents and nonresidents would be 0.5 km to 1 km from the facility.

Airborne pathogen concentrations from a postulated ground-level release decrease dramatically with distance. For example, for ground-level releases, which result in the highest exposure levels, concentrations at 0.5 km are less than 1 percent of the exposure levels at 0.03 km and concentrations at 1.0 km are about a third of those at 0.5 km (see Section F.8). Because those buffer areas restrict nearby population growth and because postulated airborne pathogen concentrations decrease dramatically with distance, population increases beyond 0.5 km are unlikely to result in large impacts.

F.4.3 Results

The resident, nonresident, and combined population estimates are presented in the sections below, consistent with the methodology describe in Section F.4.2. A discussion of the variability and uncertainty associated with key assumptions is also provided.

F.4.3.1 Current Resident Population

Table F.4-3 presents the average current resident population in a segment of each annular ring for the three sites. Those estimates are based on the 2000 U.S. Census Bureau data, as formatted by SECPOP2000, with U.S. Census Bureau PEP adjustments to July 1, 2009. As shown by Table F.4-3, the total urban site population in a segment at a 1-km radius is more than 30 times greater than the suburban site population, and the suburban site population is nearly 20 times the rural site population. That is a broad range in the resident population, which allows the analysis to provide insights into the effects of population density.

Table F.4-3. Segment-averaged resident population as of 2009 by annular rings for the three sites

	Annular ring (km)										Total
	0.03 ^a to 0.1	0.1 to 0.2	0.2 to 0.3	0.3 to 0.4	0.4 to 0.5	0.5 to 0.6	0.6 to 0.7	0.7 to 0.8	0.8 to 0.9	0.9 to 1.0	
Urban	0.0	5.1	26	133	68	155	138	219	275	176	1,194
Suburban	0.0	0.0	3.7	0.0	0.0	11	1.5	10	2.4	8.7	38
Rural	0.0	1.3	0.0	0.0	0.0	0.0	0.0	0.0	0.9	0.0	2.2

a. The NEIDL facility has an exclusion fence at 0.03 km, and it is assumed that a similar exclusion fence would be used at all sites. Therefore, estimates are not provided for distance less than 0.03 km.

F.4.3.2 Nonresident Population

All three sites have significant nonresident populations that need to be considered. A review of facilities near the three sites determined that the largest nonresident population consists of students, employees, patients, and vehicle occupants. It is difficult to comprehensively identify and estimate the entire nonresident population, so conservative estimates of known groups were used to avoid underestimating the total population.

F.4.3.3 Students, Staff, and Patients

The student, staff, and patient population estimates for the three sites are presented below.

F.4.3.3.1 Urban Site

The largest group of nonresidents near the urban site is the student, staff, and patient population associated with BU and the Boston Medical Center (BMC). This nonresident population is highly concentrated and in close proximity to the urban site. The BU and BMC nonresident population is primarily between Harrison Avenue and the Massachusetts Avenue Connector, and between Massachusetts Avenue and East Brookline Street, as shown in Figure F.4-2. The population is most concentrated in 5 sectors of the 16-sector radial grid and within a radius of 0.5 km of urban site; however, it does extend slightly beyond that area. For this analysis, the entire BU/BMC population was conservatively assumed to be in 5 sectors within 0.5 km of the urban site. Because it is difficult to obtain accurate estimates for other sectors and other sectors have lower population densities, the BU/BMC population was used as a conservative basis for estimating the nonresident population in all sectors. The assumption that all 16 sectors have a population density comparable to the BU/BMC nonresident density significantly overstates the actual nonresident population, as can be seen by Figure F.4-2, which shows that the area south and east of the urban site is largely covered by roadways (roadways are addressed in the next section). This conservative basis for estimating the average nonresident population more than compensates for any non-BU/BMC population in the 5 sectors and for any concentrated nonresident populations in the other 11 sectors.

Figure F.4-1. Map of BU and BMC facilities.

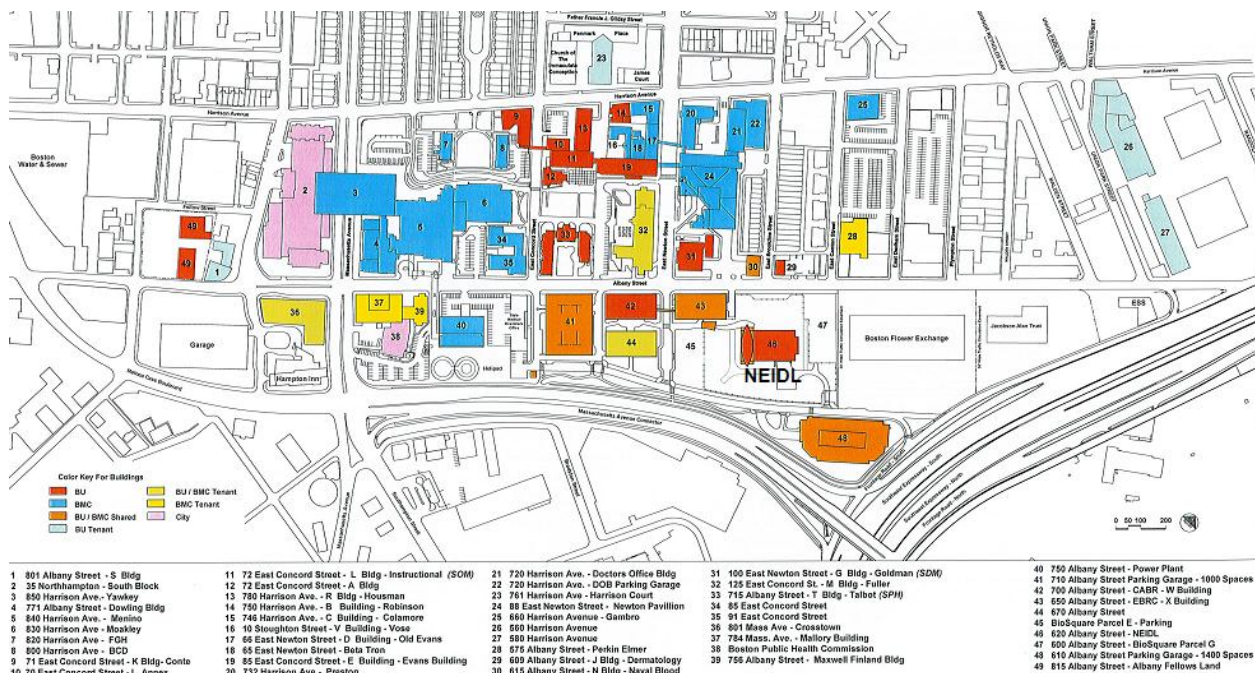

Table F.4-4 itemizes the people associated with BU and BMC that are routinely in the vicinity of the urban site. This nonresident population is only in the area during portions of a year, so population estimates need to account for the time they are present. Table F.4-4 provides an estimate of the fraction of the year each group would be present. Students and employees are assumed to be near urban an average of 25 percent of the year, which is based on 2,000 hours in an 8,760 hour year. This is likely to overestimate the time students and faculty will be present because it does not consider school breaks. The occupancy rate for BMC staffed beds is 76 percent, so it is assumed that a patient occupies each of the 508 staffed beds is occupied 76 percent of the time (BMC 2011). The fraction of the time outpatients are present is based on an average duration of 4 hours per visit in an 8,760-hour year.

Table F.4-4. Student, staff, and patient population for the urban site

Source	Number of people	Fraction of time present	Average population	Comments
Boston University:				
Faculty	1,339	25%	335	Does not account for school breaks.
Students	3,112	25%	778	Some students are also included in the resident population. Does not account for school breaks.
Boston Medical Center:				
Outpatient activity	1,006,356	0.046%	460	Includes clinic visits, ancillary visits, emergency, and ambulatory surgery.
Admitted patients	508	76%	384	The staffed bed occupancy rate is 76% (BMC 2011).
Physicians	1,290	25%	323	
Residents and fellows	791	25%	198	
Nurses	1,506	25%	377	
Employees (full-time equivalent)	4,581	25%	1,145	
Total BU and BMC			3,998	Total in 5 sectors within 0.5 km.
Average per sector			800	Based on a 5-sector area.

Source: BUMC 2008a; BMC 2011

Table F.4-5 shows there is an annual average population of 800 people per sector associated with BU and BMC within a radius of 0.5 km. These people are assumed to be uniformly distributed throughout these sectors up to a radius of 0.5 km and the number of people in each annular ring is ratioed to the area of a segment in each ring. Table F.4-5 provides the segment areas used for allocating the population to each segment. Assuming this population is all within 0.5 km is conservative because the exposure levels from a postulated pathogen release would be lower they were farther from the point of release.

Table F.4-5. Segment-averaged student, staff, and patient population by annular ring—urban site

	Annular ring (km)										Total
	0.03 ^a to 0.1	0.1 to 0.2	0.2 to 0.3	0.3 to 0.4	0.4 to 0.5	0.5 to 0.6	0.6 to 0.7	0.7 to 0.8	0.8 to 0.9	0.9 to 1.0	
Segment area (km ²)	0.0018	0.0059	0.0098	0.0137	0.0177	--	--	--	--	--	0.0489
Population per segment	29	96	161	225	289	--	--	--	--	--	800

a. The NEIDL facility has an exclusion fence at 0.03 km; therefore, estimates are not provided for distance less than 0.03 km.

F.4.3.3.2 Suburban Site

The largest nonresident population within 1 km of the suburban site is associated with the Innovation Academy Charter School (IACS), which now operates what was previously the BU Corporate Education Center. The IACS has 600 middle school and high school students (MA ESE 2011). The IACS high school operates 185 days per year with the school day lasting 7 hours (i.e., from 8:00 a.m. to 3:00 p.m.) (IACS 2010), which means the students are present about 15 percent of the year. To avoid undercounting the nonresident population, it is arbitrarily assumed that there are an additional 600 miscellaneous people are present 10 percent of the time within 1 km of the suburban site. That assumed miscellaneous population covers the potential for IACS student extracurricular activities; IACS parents, volunteers, and visitors being at IACS; and other nonresident activities within 1 km of the suburban site. One of the non-IACS-related activities involves the Vesper Country Club, where nine holes, potentially 36 golfers, caddies, grounds-crew, and such, are within the 1-km radius of the rural site. Table F.4-6 provides the basis for the average nonresident population for the suburban site. Using the direction-independent methodology described in Section F.4.2.2.1, the 173 people associated with the IACS are assumed to be uniformly distributed throughout all 16 sectors, which results in a population estimate of 11 people per sector.

Table F.4-6. Student and staff population for the suburban site

Source	Number of people	Fraction of time present	Average population	Comments
Innovation Academy Charter School (IACS):				
Staff	92	25%	23	Does not account for school breaks.
Students	600	15%	90	185 days at 7 hours per day.
Miscellaneous activities	600	10%	60	Extracurricular activities, parents, visitor, volunteers, and non-IACS activities in the area.
Total IACS:			173	Total average population.
Average per sector			11	Total per sector within 1 km.

Source: IACS 2010, 2011

The IACS is more than 0.5 km from the potential laboratory site, but the population is conservatively assumed to uniformly distributed throughout the 1-km area. Therefore, the population per segment is calculated by multiplying the 11 people per sector by the ratio of the segment area in each annular ring to the total sector area. Table F.4-7 provides the segment areas, the total sector area, and the population in each segment.

Table F.4-7. Segment-averaged student and staff population by annular ring—suburban site

	Annular ring (km)										Total
	0.03 ^a to 0.1	0.1 to 0.2	0.2 to 0.3	0.3 to 0.4	0.4 to 0.5	0.5 to 0.6	0.6 to 0.7	0.7 to 0.8	0.8 to 0.9	0.9 to 1.0	
Segment area (km ²)	0.0018	0.0059	0.0098	0.014	0.018	0.022	0.026	0.029	0.033	0.037	0.20
Population per segment	0.10	0.32	0.54	0.76	0.97	1.2	1.4	1.6	1.8	2.1	10.8

a. The NEIDL facility has an exclusion fence at 0.03 km and it is assumed that a similar exclusion fence would be used at all sites. Therefore, estimates are not provided for distance less than 0.03 km.

F.4.3.3.3 Rural Site

As shown in Figure F.4-3, the area surrounding the rural site is largely forested and protected land with a low nonresident population density. The largest nonresident population within 1 km of the rural site is associated with the Nature's Classroom, which now operates what was previously the BU Sargent Center for Outdoor Education (BU 2009). Nature's Classroom offers various 6-day and 13-day summer camp programs from July 3 through August 12 (Nature's Classroom 2011) with a capacity of 200 students (BU 2009). This 40-day period means that students would be at the facility less than 15 percent of the year. To avoid undercounting the nonresident population, it is arbitrarily assumed that there are an additional 200 miscellaneous people present 10 percent of the time within 1 km of the rural site. This assumed miscellaneous population covers the presence of parents and visitors at Nature's Classroom, and other nonresident activities within 1 km of the rural site. Table F.4-8 provides the estimates of the average nonresident population for the rural site.

1 Figure F.4-3. Rural site location.

2

3 Source: NIH 2007

Table F.4-8. Student and staff population for the rural site

Source	Number of people	Fraction of year present	Average population	Comments
Nature's Classroom:				
Staff	15	25%	4	Program only covers 11% of year.
Students	200	15%	30	Program only covers 11% of year.
Miscellaneous activities	200	10%	20	Includes parents and other activities in the area.
Total IACS:			54	Total average population.
Average per sector			3.4	Total per sector within 1 km.

Source: BU 2009; Nature's Classroom 2011

The Nature's Classroom facility is more than 0.5 km from the potential laboratory site, but the students would be hiking throughout the area, so the nonresident population is conservatively assumed to uniformly distributed throughout the 1-km area. Therefore, the population per segment is calculated by multiplying the 3.4 people per sector by the ratio of the segment area in each annular ring to the total sector area. Table F.4-9 provides the segment areas, the total sector area, and the population in each segment

Table F.4-9. Segment-averaged student and staff population by annular ring—rural site

	Annular ring (km)										Total
	0.03 ^a to 0.1	0.1 to 0.2	0.2 to 0.3	0.3 to 0.4	0.4 to 0.5	0.5 to 0.6	0.6 to 0.7	0.7 to 0.8	0.8 to 0.9	0.9 to 1.0	
Segment area (km ²)	0.0018	0.0059	0.0098	0.014	0.018	0.022	0.026	0.029	0.033	0.037	0.20
Population per segment	0.03	0.10	0.17	0.24	0.30	0.37	0.44	0.50	0.57	0.64	3.4

a. The NEIDL facility has an exclusion fence at 0.03 km and it is assumed that a similar exclusion fence would be used at all sites. Therefore, estimates are not provided for distance less than 0.03 km.

F.4.3.3.4 Vehicle Occupants

Another nonresident group considered is vehicle occupants traveling in the vicinity of each site. The vehicle occupant is estimated for each of the three sites in the following sections.

F.4.3.3.4.1 Urban Site

The urban site is surrounded by a high traffic area. The Massachusetts Department of Transportation (MDOT) reports vehicle counts for major highways. Unfortunately, MDOT data are not available for all roadways surrounding the site. The highest traffic area within 1 km is the quadrant northeast of the site,

which contains I-93 (Southeast Expressway), the Massachusetts Avenue Connector, and frontage roads. The other three quadrants are busy, but they do not contain as much traffic as the northeastern quadrant. Because sufficient data are available to estimate the traffic in the northeastern quadrant and that is the busiest quadrant, the vehicle occupancy rate for all quadrants is assumed to be the same as the rate for the northeastern quadrant. Table F.4-10 provides the basis and results of the estimate for each roadway and the totals.

Table F.4-10. Average vehicle occupants per sector within 1 km of the urban site

	I-93	Mass. Ave. Connector and Frontage Rd.	Total
24-hr vehicle count	180,700 ^a	180,700 ^a	361,400
Average hourly (vehicles)	7,529	7,529	15,058
Assumed speed (km/hr)	72	72	72
Vehicle per km	104	104	208
Roadway distance within 1 km	2	2	4
Total vehicles in four sectors within 1 km	208	208	416
Occupants per vehicle	2	2	2
Vehicle occupants in four sectors	416 ^b	416 ^b	831
People per sector			208

a. MDOT 2011

b. DOE 2010

The majority of the vehicle traffic is not in close proximity to the site, so assuming that 208 people are distributed uniformly throughout the area is conservative. Table F.4-11 provides the area of a segment in each annular ring, which was used to allocate the 208 people.

Table F.4-11. Segment-averaged nonresident population by annular ring—urban site

	Annular ring (km)										Total
	0.03 ^a to 0.1	0.1 to 0.2	0.2 to 0.3	0.3 to 0.4	0.4 to 0.5	0.5 to 0.6	0.6 to 0.7	0.7 to 0.8	0.8 to 0.9	0.9 to 1.0	
Segment area (km ²)	0.0018	0.0059	0.0098	0.014	0.018	0.022	0.026	0.029	0.033	0.037	0.20
Vehicle occupants per segment	1.9	6.2	10	15	19	23	27	31	35	40	208

a. The NEIDL facility has an exclusion fence at 0.03 km and it is assumed that a similar exclusion fence would be used at all sites. Therefore, estimates are not provided for distance less than 0.03 km.

F.4.3.3.4.2 Suburban Site

The suburban site is in a low vehicle traffic area, especially relative to the urban site. As shown in Figure F.4-4, three roadways are within 1 km of the suburban site; namely, Route 3A (Middlesex Road), Route

113 (Pawtucket Boulevard), and Dunstable Road. The other roadways within 1 km are minor roadways that distribute traffic from those three roadways but do not bring additional traffic into the area.

Figure F.4-4. Roadways within 1 km of the suburban site.

The average number of vehicles associated with each of the three roadways was estimated using the methodology described in Section F.4.2. Table F.4-12 provides the basis and results of the estimate for each roadway and the totals.

Table F.4-12. Average vehicle occupants per sector within 1 km of the suburban site

	Rt. 3A ^a	Rt. 113 ^b	Dunstable Road	Total
24-hr count (vehicles)	8,400 ^c	5,300 ^c	2,900 ^c	16,600
Average hourly (vehicles)	350	221	121	692
Assumed speed km/hour)	64	64	64	64
Vehicle density (vehicles per km)	5.4	3.4	1.9	10.7
Assumed roadway distance within 1 km (km)	2	1	2	5
Total vehicles within 1 km (vehicles)	10.9	3.4	3.8	18
Occupants per vehicle (people/vehicle) ^d	2 ^d	2 ^d	2 ^d	2^d
Vehicle occupants in 16 sectors (people)	21.7	6.9	7.5	36
Average over 16 sectors (people)				2.3

a. Route 3A, Middlesex Road, south of Westford Street.

b. Pawtucket Boulevard south of Forst Road.

c. MDOT 2011

d. DOE 2010

As shown in Figure F.4-4 both Route 113 and Dunstable Road are beyond 0.5 km of the site, and only a small portion of Route 3A is within 0.5 km of the site. Therefore, the vehicle occupants are almost totally beyond 0.5 km from the site. While the vehicles are mostly beyond 0.5 km from the site, the 2.3 people per sector are assumed to be uniformly distributed throughout the sector. That is a conservative assumption because the level of exposure decreases with distance (see Section F.8), so assuming that occupants are closer than they actually are tends to overstate exposures. Table F.4-13 provides the area of a segment in each annular ring and the number of people per segment based on that allocation by area.

Table F.4-13. Segment-averaged vehicle occupants by annular rings—suburban site

	Annular ring (km)										Total
	0.03 ^a to 0.1	0.1 to 0.2	0.2 to 0.3	0.3 to 0.4	0.4 to 0.5	0.5 to 0.6	0.6 to 0.7	0.7 to 0.8	0.8 to 0.9	0.9 to 1.0	
Segment area (km ²)	0.0018	0.0059	0.0098	0.014	0.018	0.022	0.026	0.029	0.033	0.037	0.20
Vehicle occupants per segment	0.02	0.07	0.11	0.16	0.20	0.25	0.29	0.34	0.38	0.43	2.3

a. The NEIDL facility has an exclusion fence at 0.03 km, and it is assumed that a similar exclusion fence would be used at all sites. Therefore, estimates are not provided for distance less than 0.03 km.

F.4.3.3.4.3 Rural Site

The rural site is in a very low vehicle traffic area, especially relative to the urban site. As shown in Figure F.4-5, only two roadways are within 1 km of the rural site; namely, the Windy Row Road and the Sargent Camp Road.

Figure F.4-5. Roadways within 1 km of the rural site.

The average daily vehicle counts for the Windy Row Road and Sargent Camp Road are not available in the New Hampshire Department of Transportation database (NHDOT 2011), so an alternate approach was used to estimate the vehicle counts. Many of the roadways for which traffic counts are available are state or national highways, and they have higher traffic levels than the minor roads. Traffic counts are available for Spring Road, which is south of the site and connects Route 137 to Windy Row Road, as does the Sargent Camp Road. The traffic count for Spring Road in 2008 was 240 vehicles per day (NHDOT 2011). The traffic count for Windy Row Road and Sargent Camp Road are expected to be similar to Spring Road. To ensure that the traffic count is not underestimated, a value of 1,000 vehicles per day is assumed for both Windy Row Road and Sargent Camp Road. Table F.4-14 provides the basis and results of the estimate for each roadway and the totals.

Table F.4-14. Average vehicle occupants per sector within 1 km of the rural site

	Windy Row Road	Sargent Camp Road	Total
Assumed 24-hr count (vehicles)	1,000 ^a	1,000 ^a	
Average hourly (vehicles)	42	42	83
Assumed speed (km/hour)	64	64	64
Vehicle density (vehicles per km)	0.65	0.65	1.3
Assumed roadway distance within 1 km (km)	2	1	3
Total vehicles within 1 km (vehicles)	1.3	0.6	2
Occupants per vehicle (people/vehicle)	2 ^a	2 ^a	2
Vehicle occupants in 16 sectors (people)	2.6	1.3	3.9
Average over 16 sectors (people)			0.24

a Source: NHDOT 2011

b Source: DOE 2010

While most of the rural roadways are more than 0.5 km from the site, the 0.24 person per sector is assumed to be uniformly distributed throughout the sector. Table F.4-15 provides the area of a segment in each annular ring and the number of people per segment based on the allocation by area.

Table F.4-15. Segment-average vehicle occupancy by annular ring for the rural site

	Annular ring (km)										Total
	0.03 ^a to 0.1	0.1 to 0.2	0.2 to 0.3	0.3 to 0.4	0.4 to 0.5	0.5 to 0.6	0.6 to 0.7	0.7 to 0.8	0.8 to 0.9	0.9 to 1.0	
Segment area (km ²)	0.0018	0.0059	0.0098	0.014	0.018	0.022	0.026	0.029	0.033	0.037	0.20
Vehicle occupants per segment	0.00	0.01	0.01	0.02	0.02	0.03	0.03	0.04	0.04	0.05	0.24

a. The NEIDL facility has an exclusion fence at 0.03 km, and it is assumed that a similar exclusion fence would be used at all sites. Therefore, estimates are not provided for distance less than 0.03 km.

F.4.3.4 Population Summary

Table F.4-16 presents a summary of the resident and nonresident population for all three sites. For every segment and for the total, the urban site population is considerably greater than the population of the suburban site. For the urban site, the resident population is the largest contributor to the total population; however, the BU/BMC population is the dominant contributor within 0.5 km. For most annular rings and for the total, the suburban population is greater than the population of the rural site.

Table F.4-16. Summary of the segment-averaged population by annular ring for the three sites

Population group	Annular ring (km)										Total
	0.03 ^a to 0.1	0.1 to 0.2	0.2 to 0.3	0.3 to 0.4	0.4 to 0.5	0.5 to 0.6	0.6 to 0.7	0.7 to 0.8	0.8 to 0.9	0.9 to 1.0	
Urban:											
Residents	0.000	5.1	26	133	68	155	138	219	275	176	1,194

a. The NEIDL facility has an exclusion fence at 0.03 km, and it is assumed that a similar exclusion fence would be used at all sites. Therefore, estimates are not provided for distance less than 0.03 km.

F.4.3.5 Variability and Uncertainty

Several assumptions made in this analysis have variabilities and uncertainties associated with them. Table F.4-17 below lists the major assumptions, discusses the variability and uncertainty, and assesses the extent of conservatism or non-conservatism.

Table F.4-17. Summary of key variabilities and uncertainties

Assumption	Discussion	Potential factor
Use of direction-independent model	The population differs by direction, and that difference varies from annular ring to annular ring. Averaging the population over the segments in each annular ring ignores the variability. However, the wind blows more frequently toward sectors with low population density, so use of the direction-independent model is slightly conservative (scoping calculations showed that conservatism to be 10% to 20%).	Slight conservatism overall
Census data were updated to 2009 rather than 2010 for all sites	Retaining the 2009 PEP increases rather than using the 2010 updates results in a slightly higher resident population estimate (4.5% for urban, 0.0% for suburban, and 1.4% for rural sites).	Slight conservatism (< 4.5%)
Future changes in the general population are not included for any site	Population projections for 2030 are available but are not used because the statewide factor does not reflect real differences between the sites and the change would not be large (for additional details, see Section 2.3).	Slight non-conservatism (1.2% to 26.6%, depending on site)
Effect of a new laboratory on suburban and rural sites	As discussed in Section 2.3, this could have a large effect on the more-distant surrounding population, but it would have a minor effect on the population within 0.5 km. Because the exposure level decreases with distance, the effect is muted.	Non-conservatism
Use of the BU and BMC population for all sectors of the urban site	The BU and BMC nonresident estimates are conservative, and those values are used as the basis for all sectors rather than attempting to estimate the nonresident population for all sectors. Using the 5-sector BU and BMC population for all 16 sectors could result in an overestimate of the population by a maximum possible factor of about 3. However, there are nonresidents in the other sectors so the conservatism is less.	Large conservatism for <0.5 km (perhaps factor of 2) at the urban site
Vehicle occupant estimates	The total number of vehicles and occupants per vehicle are overestimated, as discussed in Section F.4-3.3.	Large conservatism for vehicle count, but minor effect on overall population
Vehicle proximity to site	The vehicle occupants are assumed to be uniformly distributed, even though there are few vehicles within 0.5 km of the sites. This results in a much larger exposure level for the average vehicle occupant than would actually result.	Large overestimate in exposure to vehicle occupants

In summary, the overall urban nonresident population estimate is expected to significantly overstate the population within 0.5 km because the high BU and BMC population density was assumed to be the average for all sectors. That intentional overestimate of the population was used to avoid the need to estimate the population in all directions and because the analyses are being performed in a direction-independent manner. The overall suburban and rural nonresident populations might be non-conservative (i.e., underestimate the population). Because the purpose of the RA is at least partially to determine whether the risks would be significantly different if the laboratory were built at a lower population site,

the underestimate bias for the suburban and rural sites will tend to overstate the differences. The suburban and rural site populations might be underestimated, but the extreme difference between the sites and the urban site overwhelms this bias.

F.5 AIRBORNE DISPERSION ANALYSIS

F.5.1 Introduction

This calculation determines the atmospheric dispersion factor (χ/Q or chi over Q) for the NEIDL facility at the Boston site and the two alternate sites. χ/Q , as described later in this report, is the time-integrated air concentration at a given downwind location divided by the source strength of the plume. It typically is expressed in units of seconds per cubic meter (s/m^3). The calculation relies on the requirements and guidance issued by DOE to generate atmospheric dispersion factors suitable to use in a DOE nuclear facility documented safety analysis, and by extension into the risk analysis for the NEIDL. The results of that calculation, together with the source term calculations can provide an estimate of pathogens to a receptor at a given distance from the NEIDL facility, in a postulated accident scenario. Specifically, χ/Q is one term in the equation to estimate downwind dose to a receptor ($Dose = Source\ Term \times \chi/Q \times Breathing\ Rate$). As stated in *Recommendations for the Preparation of Environmental Assessments and Environmental Impact Statements* (DOE 2004), an accident is, “an unplanned event or sequence of events that results in undesirable consequences.”

The MELCOR Accident Consequence Code System, Version 2 (MACCS2) and POSTMAX computer codes were used. MACCS2 is listed in the DOE Central Registry or *toolbox*, and DOE has issued a code guidance document [DOE-EH-4.2.1.4 (DOE 2004a)]. MACCS2 is DOE/Nuclear Regulatory Commission sponsored code that has been used widely in support of probabilistic risk assessments (PRAs) for the nuclear power industry and for consequence analyses for safety documentation throughout the DOE complex. The MACCS2 module used performs all the calculations pertaining to atmospheric transport, dispersion, and deposition, as well as the decay that occurs before release and while the material is in the atmosphere. POSTMAX is a code developed at Los Alamos National Laboratory to facilitate calculation of site-specific consequence metrics from MACCS2 output files. The codes and the parameters used in the analysis are explained later in the calculation.

In addition to calculating 95th percentile χ/Q values, the 50th percentile was also calculated using the guidance in DOE 2002:

Specifically, avoid compounding conservatisms – evaluating a scenario by using conservative values for multiple parameters will yield unrealistic results.

For example, in air dispersion modeling, it is nearly always unrealistic to assume only extremely unfavorable meteorological conditions; prevailing (median) meteorological conditions generally should be used. In exceptional cases (e.g., when there is heightened controversy regarding accident risks or to enable a comparison with analysis in another document), it would be appropriate to estimate and present accident consequences for both median conditions and unfavorable conditions. Median conditions are often defined by using 50% meteorology, which represents plume concentrations that are not exceeded 50% of the time for a given direction and distance or receptor location, and are often characterized by stability class D and moderate wind speeds. ... Unfavorable conditions are often defined using 95% meteorology, which represents plume concentrations that are not exceeded 95% of the time, and are often characterized by stability class F and low wind speeds.

To be consistent with the above guidance, the median (50th percentile) results were calculated and reported in addition to the 95th percentile results.

When the airborne dispersion analyses were performed, the maximum distance to be included in the analysis was not known, so the calculations were performed to a distance of 20 km. As discussed in Section F.4, the exposure calculations are performed to a distance of only 1 km, so not all the results of this calculation were used in the analyses.

F.5.2 Methodology

The U.S. Environmental Protection Agency (EPA), DOE, and the Nuclear Regulatory Commission have specified in various handbooks, guidance, and standards the use of Gaussian Plume models for the modeling of downwind concentrations of hazardous constituents resulting from an accidental release. In addition, the Defense Threat Reduction Agency also uses a basic Gaussian Plume model to provide estimates of potential down-wind concentrations of biological materials resulting from a release. Because NIH has no standard model or guidance for performing atmospheric dispersion analysis, atmospheric transport modeling using a standard Gaussian Plume approach was used, on the basis of the above government agencies recommendations and standards, to address the potential impacts from the inadvertent release of specified biological agents from the NEIDL. Similar evaluations of the transport of bacterial and viral pathogens have been made using the Gaussian Plume model. For example,

- The 1979 anthrax outbreak in Sverdlovsk, Russia, was modeled using a Gaussian Plume model together with meteorological conditions at the time to conclude that the most likely source of the anthrax release was from a nearby military facility (Meselson et al. 1994).

- Garner 1995 describes the use of a Gaussian Plume model to “the factors affecting the spread and dispersion of virus plumes.” The report states that some of the advantages of using this model are
 - It produces results that agree with experimental data;
 - It is relatively straightforward to perform the calculations;
 - It is conceptually appealing;
 - It is consistent with the random nature of turbulence;
 - It is compatible with input weather observations that are readily available; and
 - Results can be obtained quickly to satisfy the demands of emergency decision-making.

The report goes on to state some limitations as

- Distances past 10 km from the source result in less predictable results
- The model must be modified for non-flat terrains (this was done for the MACCS2 code as described below in section 2.1)
- Vertical dispersion might not provide results that are as good as horizontal dispersion (this is not a significant effect for the results provided by MACCS2 for this analysis, which are for ground-level receptors)

Off-site dispersion calculations were performed using a pair of computer codes, the MACCS2 code, and the POSTMAX dispersion analysis postprocessor code. The methodology can be summarized as

1. MACCS2 calculates the ground-level air concentration:
 - a. For each hour of the year,
 - b. At the specified distances surrounding the release point,
 - c. Using the historical weather conditions.
2. For χ/Q calculations, POSTMAX calculates
 - a. The ground-level air concentration for the maximally exposed off-site individual for each hour of the year, and
 - b. The cumulative distribution function for the ground-level air concentration.
3. From the 95th and 50th percentile ground-level air concentration (and other MACCS2 input values), the 95th and 50th percentile atmospheric dispersion factors (χ/Q) is calculated.

A single year of site-specific meteorological data was obtained for each of the three comparable locations; 5 years of data were obtained for the Boston site for comparison to the single year of data to confirm there were no major discrepancies. The method used to derive the 95th percentile is consistent with the statistical treatment of calculated χ/Q (the normalization of the distribution of spores/particles/and such in

the air, χ , to the spore/particle source strength, Q) values described in Regulatory Position 3 of Nuclear Regulatory Commission Regulatory Guide 1.145 (RG 1.145) for atmospheric dispersion modeling at nuclear power plants. That approach has been adopted for performing the atmospheric dispersion calculations supporting this NEIDL risk assessment.

Gaussian Plume models, such as MACCS2, differ from a single plume model in that the weather meteorological data for an entire year can be used to obtain representative values for the time-integrated dispersion factor, χ/Q , for a given location of a release. That is in contrast to a snapshot in time of χ/Q from just one data set. For example, rain might or might not occur during an actual release; therefore, washout might or might not be a factor in the χ/Q for a plume. The Gaussian model, however, can take into account actual rain duration and rain rate over every hour of a year and integrate the results in a cumulative probability distribution function to determine realistically bounding values of χ/Q (e.g., the 95th or 50th percentile values) for a given distance (x) from the point of release. That is not to say that just because the resulting 95th or 50th percentile χ/Q for one site A is lower than another site B, that if an actual release occurred, the χ/Q at site A will always be lower than site B.

Extreme weather events, such as high winds that disperse pathogens farther (but necessarily more diluted as a result), can always happen. However, using this methodology, results in reasonable and defensible dispersion factors for each site because the calculation methodology uses a year's worth of hourly averaged meteorological data for each site, then calculating a χ/Q . The primary output of the MACCS2 model for the purposes of this risk assessment is χ/Q , which is concentration normalized by the source strength. Therefore, for the purposes of this discussion, the absolute value of source strength does not matter.

The methodology is explained further below.

F.5.2.1 MACCS2 Computer Code

The MACCS2 computer code is described and explained in the following documents:

- NUREG/CR-6613 *Code Manual for MACCS2: Volume 1, User's Guide*, Sandia National Laboratory, SAND97-0594, May 1998
- NUREG/CR-4691 *MELCOR Accident Consequence Code System (MACCS), Model Description*, Sandia National Laboratory, SAND86-1562, February 1990
- DOE-EH-4.2.1.4-MACCS-Code Guidance, *MACCS2 Computer Code Application Guidance for Documented Safety Analysis, Final Report*, U.S. Dept. of Energy, June 2004 (DOE 2004a)

The MACCS2 code contains three separate modules to perform transport and dose calculations: ATMOS, EARLY, and CHRONC. For each module used, a different input file is created. Also, depending on the module used, MACCS2 can require other input files such as meteorological data files, a site data file containing the population distribution around the postulated release location, and a nuclide dose-conversion factor file. In this calculation, only the ATMOS module is used and the only additional input files required (for MACCS2) are the meteorological data files. Execution of the EARLY and CHRONC modules is suppressed by setting input variable ENDAT1 (in data group OC) to .TRUE.

The ATMOS module performs all the calculations pertaining to atmospheric transport, dispersion, and deposition, as well as the decay that occurs before release and while the material is in the atmosphere. The results of the calculations are stored for use by the EARLY and CHRONC modules when those modules are included as part of the calculation. The downwind transport of up to four plumes can be modeled. In addition to the air and ground concentrations, ATMOS stores information on wind direction, plume arrival and departure times, and plume dimensions.

The ATMOS module of MACCS2 offers several methodology options. Those options, and their implementation in this calculation, are explained below. The explanations include some discussions of the MACCS2 input parameters.

F.5.2.1.1 Dispersion Parameters

The Gaussian Plume model of atmospheric dispersion uses spatially dependent dispersion parameters, σ_y and σ_z [for a discussion on the terms, see the Code Manual for MACCS2 (NUREG/CR-6613)]. The dispersion parameters can be supplied to MACCS2 in two different ways: as power-law functions or in the form of pre-calculated tables for a lookup-table algorithm.

The power-law functions developed by Tadmor and Gur are used in this calculation for the base case and the ground-level release case. This is consistent with the guidance in DOE-EH-4.2.1.4 (DOE 2004a) for distances > 100 m from the source. For comparative purposes, the base case was rerun with the dispersion coefficients from Jülich, Germany (hereafter referred to as Jülich). The release height in the Jülich test series (50 m) closely resembles that of the NEIDL stack height (51.5 m); the surface roughness around the NEIDL (urban, which correlates to roughness lengths on the order of 1 to 2 m) is bounded by that of the Jülich test series (0.5 to 3 m); the range of the Jülich test series was 11 km which is greater than the 10 km distance chosen for the last radial zone modeled; and the sampling height from Jülich was between 1–250 m, which is adequate for both ground level and elevated receptors. Per Till and Meyer

(Till and Meyer 1983, p. 2-34), “the diffusion parameters measured in Jülich should be applicable to sites with medium to higher surface roughness, which is due to settlements, vegetation, and other ground obstacles.”

F.5.2.1.2 Surface Roughness

The Tadmor and Gur dispersion parameters are based on a surface roughness of 3 cm. For surface roughness lengths (z_0) other than 3 cm, the vertical standard deviation of plume spread is calculated by (DOE-EH-4.2.1.4, p 4-12, p. A-19):

$$\sigma_z(x, z_0) = (z_0/3\text{cm})^{0.2} \times \sigma_z(x, 3\text{cm})$$

While MACCS2 does not specifically have an input variable for surface roughness, it does have a scaling factor for σ_z (variable ZSCALE). Therefore, the most appropriate method for modeling the local surface roughness is to set ZSCALE to $(z_0/3\text{cm})^{0.2}$, when using the Tadmor and Gur dispersion parameters. No vertical scaling factor was used for the comparative case with the Jülich dispersion parameters as the roughness length from the test series was on the order of 1–2 m.

F.5.2.1.3 Dry Deposition

MACCS2 has the option of depleting the plume because of dry deposition (i.e., gravitational settling) of particles from the plume. The dry deposition model is used when variable DRYDEP is .TRUE. This calculation recognizes dry deposition as a realistic phenomenon for particulates. Dry deposition is not appropriate for gaseous releases.

F.5.2.1.4 Wet Deposition

MACCS2 has the option of depleting the plume because of wet deposition, that is, as the raindrops, for example, fall through the plume, the raindrops strike and collect particles from the plume. The wet deposition model is used when variable WETDEP is .TRUE. (and not used when WETDEP is .FALSE.). This analysis does not include wet deposition, as recommended in DOE-EH-4.2.1.4 (p. 4-11, 4-41).

F.5.2.1.5 Buoyant Plume Rise

MACCS2 will calculate the buoyant plume rise for heated releases, such as during a fire. For MACCS2 to calculate the buoyant plume rise, the user specifies the plume heat. The cases performed in this analysis conservatively do not consider the plume to be heated.

F.5.2.1.6 Plume Rise

A plume rise model is incorporated into MACCS2. There are three basic components of the model: (1) entrainment of buoyant plumes in a building wake, (2) plume rise under unstable and neutral conditions (classes A to D), and (3) plume rise under stable conditions (classes E to F).

In the cases of this analysis, the building wake portion of the plume rise model is suppressed by setting variable SCLCRW to 1.0E6 (the maximum value). MACCS2 allows the user to modify the plume rise model with separate scaling factors for the unstable and neutral conditions (classes A to D), and the stable conditions (classes E to F). This analysis uses the plume rise model as programmed by setting the scaling factors (variables SCLADP and SCLEFP) to 1.0.

Figure F.5-1 below illustrates some of the above phenomenon. The figure is taken from DOE-EH-4.2.1.4 (p. A-9) and modified to make it applicable to any type of facility rather than specifically to nuclear facilities. The figure graphically shows the phenomena of turbulence, plume rise, dry deposition and wet deposition (i.e., washout).

Figure F.5-1. Basic processes occurring during accidental releases and dose pathways.

F.5.2.1.7 Plume Meander

MACCS2 is able to account for the effect of meander during transport of the plume. The plume meander model can be turned off by setting variable TIMBAS to the duration of the plume PLUDUR (NUREG-6613, p. 5-18). This analysis conservatively does not include plume meander.

F.5.2.1.8 Wake Effects

Physically, the initial size of the plume is determined by the width and height of the building wake. The base case in this analysis credits that phenomenon by using the as-built NEIDL dimensions. For the seismic event case, where the building is assumed not to survive, this analysis conservatively assumes a source point release. To model a point source release with MACCS2, the building height (variable BUILDH), the initial σ_y (variable SIGYINIT), and the initial σ_z (variable SIGZINIT) are set to their minimum input values (1.0, 0.1, and 0.1 m, respectively).

F.5.2.1.9 Decay

DOE-EH-4.2.1.4 recommends accounting for decay and in-growth if the initial radionuclides involved at the start of the accident condition have half-lives shorter than the travel time to the receptor. In the case of this calculation, decay of biological pathogens is conservatively not considered over the short travel times to the receptors. A long half-life isotope (i.e., C-14) was used to eliminate decay effects for this calculation. C-14 has a half-life of 5700 years; thus, for the relatively short release and transport times, this results in essentially no decay. Any credit for the actual decay of pathogens in the atmosphere will be included in the application of the data in other calculation packages, as appropriate.

F.5.2.1.10 Statistical Sampling

MACCS2 is capable of statistically sampling the input meteorological data file to analyze the plume behavior. However, analyses with POSTMAX do not use statistical sampling. Instead, each hourly observation in the meteorological file is analyzed by MACCS2 to generate the appropriate input for POSTMAX. MACCS2 samples (analyzes) every hour of the year when variable meteorology code (METCOD) is 5 and variable number of samples (NSMPLS) is 24.

F.5.2.2 POSTMAX Computer Code

The POSTMAX computer code was developed at LANL to facilitate calculation of site-specific χ/Q values. Software quality assurance for POSTMAX is documented in LA-UR-09-1601, *POSTMAX V2.0 User's Guide*, Raymond F. Sartor, February 2009 (Sartor 2009).

The desired POSTMAX result is the 95th percentile ground-level concentration for a receptor at the site boundary. Each execution of MACCS2 calculates a ground-level concentration for each hourly weather observation at the spatial grid (distances) specified. The POSTMAX computer code takes the MACCS2 results and (1) statistically accounts for the distance to the site boundary, and (2) builds the cumulative distribution, which identifies the 95th percentile value.

For each MACCS2 input file, POSTMAX generates 8760 ground-level concentration values corresponding to the site boundary (or maximum value beyond the site boundary). Those ground-level concentration values are not for one specific site boundary location, but rather for the worst public location for each hour of the year, i.e., the site boundary location for the wind direction of the hour. The cumulative distribution for the year is developed by sorting the ground-level concentration values in ascending order. POSTMAX can combine the results of up to 6 years. POSTMAX, in effect, combines the results from separate years into one table and sorts the table.

F.5.2.3 Limitations

F.5.2.3.1 Meteorological Data

Hourly averaged values for wind speed, wind direction, atmospheric stability, and precipitation rate were obtained from NOAA's National Climatic Data Center online and then placed into the required year-long weather files format specifically for use in MACCS2 from nearby weather stations with available data for each site. The weather stations chosen were as shown in Table F.5-1, because no meteorological data were found exactly at the three alternate sites that were compatible with the MACCS2 format.

Table F.5-1. Towers used for meteorological data

Site	Meteorological tower used	Approximate distance between site and tower
Urban site (Albany Street, Boston)	Boston Logan Airport	4 miles
Suburban site (Tyng Road, Tyngsboro, MA)	Fitchburg Municipal Airport	18 miles
Rural site (Sargent Camp Road, Hancock, NH)	Jaffrey Municipal Airport	9 miles

The weather conditions at the time of an actual release cannot be predicted. Therefore, the methodology presented below presents both the 50th and 95th percentile χ/Q values to address a broad range of potential conditions.

F.5.2.3.2 Safety Advisory 2009-05

In August 2009, the DOE Office of Health, Safety and Security issued Safety Advisory 2009-05, *Errors in MACCS2 χ/Q Calculations* [DOE 2009]. That advisory identified a problem and corrective action when using a lookup table for sigma-y and sigma-z. Because this calculation uses the power law formula for sigma-y and sigma-z, that issue is not relevant to this calculation. The advisory also recommends turning off the DAY_NIGHT mixing height option when using version 2.4. Because this calculation uses version 1.13.1, that recommendation is not relevant to this calculation.

F.5.2.4 Assumptions

F.5.2.4.1 Release Methodology

Assumption: The material is released from the facility ventilation exhaust stack for operational events and from the ground level as a single point source for the seismic event case.

Justification: This assumption for releases from the exhaust stack is realistic for operational events in which the building integrity and the ventilation system is maintained. For a seismic event, the building is conservatively assumed to fail (e.g., collapse) and the release cannot be assumed to be through the ventilation stack; thus, it is conservative to assume a ground-level point source release because multiple release locations or an area or volume release would disperse and dilute the release.

F.5.2.4.2 Release Duration

Assumption: The release duration is one hour (3,600 seconds).

Justification: The final χ/Q value is calculated from the time-integrated air concentrations given by MACCS2. Because the air concentrations are time-integrated, the release duration does not affect the final χ/Q values. Notice, however, changing the release duration could change the operation of the plume meander model. As stated previously, however, plume meander was turned off, so the value of release duration does not affect the desired results.

F.5.2.4.3 Release Height—Non-buoyant Plumes

Assumption: It is assumed that the plume is buoyantly neutral.

Justification: Buoyancy raises the plume above the ground, which decreases the ground-level concentration and dose consequences. Thus, it is conservative to suppress this option.

F.5.2.4.4 Stability Class

Assumption: Stability class for each hour of the year for each site was determined using the Pasquill stability categories.

Justification: Regulatory Guide 1.23 states that the preferred method for determining Pasquill stability classes is the vertical temperature difference. However, the meteorological data obtained did not have temperature at the recommended heights, so the vertical temperature difference method was unable to be used. Thus, an alternative method to derive the Pasquill stability classes (based on wind speed, insolation and cloud cover) was chosen from available meteorological data is presented in Table F.5-2 (Till and Meyer 1983). The more stable the atmosphere, the less dispersion in the vertical and horizontal directions and, therefore, the higher the concentration of particulates. The atmospheric stability class is a direct input into the MACCS2 model in the meteorological data file. MACCS2 uses stability class in determining plume dispersion using the vertical and horizontal dispersion coefficients σ_y and σ_z .

Table F.5-2. Pasquill stability classes as a function of wind speed, insolation, and cloud cover

Surface wind speed (m/s)	Daytime insolation			Night	
	Strong	Moderate	Slight	Thinly overcast or > 4/8 cloud cover	≤ 3/8 cloud cover
< 2	A	A–B	B	--	--
2-3	A–B	B	C	E	F
3-5	B	B–C	C	D	E
5-6	C	C–D	D	D	D
> 6	C	D	D	D	D

Source: Till and Meyer 1983, Table 2-1

F.5.2.4.5 Building Dimensions

Assumption: If a new laboratory is built at either of the two alternate sites, the building dimensions would be the same as the as-built facility in Boston.

Justification: This assumption is necessary to make meaningful comparisons between the differing topographies and meteorology of the two alternate sites.

F.5.3 Results

F.5.3.1 Description of Cases and Results

The following provides a brief description of the cases run for each of the three cases (i.e., Base Case, Ground-Level Release Case, and Jülich Dispersion Parameters Case). Results are presented for each of

the three sites evaluated (i.e., urban, suburban, and rural sites). The descriptions below correspond to the data presented in the following Tables F.5-3 to F.5-5 and Figures F.5-2 to F.5-5.

Base Case—The first model run (i.e., case) was called the base case; other cases are a variation of this one. As a summary of the above sections on assumptions and inputs, the base case assumed the following: dry deposition velocity of 0.01 m/s; no wet deposition; no buoyant plume (e.g., no fire); an elevated release from the NEIDL exhaust stack; dispersion parameters derived from Tadmor and Gur; and building wake effects turned “on” (e.g., actual NEIDL dimensions used).

As previously described, the base case (and all other cases) was run twice for the Boston site: once using an aggregate of 5 years of meteorological data and once using only one year of meteorological data. For the Boston site, 5 consecutive years of meteorological data were run through MACCS2 and the aggregate 95th percentile χ/Q was determined from POSTMAX. Then the same cases were run with just a single year of meteorological data to compare the results. Results, as shown in tables and graphically in the figures below, indicate that the differences in 95th percentile χ/Q were not significant. Therefore, it was determined that for the two alternate sites (Tyngsboro and Hancock), only single year data was needed because the extra time required for obtaining and formatting meteorological data, running the codes several extra times, and analyzing the extra data did not significantly affect the results.

As can be seen in Table F.5-3 and graphically in Figure F.5-2, the values start on the order of 10 to 5 for receptors close to the release and decrease, as expected, the further one gets from the source. By the time the plume reaches a distance of 20 km, the χ/Q has lowered by two orders of magnitude. Also, the 95th percentile results are approximately a factor of 2 to 4 higher than the 50th percentile results, depending on distance.

Ground-Level Release Case—This case is the same as the Base Case except the source is assumed to be released from the ground instead of from the exhaust stacks. Because this type of release would be realistic under circumstances where the NEIDL facility has failed (e.g., large seismic event), it was also reasonable to assume that building wake effects should be turned off. The 95th percentile χ/Q near the point of release are significantly larger than the Base Case, approximately to two orders of magnitude larger at distances close to the release. This is anticipated as the 95th percentile χ/Q is for a ground-level receptor. At large distances from the release (e.g., 3–4 km) from the release, the 95th percentile χ/Q is lower than the base case; afterwards the two cases approach each other.

1 *Jülich Dispersion Parameters Case*—This case is the same as the Base Case except dispersion parameters
2 derived from the Jülich test series were used instead of from Tadmor and Gur and, as a result, no vertical
3 scaling factor was used. The 95th percentile χ/Q s were generally lower than the Base Case at all distances.
4 However, for the two alternate sites the Jülich Case was able to provide a greater fidelity in χ/Q between
5 distances than the base case.

6
7 Tables F.5-3 through F.5-5 below summarize the results (50th percentile and 95th percentile) for each of
8 the three sites, respectively (i.e., urban, suburban, and rural). Each table shows the results of each of the
9 three cases (Base Case, Ground-Level, and Jülich case) at each distance modeled. Figures F.5-2 and F.5-3
10 graphically present the urban site results for all three cases using both 1 year of meteorological data and 5
11 years of meteorological data. As shown, the results are similar and the 1 year and 5 year data sets. Figures
12 F.5-4 and F.5-5 graphically present the suburban site results for all three cases.

13
14 At the extremely close distance of 25 m, the Ground-Level case shows approximately an order of
15 magnitude higher result than even at 100 m. That is expected given the release and the receptor are both
16 assumed to be at ground level. For the base case and the Jülich case, at the extremely close distance of 25
17 m, the results show approximately the same or sometimes even lower values than the 100-m distance.
18 That is expected because these cases are elevated stack releases, and it takes some plume-travel distance
19 for the plume to spread out enough to reach a ground-level receptor. Because POSTMAX calculates the
20 highest concentration at or beyond the distance requested, often the 100-m distance resulted in higher
21 concentrations because of that phenomenon.

1

Table F.5-3. 1-Year and 5-year χ/Q (s/m³) results—urban site

Distance from release (m)	Base case				Ground-level case		Jülich case

Figure F.5-6 graphically presents the results for all three sites for the Base Case and Figure F.5-7 presents the results for all three sites for the Ground-Level Release Case.

Figure F.5-6. Base case comparison of all three sites.

Figure F.5-7. Ground-level release comparison for all three sites (note: Tyng Ground and NH Ground curves are nearly identical).

F.5.3.2 Wind Speed and Direction

In addition to the above dispersion results, the following information is added for illustrative and comparative purposes. One can take the meteorological data for each of the three sites and determine a 50 and 95 percent wind speed. That data can give one an idea of how fast a resulting plume will travel to a receptor after a postulated release. The slower the wind speed the lower the dispersion, thus, the values for 95th percentile are lower than 50th percentile. The results are shown in Table F.5-6 below:

Table F.5-6. Wind speed for the three sites

Percentile	Boston site	Suburban site	Rural site
50 th	5.1 m/s	3.1 m/s	3.1 m/s
95 th	1.5 m/s	1.5 m/s	1.5 m/s

Similarly, one can determine the probability of the wind to blow from any wind sector and display it on a wind rose. For example, the urban site wind roses for one year of meteorological data and 5 years of meteorological data are presented Figures F.5-8 and F.5-9, and the data are presented in Table F.5-7 for the sectors and percentage of time that the wind blows in a given direction. As can be shown in Figures F.5-8 and F.5-9, the wind roses of 1 year and 5 years of data are similar.

Figure F.5-8. Wind rose for single-year data—urban site.

Figure F.5-9. Wind rose for 5-year data—urban site.

Table F.5-7. Single-year and 5-year wind speed data—urban site

Sector	Percentage of time—1 year of data	Percentage of time—5 years of data
1	8.4%	5.7%
2	3.2%	3.4%
3	3.7%	3.2%
4	5.7%	4.6%
5	6.3%	6.4%
6	3.5%	4.5%
7	1.9%	2.8%
8	1.9%	2.2%
9	7.2%	7.8%
10	7.4%	6.3%
11	9.1%	9.5%
12	5.2%	5.7%
13	15.4%	13.3%
14	9.1%	9.8%
15	7.7%	7.9%
16	4.4%	6.7%

F.5.3.3 Comparison to FEIS Dispersion Calculations

The NEIDL Final Environmental Impact Statement (FEIS) (NIH 2005) included results of a calculation performed for airborne release of 400,000 respirable anthrax spores from the facility exhaust stacks with

varying levels of HEPA filtration (zero HEPAs, 1 stage, and 2 stages). It is noted that the FEIS calculations were performed for highly dispersable anthrax spores, which will not be used at NEIDL, to give upper-bound (*worst-case*) results. The results were presented using multiple methods, including a wind tunnel and EPA's dispersion code ISC-PRIME. Results were most conservative with the wind tunnel, but for comparative purposes here, the results from the MACCS2 code will be compared with the results from ISC-PRIME. The FEIS does not directly report a χ/Q value, but one can be back calculated with the information given. Namely,

- A release of 400,000 spores
- A breathing rate of 30 liters/minute ($5 \times 10^{-4} \text{ m}^3/\text{sec}$)
- A calculated maximum number of spores that might be inhaled is 0.1755 spores (zero HEPA filter case)

$$\text{Thus, the } \chi/Q = \frac{0.1755 \text{ spores}}{400000 \text{ spores} \cdot 5E-4 \frac{\text{m}^3}{\text{sec}}} = 9E-4 \text{ sec/m}^3$$

Similarly, the FEIS reports the case with two HEPA filters intact, which is expected for an operational event, will result in a maximum number of spores of 0.036 spores. This corresponds to a χ/Q of $1.8E-4 \text{ s/m}^3$. Those results are consistent with the MACCS2 Boston site Base Case results presented in Table F.5-8. For example the MACCS2 results for a receptor 100 m away is a χ/Q of $4.01E-5 \text{ sec/m}^3$. The results are very close given the difference in the numerical methods (computer codes) chosen and the difference in assumptions. For example, the FEIS assumes an elevated release with an elevated receptor, while the MACCS2 model assumes an elevated release with a ground-level receptor.

Also, for illustrative purposes, if one back-calculates the χ/Q using the FEIS most conservative values percentile χ/Q is $3.39E-3 \text{ sec/m}^3$ and the corresponding 50th percentile χ/Q is $4.27E-4 \text{ sec/m}^3$. Thus, while the results between ISC-PRIME and MACCS2 are not directly comparable, they are very close to one another considering uncertainty in any code and difference in assumptions. The above discussion is summarized in Table F.5-8:

Table F.5-8 Comparison of MACCS2/POSTMAX χ/Q (s/m^3) results to FEIS χ/Q results-urban site

Distance (m)	MACCS2 base case (95 th percentile)*	FEIS using ISC-PRIME	MACCS 2 ground-level release (95 th percentile)*	MACCS 2 ground-level release (50 th percentile)*	FEIS wind tunnel
100	4.01E-05	9E-4**	3.39E-03	4.27E-04	1.5E-3
200	3.46E-05		1.12E-03	1.29E-04	

* Using 5 years of meteorological data

** Distance is not given in the FEIS, although it appears to be less than 100 m. For comparative purposes, both the 100- and 200-m MACCS2 values are used.

In addition, one can compare this to the recommended χ/Q value from DOE-STD-1189 (DOE 2008) (p. A-6); namely, assuming no plume buoyancy, F-stability class, 1.0 m/sec wind speed, a small building size of 10 m \times 25 m, and 1 cm/sec deposition velocity, the resulting χ/Q at 100 m is 3.5E-3 s/m³.

F.6 CENTRIFUGE EVENTS

F.6.1 Introduction

Centrifuges use centrifugal force to separate mixtures of materials having differing densities and will be used in the NEIDL to concentrate infectious pathogen particles in suspensions. NEIDL will use a variety of different types of centrifuges ranging from small, bench-top, low-speed microcentrifuges to large, floor-mounted, ultra-high-speed ultracentrifuges (Rarick 2009). Centrifuges can accept a variety of fixed-angle rotors and swinging buckets/cups, intended for different containers and uses. The specific centrifuge and rotor used for any specific task depends on the purpose of the centrifugation.

A pathogen aerosol release resulting from a centrifuge-related event sequence has been selected as a representative event sequence to be analyzed (see Appendix E) for laboratory-associated infections (LAIs). A centrifuge-related event was selected because it is one of the more frequent sources of aerosol releases in the laboratory setting and aerosol releases pose a significant threat to the laboratory workers.

F.6.2 Methodology

This analysis relies on both generic and NEIDL-specific information. *Biosafety in Microbiological and Biomedical Laboratories* 5th ed. (CDC and NIH 2007), referred to as BMBL, provides generic guidance for the biocontainment of pathogens in laboratories of this type. The *Boston University Medical Center Biosafety Manual* (BUMC 2011), referred to as the BUMC Biosafety Manual, and NEIDL-specific SOPs provide NEIDL-specific procedures.

This analysis focuses on centrifuge operations and potential exposures to a pathogen (or pathogens) that could result. The scope of this centrifuge event sequence analysis is defined as follows:

- Activities directly associated with placing containers into centrifuge rotors or buckets/cups, placing the rotor or buckets/cups into the centrifuge, operating the centrifuge, removing the rotor or buckets/cups from the centrifuge, and removing the containers from the rotor or buckets/cups are included.

Note: This analysis does not include activities associated with general pathogen sample handling that might be performed for a variety of purposes. For example, general activities associated with

sample preparation, transfer of pathogens from one container to another, and movement of containers within the various laboratory spaces are not considered here. These general activities are addressed in other event sequence evaluations, as appropriate.

- Centrifuge equipment malfunctions, personnel errors, and loss of utilities (e.g., electricity and ventilation) associated with the centrifuge are included.
- The analysis includes progression of the event sequence from the initiating event through to the point of primary exposure.

Note: This analysis defines the routes of exposure and estimates the number of people exposed, but it does not analyze the health effects from exposures or consider subsequent exposures. The health effects resulting from exposure were evaluated and documented in other calculation packages and reports.

- Aerosol releases from a centrifuge can result in inhalation, ingestion, and direct contact and those three routes of exposure are considered in this RA. Puncture exposures are not relevant for centrifuge releases but are addressed by other analyses.

Note: For this analysis, it is conservatively assumed that a person potentially inhaling, ingesting, or directly contacting a pathogen is exposed regardless of level of exposure.

- The analysis addresses accidental releases only and does not consider malevolent acts, which are addressed in a separate analysis.

It should also be noted that this analysis does not address event sequences where centrifuge operations are only incidental and are not a key part of the incident. For example, this analysis does not consider centrifuge event sequences caused by an earthquake that coincidentally occurs while a centrifuge is in operation. An earthquake has the potential to cause a release independent of the centrifuge operation. These types of circumstances are addressed as part of other event sequence analyses (e.g., earthquake), as appropriate.

A variety of specific analyses have been performed for the centrifuge release scenarios. Rather than attempt to describe the methodology for each portion of the methodology here, the methodology and results are presented together in the following section.

F.6.3 Results

This section presents the results of the analyses. It begins with the process for selection of event sequences to be analyzed and then presents the analyses of those BSL-3 and BSL-4 event sequences.

F.6.3.1 Selection of Event Sequences

Operations associated with centrifuges have the potential to expose workers as a result of aerosol formation and release. The aerosol has the potential of exposing inadequately protected laboratory workers via inhalation to the lungs, direct contact with mucous membranes and eyes, and ingestion via an open mouth while breathing or speaking (Appendix E).

Factors that were considered in the selection of event sequences for analysis include the following:

- *Detection and reporting*—Event sequences that are more likely to be detected and reported are less likely to result in initial infection and secondary transmission because of the response speed and effectiveness of medical intervention. Therefore, event sequences where early or immediate detection was less likely were selected over similar event sequences that are readily detected.
- *Magnitude of release*—Event sequences that result in greater aerosol releases were selected over event sequences with lesser releases. Other factors being the same, event sequences with greater releases will generally result in the greater consequences and are selected preferentially.

The following paragraphs describe some of the event sequences considered and provide a rationale for their selection or dismissal from further consideration.

- *Dropped container while loading rotor*—A container could be dropped during rotor loading, which could produce an aerosol and potentially result in a release. Rotors are required to be loaded in a BSC (BUMC 2011), which is designed to prevent potential aerosols from being released to the room. The drop height while loading or opening a rotor would likely be no greater than the interior height of the BSC. As a result of the low energy imparted to the container, this event is unlikely to result in large aerosol formation or release. Drop of a container while loading a rotor is similar to other container handling events, which are addressed in other analyses. Because of the low aerosol generation and similarity to general handling activities, such an event sequence was *not selected for analysis*.
- *Dropped rotor during transfer*—A loaded and sealed rotor could be dropped when it is being transferred to the centrifuge, or when it is being removed after centrifugation. This is also a relatively low energy event (the screening evaluation assumed a maximum drop of 4 feet) that was considered unlikely to generate large releases, includes two barriers and is similar to other container handling events addressed in other analyses. Therefore, such an event sequence was *not selected for analysis*.
- *Centrifuge explosion*—There have been several instances of centrifuges *exploding* (e.g., the rotor breaking up because of material fatigue, which results in pieces being ejected at high speeds) (AIHA 2010). While that type of event sequence might have the potential to produce a high

aerosol release fraction, the event sequence would be immediately detected and appropriate mitigative measures (e.g., evacuating the area and notifying the Control Center) would be implemented unless the worker is incapacitated. As a result of the high probability of detection, the risk of subsequent transmission was considered minimal, and such a scenario was *not considered further*.

- *Leak/spill inside rotor*—A leak inside the rotor as a result of human error or container leak is a possible event sequence that might not be detected. The event has the potential to generate significant amounts of aerosol, which could be released if the rotor is not properly sealed or if opened outside a BSC in violation of SOPs. As a result of the potential for aerosol generation without detection, such a scenario is *retained for detailed evaluation*.

The event sequence involving a container leak inside a rotor was selected for analysis for both BSL-3 and BSL-4 laboratories because it has the potential to release aerosols without detection. The consequences of this event sequence are considered to bound the consequences of other event sequences (i.e., its consequences are as severe or more severe). The operating experience includes multiple events that involved leakage from containers during centrifugation (see Attachment A of this appendix) and this experience is used as guidance in development of the event sequence. Respiratory protection (i.e., PAPR for BSL-3 and positive-pressure suits for BSL-4) is required when working with any pathogen (BU 2010) and the event sequences must include this requirement.

The centrifuge event sequences selected for analysis are as follows:

- BSL-3 centrifuge event sequence *with full* respiratory protection—This event was selected to determine the adequacy of the respiratory protection during a release.
- BSL-3 centrifuge event sequence *with partial* respiratory protection—This event was selected to determine the potential consequences if a respirator does not provide full protection.
- BSL-4 centrifuge event sequence *with partial* respiratory protection—This event was selected to determine the potential consequences if a positive-pressure suit does not provide full protection. Analysis of a BSL-4 event with full respiratory protection was not selected because there would be no exposure.

Each of those events was analyzed separately in the following sections.

F.6.3.2 BSL-3 Centrifuge Aerosol Release with Full Respiratory Protection

This section addresses an event sequence involving an aerosol release from a centrifuge in the BSL-3 laboratory with full respiratory protection for the laboratory workers involved. This section describes the event sequence, including the biocontainment features, the frequency category, the consequences, including the exposure category, and the potential extent of exposure.

F.6.3.2.1 Event Sequence Description

A series of experiments designed to mimic the potential event sequences in laboratories was conducted by the Health Protection Agency, an independent organization in the United Kingdom, to obtain data on aerosol releases from those events. The experiments included two centrifuge events, one with a fixed-angle rotor and one with a swinging bucket rotor. The event sequence described here was modeled after the fixed-angle rotor experiment because it resulted in higher aerosol releases and, in fact, the fixed-angle rotor centrifuge experiment resulted in one of the highest aerosol releases of any of the experiments performed. While focusing on the fixed-angle rotor event, this analysis is also applicable to and bounds a swinging bucket event (Bennett and Parks 2006).

The hypothetical scenario evaluated for the NEIDL involves the aerosol release of a pathogen from a bench-top centrifuge and is representative of a variety of centrifuge event sequences that could occur in the BSL-3 laboratory. The following describes the initial conditions and the event sequence.

Initial Conditions—The conditions leading up to this event sequence are as follows.

- A bench-top centrifuge is operated with an aerosol-tight rotor lid or swinging bucket cap is operated outside a BSC. This is a common configuration for centrifugation in newly equipped BSL-3 laboratories.
- The primary containers have caps, but not all the caps identified for centrifugation in NEIDL have aerosol-tight seals.
- The centrifuge contains multiple conical tubes collectively containing the typical working volume for the given pathogen suspension being considered (e.g., multiple tubes with a combined volume of up to 150 mL).
- The pathogen suspension contains the maximum concentration for that pathogen that is expected to be used in NEIDL. Lower concentrations are expected to result in correspondingly lower exposures.

- It is assumed that from one to four laboratory workers in the vicinity of the centrifuge at the time of the event sequence. The number of people in a room during centrifugation is not expected to exceed four (BUMC 2009).
- As required, the laboratory workers in the room are wearing BSL-3 dedicated shoes, shoe covers, scrub suits with elastic cuffs, a back-fastening gown, and double gloves (BUMC 2010). This is the minimum PPE required for all BSL-3 activities.
- It is assumed that the workers are wearing respiratory protection (i.e., a PAPR) as required by the SOPs (BUMC 2010).

A number of biocontainment features prevent or mitigate the consequences of this event sequence. The role of each biocontainment feature for this event sequence is shown in Table F.6-1. Section F.2 provides a description of biocontainment features.

Table F.6-1. Exposed group protected by each biocontainment feature—BSL-3 centrifuge aerosol release with full respiratory protection.

Exposed group	Admin. controls		Safety equipment							Facility	
	Procedures	Training	Container	Rotor/buckets	Centrifuge chamber ^a	BSC	PPE	Respiratory protection	Positive-pressure suit	HVAC system	Sealed walls, ceilings, and floors
Laboratory worker	M ^b /P ^c	M/P	M ^e	M/P	- ^d	-	-	M	-	M	-
Facility worker	P	P	M	M/P	-	-	-	-	-	M	M
Public	P	P	M	M/P	-	-	-	-	-	M	M

- a. Centrifuge chambers are not necessarily aerosol-tight and might provide only partial mitigation even when closed. Centrifuge lids provide no mitigation when open, so this is a minor mitigating effect and, therefore, not considered in this evaluation.
- b. M signifies a mitigative feature
- c. P signifies a preventive feature
- d. This biocontainment feature is either not relevant for this event sequence or it does not have a preventive or mitigative role for this exposed group.
- e. The cells with cross-hatching indicate a biocontainment feature that is assumed to fail or have partial performance for this event sequence.

Event sequence description— The event sequence analyzed was modeled in consideration of incidents that have occurred at other facilities (see Attachment A of this appendix) and incident experiments that

have been performed by the Health Protection Agency (Bennett and Parks 2006). The following describe the assumed event sequence and provide the basis for the assumptions:

- A portion of the suspension leaks from the container before or during centrifugation. The leak might be the result of a personnel error or equipment defects, which might include an inadequately sealed container, a defective or missing seal(s) in the lid that is not detected by the worker, use of a leaking container, or a container that cracked during centrifugation. Attachment A of this appendix identifies several incidents involving a container leak associated with centrifugation.
- The suspension leaking into the rotor is assumed to be either the total working volume of the pathogen or 10 mL, whichever is greater. A maximum leakage of 10 mL is used here, consistent with the quantity deemed reasonable by the investigators performing the experiments on which the release calculation is based (Bennett and Parks 2006).
- It is assumed that the centrifuge continues to operate and that the imbalance detection system or operator does not shut off the centrifuge promptly either because (1) the leakage is distributed in a way that does not result in a detectable imbalance, or (2) the imbalance detection system fails.
- The rotor is not aerosol-tight because the seal is either damaged, is installed improperly, or is not installed. This human error is not unexpected at some point in NEIDL operations and is consistent with experiments on which the event sequence is based (Bennett and Parks 2006).
- After centrifugation is completed, the centrifuge chamber door is promptly opened, thereby allowing the aerosol generated to be released from the centrifuge chamber without restriction. This is a conservative assumption (i.e., likely to overstate the result) that is not prevented by procedures. Centrifuge chamber doors are not generally aerosol-tight, but prompt opening of the door increases the release to the room and is consistent with the experiment (Bennett and Parks 2006).
- The laboratory workers remain in the immediate vicinity and are unaware of the aerosol release. No corrective action is assumed to be taken for this event sequence. This is a conservative assumption that is consistent with the failure to detect the leak.
- The HVAC system is operating and has a rate of at least eight air exchanges per hour, which is the minimum design exchange rate (BUMC 2009c). Using the minimum air exchange rate minimizes the aerosol dilution in the room and maximizes worker exposure.

F.6.3.2.2 Frequency Category

The postulated event sequence described above involves an undetected/unreported release because an undetected/unreported event has the greatest potential for secondary transmission to the public. One of the

four centrifuge-related incidents identified in Attachment A was detected but not reported, and the other three were both detected and reported. There was no indication that the workers were wearing or were required to wear respiratory protection during these events. As discussed in Section F.6.2.4.1, the operating incident data is not suitable for use in determining the frequency of this event sequence for several reasons, including the absence of the number of operating hours associated with those incidents (see Section F.1.3).

Modern centrifuges have safety features that minimize the risk of an aerosol release. Those features can include imbalance detection and shutdown circuitry, certified aerosol-tight rotor/bucket seals, incorporation of a fluid containment annulus in the rotor, HEPA-filtered air evacuation systems, and automatic rotor identification systems that prevent operation at speeds beyond the recommendations for the rotor/bucket.

This event sequence requires three distinct events or conditions to occur: (1) a leakage into the rotor, (2) failure of the aerosol-tight rotor seal to contain the aerosol, and (3) a failure to detect or report the incident. If those events or conditions were all independent, the event sequence would be considered to be in frequency category B (1 in 100 to 10,000 years). However, as noted by BMBL (CDC and NIH 2007), “The safety characteristics of modern centrifuges are only effective if the equipment is operated properly.” Because the laboratory worker plays a significant role in the prevention and identification of this event sequence, the sequence is conservatively assigned to the frequency category A (1 in 1 to 100 years).

F.6.3.2.3 Exposure Category

The exposure category for this event sequence is addressed below for each potentially exposed group. *Laboratory worker*—As discussed in Section 3.2.1, it is expected that there will be from 1 to 4 people in the room at the time of a centrifuge aerosol release event, so the exposure category is MEDIUM. All laboratory workers in the room at the time of the event have the potential of being exposed, depending on their location relative to the room air flow.

Facility worker—The BSL-3 HVAC system is a once-through design, so a release in one room will not be circulated to any other portions of the NEIDL and will not expose facility workers in the rest of the facility. Attachment A identifies six HVAC system faults at BSL-3 laboratories. Only one incident, which is assumed to involve an HVAC system failure though not explicitly stated, resulted in exposure. The other five incidents identified in Attachment A did not result in spread of a pathogen, but could have if an

aerosol release of a pathogen had occurred concurrently. In three of the incidents identified in Attachment A, the HVAC systems failed because of a loss of off-site power and failure of the emergency diesel generators to cycle and accept the load.

For a facility worker to potentially be exposed to the centrifuge aerosol release event described above, the HVAC system would need to both fail to purge air from the room and also fail to isolate the room concurrent with a centrifuge release event. Section A.4 of Attachment A provides a summary of several ventilation system failures at biosafety laboratories. Potential HVAC system failures are addressed below:

1. *Loss of HVAC airflow*—The loss of HVAC flow events identified in Attachment A were the result of a loss of offsite power plus the failure of the emergency diesel generators to provide power. Other mechanism can cause a loss of HVAC airflow such as fires or multiple equipment failures, but this evaluation addresses a loss of power because that is the most frequent cause based on the operational data. For all power to be lost to the HVAC fans, the following must occur:

- a. *Loss of off-site power*—NEIDL has four electrical transformers for offsite power with only one or two required for normal operations, depending on the season and the HVAC requirements. Therefore, there is N + 2 redundancy for offsite power (Tetra Tech 2009a, 2009b).

For nuclear power plants, the rate for loss of offsite power is $3.59 \times 10^{-2}/\text{yr}$, which corresponds to $4.1 \times 10^{-6}/\text{hr}$ [$(3.59 \times 10^{-2}/\text{yr}) / (365 \text{ days/yr}) / (24 \text{ hrs/day})$]. (NUREG/CR-6928) If one assumes a 1-hour window for loss of HVAC (i.e., loss of power) and concurrent centrifuge release, the unavailability is defined as follows (NUREG/CR-6823):

$$\begin{aligned}\text{unavailability} &= (\text{outage frequency}) \times (\text{outage duration}) \\ &= (4.1 \times 10^{-6}/\text{hr}) \times (1 \text{ hr}) \\ &= 4.1 \times 10^{-6}\end{aligned}$$

- b. *Failure of emergency diesel generators*—NEIDL has two emergency diesel generators, each of which is capable of providing power to the HVAC blowers (Tetra Tech 2009a, 2009b). For nuclear power plants, the unreliability of emergency diesel generators to supply power is 2.9×10^{-3} per demand (NUREG/CR-6928).
- c. *Loss of both off-site power and emergency diesel generators*—Therefore, on the basis of the nuclear power experience, the conditional probability that off-site power and emergency diesel generators would fail during a 1-hour window of time, for example during an aerosol release from a centrifuge, is 1×10^{-8} [$(4.1 \times 10^{-6}) \times (2.9 \times 10^{-3})$]. On

the basis of that calculation, the loss of all power to the HVAC fans concurrent with a centrifuge aerosol release event is beyond reasonably foreseeable, frequency category D (1 in more than 1 million years).

2. *Loss of HVAC isolation following loss of HVAC airflow*—If the HVAC system is not able to purge air from the laboratories, potentially because of a loss of power as discussed above, the situation would be detected by the NEIDL building automation control systems and appropriate actions would be taken promptly. There are differences between NEIDL BSL-3 and BSL-4 control systems. In the BSL-3 areas, an attempt is made to maintain directional air flow to the extent possible because the isolation dampers are low leakage rather than air-tight dampers. However, if the BSL-3 directional airflow cannot be maintained, the isolation dampers will be closed. In the BSL-4 areas equipped with air-tight dampers, the control system will seal the area on a loss of HVAC. It is estimated failure of the dampers to close on demand is < 0.01 per demand (NUREG/CR-6928) (Tetra Tech 2009, 2009a, 2009b).

A centrifuge-related aerosol release event concurrent with a loss of HVAC flow, loss of HVAC isolation, and flow of contaminated air to uncontaminated areas is beyond reasonably foreseeable, frequency category D (1 in more than 1 million years), as demonstrated by the estimated conditional probability of $< 1 \times 10^{-8}$ (i.e., $1 \times 10^{-8} \times 0.01$) for concurrent loss of off-site power, failure of the emergency diesel generators, and failure to isolate the room.

However, it is also important to consider common-cause failures that would produce both a centrifuge aerosol release and a simultaneous HVAC system fault. Centrifuges are standalone pieces of equipment, and the only common feature they have with the HVAC system is the supply of electrical power, which is unlikely to cause both a centrifuge aerosol release and a failure or reverse-flow of the HVAC system. Because of the independence of the two systems, an infrequent event such as an earthquake is the only common cause that has been identified for this event sequence (the earthquake is analyzed as a separate event).

On the basis of the above evaluation, no reasonable mechanism for exposure of the facility worker was identified, and the facility worker exposure category for a centrifuge aerosol release event is NONE.

Public—Any release from a BSL-3 centrifuge will be drawn into the HVAC system, diluted with air from other portions of the facility (i.e., non-contaminated) and HEPA filtered before discharge. The HVAC system flow rate is 6,900 cubic feet per minute (cfm) for the BSL-3 and the 11,900 cfm for the BSL-4

area (RWDI 2005), thereby reducing the concentration of any entrained pathogen particles by orders of magnitude. The BSL-3 HEPA filter is at least 99.97 percent efficient at removing airborne particles 0.3 micrometer (μm) in diameter (NIH 2008), with higher efficiencies for all other particle sizes, thereby removing nearly all the aerosol particles. The HEPA-filtered air from the HVAC system is ultimately discharged through the stack, where any particles not filtered out will undergo atmospheric dispersion. Atmospheric conditions (e.g., sunlight) will inactivate some infectious particles over time (Bozzette 2011), but that inactivation is conservatively ignored for this analysis. As a result of the dilution, filtration, and dispersion, the public exposure category for a centrifuge aerosol release event is NONE. This category pertains only to direct exposure and the potential for secondary exposures are considered elsewhere.

F.6.3.2.4 Extent of Exposure

Routes of exposure—It is assumed that two to four laboratory workers are in the room at the time of the release and they might all be exposed to the aerosol. The laboratory workers potentially would be exposed via various routes:

1. The laboratory workers could be exposed via inhalation into the lungs. The air would be contaminated with aerosolized particles so breathing could potentially expose the workers via the inhalation route. Inhalation exposure is typically only considered for aerosolized particles with an aerodynamic equivalent diameter no greater than 10 μm (DOE 2000).
2. The laboratory workers could also be exposed via direct contact (i.e., exposure of mucous membranes of the eyes or nasal passages).
3. As a result of breathing or speaking, the worker could also be exposed via the ingestion route.

Laboratory workers are potentially exposed via the inhalation, direct contact, and ingestion routes of exposure. The extent of exposure could be larger for the inhalation route than for the other routes because inhalation involves a continuous exchange of a large volume of air. The extent of exposure is assumed to be the same for each route in this analysis.

Methodology for exposure calculation—The actual exposure for any individual is dependent on many factors including location, response to the incident, and local airflow pattern. The following paragraphs provide a basis for estimating the potential pathogen exposure.

The airborne pathogen concentration in the laboratory is based on experiments that replicated event sequences of this type. The aim of those experiments was to “[t]o quantify microbial aerosols generated

by a series of laboratory accidents and to use these data in risk assessment.” (Bennett and Parks 2006) While the experiments were performed with *Bacillus atrophaeus*, the experimental results are assumed to be applicable to the pathogens evaluated for NEIDL because (1) the aim of the experiments and the discussion in the report addresses microorganisms in a general sense rather than *B. atrophaeus* in particular, (2) the report does not specify any limitations on applicability, and (3) the smaller size of viruses provides reason to believe the results are applicable to viruses. The general equation resulting from the experiments is presented below. The spray factor (SF) is the ratio of the pathogen concentration in the room air (i.e., the aerosol concentration, AC) to the pathogen concentration in the liquid suspension (i.e., the suspension concentration, SC). Therefore,

$$AC = SC \times SF \quad \text{[equation F.6-1]}$$

where

AC The aerosol concentration in a room (per m³)
SC The suspension concentration (per mL),² which are assumed to be the maximum working volumes presented in Section F.3.3.3

For a centrifuge fixed-angle rotor spill, the SF is 4.6×10^{-6} mL/m³ (Bennett and Parks 2006). A release from a fixed-angle rotor was selected because the SF for a fixed-angle rotor release is more than 20 times greater than the SF from the swinging bucket rotor experiment (4.6×10^{-6} mL/m³ versus 0.17×10^{-6} mL/m³). Therefore, the results of this fixed-angle rotor analysis are conservatively applicable to swinging bucket centrifugation operations.

The above equation for calculation of the airborne concentration is a general equation that does not account for variations in the SC. Using the above general equation for a Rift Valley fever virus (RVFV) SC of 1×10^9 CCID₅₀/mL and MICLD₅₀/mL,³ the maximum SC in the NEIDL inventory results in the following air concentration:

² Suspension concentrations for bacteria are given in terms of colony forming units (CFU). Concentrations for viruses are given in various units, including plaque forming units (PFU), median cell culture infective doses (CCID₅₀), and median mouse intracerebral lethal doses (MICLD₅₀) per milliliter. Section F.3.1.2 provides some background information on the methods and units associated with the concentration measurements.

³ The concentrations are reported as both 1×10^9 CCID₅₀/mL and 1×10^9 MICLD₅₀/mL. For the sake of simplicity, the RVFV concentration is reported only in units of CCID₅₀ with the understanding that the units of MICLD₅₀ also might apply. RVFV concentrations are also given as 1×10^8 PFU/mL.

$$AC = SC \times SF$$

$$AC = (1 \times 10^9 \text{ CCID}_{50}/\text{mL}) \times (4.6 \times 10^{-6} \text{ mL}/\text{m}^3)$$

$$AC = 4,600 \text{ CCID}_{50}/\text{m}^3$$

An equation that adjusts the SF for variations in the SC specifically for the fixed-angle rotor release is presented below (Bennett and Parks 2006). Using the same RVFV SC of $1 \times 10^9 \text{ CCID}_{50}/\text{mL}$ results in the following result:

$$AC = SC^{0.81} / (4.3 \times 10^3 \text{ mL}/\text{m}^3) \quad [\text{equation F.6-2}]$$

$$AC = (1 \times 10^9 \text{ CCID}_{50}/\text{mL})^{0.81} / (4.3 \times 10^3 \text{ mL}/\text{m}^3)$$

$$AC = 4,500 \text{ CCID}_{50}/\text{m}^3$$

The above calculations show that the general equation (equation F.6-1) and the equation that adjusts the SF (equation F.6-2) for the solution concentration produce nearly identical results, but the general equation results in slightly higher air concentrations at this maximum solution concentration. The general equation is used for this analysis because of this slight conservative bias at the concentration range of greatest concern.

The potential worker exposure is the airborne pathogen concentration in the air inhaled multiplied by the volume of air inhaled. It is conservatively assumed that all infectious particles inhaled are retained in the body. The pathogen concentration in the inhaled air is the airborne concentration in the room air multiplied by the fraction of aerosol particles that pass through the PAPR filter. The amount of air inhaled is the breathing rate times the effective duration of exposure. Therefore, the average number of infectious particles a worker inhales (N) is equal to the aerosol concentration (AC) times the PAPR leak path factor (LPF) times the breathing rate (BR) multiplied by the time of exposure (T).

$$N = AC \times LPF \times BR \times T \quad [\text{equation F.6-3}]$$

$$N = (SC \times SF) \times LPF \times BR \times T$$

where

BR The breathing rate for the worker is assumed to be $3.33\text{E-}04 \text{ m}^3/\text{s}$ or $0.020 \text{ m}^3/\text{min}$ (DOE 2004a).

LPF The leak path factor is the fraction of airborne particles that would leak past the confinement or filtration system. For this event sequence, the PAPRs will have an APF⁴ of 1,000 (29 CFR 1910.134 and NIH 2010), which is the inverse of the LPF of 0.001.

T The time of exposure is the breathing time at the peak concentration. The air exchange rate for NEIDL is at least eight air exchanges per hour (BUMC 2009c), which equates to an air exchange every 7.5 minutes [(1 hr / 8 exchanges) × 60 min/hr = 7.5 min]. The concentration of aerosols in the room will be dependent on the airflow patterns in the room and the nature of the release. The majority of the aerosol would be removed after 1 air exchange (i.e., 7.5 minutes) and 90 percent would be removed after 2.3 air exchanges (i.e., 17.25 minutes = 2.3 × 7.5 minutes) (NIH 2008). A laboratory worker remaining in the area for approximately one hour with the concentration decreasing as the release is purged from the room is approximately the same as a 10-minute exposure at the peak concentration. The exposure is modeled as a 10-minute exposure at peak concentration.

For the previous example involving the centrifuge release of 1×10^9 CCID₅₀/mL suspension, the amount of pathogen inhaled is then calculated as follows:

$$N = (SC \times SF) \times LPF \times BR \times T$$

$$N = [(1 \times 10^9 \text{ CCID}_{50}/\text{mL}) \times (4.6 \times 10^{-6} \text{ mL}/\text{m}^3)] \times (0.001) \times (0.020 \text{ m}^3/\text{min}) \times (10 \text{ min})$$

$$N = 0.9 \text{ CCID}_{50}$$

An average exposure of less than 1 CCID₅₀ indicates that although there might be instances where one or more CCID₅₀ is inhaled, there could also be instances where zero CCID₅₀ are inhaled, for an average inhalation of less than one.

Variability and uncertainty—There are a number of uncertainties associated with the exposure calculation and its applicability to this accident as described below.

- The experiments on which the AC (aerosol concentration) is based were performed in a room without ventilation. The airflow of an operating HVAC system in the NEIDL will continually dilute and purge the aerosol from the room; therefore, AC in the above estimate could be

⁴ The APF is the workplace level of respiratory protection that a respirator or class of respirators is expected to provide to employees when the employer implements a continuing, effective respiratory protection program (which includes fit testing and proper training) as specified by this section. (29 CFR 1910.134)

overstated. In addition, concentrations upwind of the release will be lower than concentrations downwind.

- The experiment was performed with a rotor described as *outdated*, which will not be used at NEIDL. It is anticipated that the rotors used in NEIDL will provide greater confinement than the outdated rotors.
- The experiment was performed with a centrifuge operating at 4,700 revolutions per minute. A centrifuge operating at higher speeds could generate more aerosols. Bench-top centrifuges that are planned for use with fixed-angle rotors in NEIDL have speeds of up to 25,000 revolutions per minute (e.g., Beckman Coulter model Avanti J-26 XP).
- If laboratory workers detect the release and evacuate the laboratory promptly, or are upwind from the point of release, the exposure could be zero. Conversely, if a worker does not detect the release and happens to be slightly downwind from the release, the exposure could be greater.
- There is no indication of a particle size cutoff or distribution for the experiments on which this calculation is based, so it is not possible to determine if the SF value only includes aerosol particles with an aerodynamic equivalent diameter no greater than 10 µm. If the calculated AC includes particles greater than 10 µm, the estimated inhalation exposure could be overstated.

Some of the above variables might tend to increase the exposure and some might tend to decrease the exposure relative to the calculated values. To account for those and other variables and uncertainties, the calculated values will be reported as a range. Because the laboratory worker could remain virtually unexposed from a given accident merely by virtue of being upwind of the release, the lower end of the exposure range is assumed to be zero, which means there is no exposure. To account for the variables and uncertainties that might tend to increase the exposure, such as the HVAC system moving the release toward the worker, the upper end of the range is assumed to be 10 times the calculated value. For example, a calculated exposure of 0.9 CCID₅₀ would be multiplied by 10 to give 9 CCID₅₀. Although that adjustment is not based on a numeric uncertainty analysis because of the lack of data, the addition of this conservatism to account for variability and uncertainty is consistent with the DOE NEPA Guidance.

Exposure range calculation—Table F.6-2 below provides the maximum suspension quantity and concentration for each of the pathogens that might be used in the BSL-3 laboratory and a calculated exposure that results from personnel remaining in the vicinity of a centrifuge aerosol release indefinitely. Pathogens that can be used only in a BSL-4 laboratory are not considered in this analysis. The results presented in Table F.6-2 are applicable for inhalation, direct contact, and ingestion exposure of laboratory

workers. Using the equation presented (equation F.6-3) in the previous subsection and inserting the SC for RVFV (i.e., 1×10^9 CCID₅₀/mL from Table F.6-2) yields:

$$N = (SC \times SF) \times LPF \times BR \times T$$

$$N = [(1 \times 10^9 \text{ CCID}_{50}/\text{mL}) \times (4.6 \times 10^{-6} \text{ mL}/\text{m}^3)] \times (0.001) \times (0.020 \text{ m}^3/\text{min}) \times (10 \text{ min})$$

$$= 0.9 \text{ CCID}_{50}$$

Multiplying that value by 10 (as described previously) results in a value of 9 CCID₅₀. The exposure range for RVFV is then reported as 0 to 9 CCID₅₀.

Table F.6-2. Laboratory worker exposures—BSL-3 centrifuge aerosol release with full respiratory protection

Pathogen ^a	BSL	Typical volume Volume (mL) ^b	Suspension concentration (/mL) ^{b,c}	Calculated exposure ^c	Exposure range ^c
<i>B. anthracis</i> ^d	3/2	50	2.4×10^8 CFU	0.2 CFU	0–2 CFU
<i>F. tularensis</i>	3	1	2.0×10^9 CFU	0.2 CFU ^e	0–2 CFU
<i>Y. pestis</i>	3	5	2.0×10^7 CFU	0.009 CFU ^f	0–0.09 CFU
1918 H1N1V	3	150	1.0×10^8 PFU	0.09 PFU	0–0.9 PFU
SARS-CoV	3	150	1.0×10^7 PFU	0.009 PFU	0–0.09 PFU
RVFV	3	150	1.0×10^8 PFU or 1.0×10^9 CCID ₅₀ ^g	0.09 PFU 0.9 CCID ₅₀ ^g	0–0.9 PFU 0–9 CCID ₅₀ ^g
ANDV	3/4	150	1.0×10^6 CCID ₅₀	0.0009 CCID ₅₀	0–0.009 CCID ₅₀

a. *Bacillus anthracis* (*B. anthracis*), *Francisella tularensis* (*F. tularensis*), *Yersinia pestis* (*Y. pestis*), 1918 H1N1 influenza virus (1918 H1N1V), SARS-associated coronavirus (SARS-CoV), Rift Valley fever virus (RVFV), and Andes virus (ANDV).

b. Based on the maximum working volumes in Section F.3.

c. Concentrations and exposures are given in terms of colony forming units (CFU) for bacteria. For viruses, concentrations and exposures are given in terms of plaque forming units (PFU), median cell culture infective dose (CCID₅₀), or median mouse intracerebral lethal dose (MICLD₅₀).

d. Spores in a liquid suspension.

e. The calculated exposure includes a factor of 0.1 because the typical volume of 1 mL is 10 percent of the 10-mL leak used in the experiment.

f. The calculated exposure includes a factor of 0.5 because the typical volume of 5 mL is 50 percent of the 10-mL leak used in the experiment.

g. Two values are reported for RVFV with different units. The CCID₅₀ value is an order of magnitude greater because this measurement is more sensitive than the PFU measurement. The units of MICLD₅₀ also apply to the CCID₅₀ value.

The current NEIDL SOPs do not include centrifugation of *F. tularensis* or *Y. pestis* (BUMC 2010b, 2010c) but those pathogens are included in Table F.6-2 because 1) they could be centrifuged at some point in the future, and (2) this analysis is intended to envelope other activities that have the potential to generate aerosols. Therefore, all pathogens being considered in this analysis that might be used in a BSL-3 laboratory are included in Table F.6-2.

The experiment used as the basis for this calculation was performed with a 10-mL suspension leakage in the rotor. The typical volume for *F. tularensis* is only 1 mL and the typical volume for *Y. pestis* is only 5 mL, so it is not possible to have a 10-mL leakage for those pathogens. No experimental data are available for the aerosol generation from smaller leaks, so, so it is assumed that the aerosol concentration is reduced in proportion to the reduced volume for pathogens with a typical volume of less than 10 mL. Therefore, the calculated exposures are multiplied by of 0.1 for *F. tularensis* and 0.5 for *Y. pestis*.

F.6.3.2.5 Summary

Table F.6-3 summarizes the results of the above analysis of the BSL-3 centrifuge aerosol release with full respiratory protection.

Table F.6-3. Summary of results—BSL-3 centrifuge aerosol release with full respiratory protection

Frequency category	Exposed group: category	Route of exposure	Pathogen ^a	Exposure range ^b
A (1 in 1 to 100 years)	Laboratory workers: MODERATE (1-4)	Direct contact Ingestion Inhalation	<i>B. anthracis</i> ^c	0–2 CFU
			<i>F. tularensis</i>	0–2 CFU
			<i>Y. pestis</i>	0–0.09 CFU
			1918 H1N1V	0–0.9 PFU
			SARS-CoV	0–0.09 PFU
			RVFV	0–0.9 PFU 0–9 CCID ₅₀ ^d
			ANDV	0–0.009 CCID ₅₀
	Facility worker: NONE (0)	--	--	--
	Public: NONE (0)	--	--	--

a. *Bacillus anthracis* (*B. anthracis*), *Francisella tularensis* (*F. tularensis*), *Yersinia pestis* (*Y. pestis*), 1918 H1N1 influenza virus (1918 H1N1V), SARS-associated coronavirus (SARS-CoV), Rift Valley fever virus (RVFV), and Andes virus (ANDV).

b. Exposures are given in terms of colony forming units (CFU) for bacteria. For viruses, exposures are given in terms of plaque forming units (PFU), median cell culture infective dose (CCID₅₀), or median mouse intracerebral lethal dose (MICLD₅₀).

c. Spores

d. Two values are reported for RVFV with different units. The CCID₅₀ value is an order of magnitude greater because this measurement is more sensitive than the PFU measurement. The units of MICLD₅₀ also apply to the CCID₅₀ value.

F.6.3.3 BSL-3 Centrifuge Aerosol Release with Partial Respiratory Protection

This section addresses an event sequence involving an aerosol release from a centrifuge in the BSL-3 with only partial respiratory protection (i.e., failure modes as described in Section F.6.3.3.1 below) for one of the laboratory workers. This section describes the event sequence, including the biocontainment features, frequency category, exposure category, and potential extent of exposure. This event sequence is similar to the event sequence analyzed in Section F.6.3.2 with the exception that this event sequence includes the potential for partial loss of respiratory protection. The discussion below does not repeat the common features of the analysis addressed in Section F.6.3.2 but merely addresses the differences.

F.6.3.3.1 Event Sequence Description

This hypothetical scenario involves the aerosol release of a pathogen from a bench-top centrifuge and is representative of a variety of centrifuge event sequences that could occur in the NEIDL BSL-3 laboratories. The following paragraphs describe the initial conditions and the event sequence.

Initial Conditions—The only difference between the initial conditions of this event sequence and the event sequence described in Section F.6.3.2 is that this event sequence includes the potential that one or more laboratory workers in the vicinity of the release have only partial respiratory protection. The PAPR's biocontainment function is to filter potentially infectious particles from the air being inhaled by the worker. Section A.3 of Attachment A provides a summary of PAPR incidents involving reduced respiratory protection. The PAPR failure modes considered here are as follows:

- **Leakage**—Because of the positive pressure within the respirator, any leakage of a PAPR (e.g., leak at fixture or seal) is predominantly outward rather than inward and, thus, is not a threat to the laboratory worker. Therefore, this failure mode is not considered further.
- **Detected reduced airflow**—Some failures, such as loss of power, blower failure, or air hose detachment could result in loss of airflow that is promptly detected. If the airflow is severely reduced, the laboratory worker would be expected to exit the room promptly. A worker could be exposed to the release for a time if the PAPR was removed before exiting the room. A PAPR failing in this mode concurrent with an undetected centrifuge event sequence is beyond reasonably foreseeable, frequency category D (1 in more than 1 million years), and is not considered further.
- **Undetected reduced airflow**—PAPR failures can also result in an undetected reduction of the filtered air supplied to the PAPR. The PAPR failures could result from such problems as loose hose assemblies that leak or crimped hoses that restrict airflow. Such incidents increase the chance for over-breathing and partial reduction in effectiveness, but the PAPR would still provide filtered air and such incidents are not considered further.
- **Reduced filtration efficiency**—There are several conditions that can result in a reduced filtration efficiency for a PAPR. Those failures could result from such conditions as substandard filters, cracked filter assemblies, improperly installed filters, or filter breaches. Substandard filters could have a common cause and all workers could have substandard filters, but the filters are likely to provide nearly full protection and this specific failure is not considered further. A cracked filter housing or breached filter on a single PAPR is the most likely failure of concern and is selected for further analysis.

Therefore, the initial conditions for this event sequence are the same as for the sequence described in Section F.6.3.2 except that one of the laboratory workers has only partial respiratory protection. The likelihood that the reduced respiratory protection will be detected increases as the extent of degradation increases. A small degradation would not be as likely to be detected, but the effect on exposure would be small. Conversely, a large degradation in protection has the potential for a large increase in exposure, but the likelihood of detection is also large. No data were found that would support an estimate in the reduction of the respiratory protection for the described failure modes. While an order of magnitude reduction in effectiveness seems like a reasonable estimate, a two order of magnitude degradation in filter efficiency is conservatively used here to better assess the significance of the respiratory protection. The role of each biocontainment feature for this event sequence, including the PAPRs, is shown in Table F.6-4. The only difference between the biocontainment features in this event sequence and the one addressed in Section F.6.3-2 is the partial performance of the PAPR for one laboratory worker.

Table F.6-4. Exposed group protected by each biocontainment feature—BSL-3 centrifuge aerosol release with partial respiratory protection

Exposure group	Admin. controls		Safety equipment							Facility	
	Procedures	Training	Container	Rotor	Centrifuge chamber ^a	BSC	PPE	PAPR	Positive-pressure suit	HVAC system	Sealed walls, floors, and ceilings
Laboratory worker	M ^b /P ^c	M/P	M ^e	M/P	- ^d	-	-	M ^f	-	M	-
Facility worker	P	P	M	M/P	-	-	-	-	-	M	M
Public	P	P	M	M/P	-	-	-	-	-	M	M

a. Not all centrifuge chambers are aerosol-tight. Centrifuge chambers that are not aerosol-tight provide some mitigation while closed. Centrifuge lids provide no mitigation when open, so this is a minor mitigating effect.

b. M signifies a mitigative feature

c. P signifies a preventive feature

d. This biocontainment feature is not relevant for this event sequence or does not have a preventive or mitigative role for this exposed group.

e. The cells with cross-hatching indicate a biocontainment feature that is assumed to fail or have partial performance for this event sequence.

f. PAPR are assumed to provide only partial respiratory protection for one worker and full protection for any other workers in the room.

Event sequence description—This event sequence proceeds from the initial conditions in the same manner as the event sequence discussed in Section F.6.3.2 with the only exception that the initial

conditions include one laboratory worker with only partial respiratory protection. As a result, the laboratory worker with partial respiratory protection has the potential of a higher exposure to the release.

F.6.3.3.2 Frequency Category

This event sequence involves the combination of a centrifuge aerosol release event sequence concurrent with one laboratory worker with partial respiratory protection. The centrifuge event frequency estimation in Section F.6.3.2.2, frequency category A (1 in 1 to 100 years), is also applicable for the centrifuge aerosol release portion of this event sequence.

This condition requires that the respiratory protection provided by the PAPR be reduced either while in use, such as an impact that damages the housing, or before use. In either case, it is essential that the reduced protection not be detected in check-out, inspection, donning, or use in order for this scenario to occur. NEIDL workers are trained to inspect and test PAPR before entry into the laboratories (BUMC 2010a). The combination of a degradation of this severity in conjunction with a failure to detect makes this conditional improbable. The conditional probability that one of the four or fewer PAPRs in use has an undetected two order of magnitude reduction in filtration is conservatively assumed to be no greater than 1 in 100 (0.01), which equates to a one category reduction in the frequency category. (Note: the results of Appendix K show that this potential reduction in PAPR effectiveness does not significantly affect worker risk.)

Because of the conditional probability of partial respiratory protection for one laboratory worker, this event sequence is considered to be in frequency category B (1 in 100 to 10,000 years).

F.6.3.3.3 Exposure Category

The exposure of laboratory workers, facility workers, and the public for this event sequence is discussed below.

Laboratory worker—As discussed in Section F.6.3.2.3, it is expected that one to four people will be in the room at the time of a centrifuge aerosol release event; however, only one laboratory worker is expected to have a PAPR with reduced respiratory protection. Therefore, the exposure category is LOW (i.e., 1 laboratory worker) for the higher level of exposure and remains at MODERATE for the lower level of exposure.

Facility worker—The potential for facility worker exposure from this event sequence is the same as the potential addressed in Section F.6.3.2.3 because respiratory protection for the worker will have no effect on facility worker exposures. Therefore, the facility worker exposure category for a centrifuge aerosol release event is NONE.

Public—The potential for public exposure from this event sequence is the same as the potential addressed in Section F.6.3.2.3 because respiratory protection for the worker will have no effect on public exposure. As a result of the dilution, filtration, and dispersion, the public exposure category for a centrifuge aerosol release event is NONE.

F.6.3.3.4 Extent of Exposure

Routes of exposure—As discussed in Section F.6.3.2.4, a laboratory worker with partial respiratory protection is also potentially exposed via the inhalation, direct contact, and ingestion routes of exposure. The inhalation route will be used as the basis for estimating the extent of exposure for the other routes.

Calculated exposure—The methodology used to calculate exposure is identical to the calculation performed in Section F.6.3.2.4 with the exception of the difference in the laboratory worker's respiratory protection. For this event sequence, the PAPR LPF for the laboratory worker with reduced respiratory protection is assumed to be 0.1 rather than 0.001. Table F.6-5 below provides the maximum suspension quantity and concentration for each of the pathogens that might be used in the BSL-3 and a calculated exposure that results from a person remaining in the vicinity of a centrifuge aerosol release indefinitely. Pathogens that can be used in a BSL-4 only are not considered in this analysis. The results presented in Table F.6-5 are applicable for inhalation, direct contact, and ingestion exposure of laboratory workers. Using the formula presented in the previous subsection and inserting the SC for RVFV (i.e., $1 \times 10^9/\text{mL}$ from Table F.6-5) yields:

$$\begin{aligned} N &= (1 \times 10^9 \text{ CCID}_{50}/\text{mL}) \times (4.6 \times 10^{-6} \text{ mL}/\text{m}^3) \times (0.1) \times (0.020 \text{ m}^3/\text{min}) \times (10 \text{ min}) \\ &= 90 \text{ CCID}_{50} \end{aligned}$$

Increasing that value by a factor of 10 to account for uncertainty and variability results in a value of 900 CCID₅₀. The exposure range for RVFV is then reported as 0 to 900 CCID₅₀.

Table F.6-5. Laboratory worker exposures—BSL-3 centrifuge aerosol release with partial respiratory protection

Pathogen ^a	BSL	Suspension concentration (/mL) ^{b c}	Calculated exposure ^c	Exposure range ^c
<i>B. anthracis</i> ^d	3 / 2	2.4×10^8 CFU	20 CFU	0–200 CFU
<i>F. tularensis</i>	3	2.0×10^9 CFU	20 CFU	0–200 CFU
<i>Y. pestis</i>	3	2.0×10^7 CFU	0.9 CFU	0–9 CFU
1918 H1N1 influenza virus	3	1.0×10^8 PFU	9 PFU	0–90 PFU
SARS-CoV	3	1.0×10^7 PFU	0.9 PFU	0–9 PFU
RVFV	3	1.0×10^8 PFU 1.0×10^9 CCID ₅₀ ^e	9 PFU 90 CCID ₅₀ ^e	0–90 PFU 0–900 CCID ₅₀ ^e
ANDV	3 / 4	1.0×10^6 CCID ₅₀	0.09 CCID ₅₀	0–0.9 CCID ₅₀

a. *Bacillus anthracis* (*B. anthracis*), *Francisella tularensis* (*F. tularensis*), *Yersinia pestis* (*Y. pestis*), 1918 H1N1 influenza virus (1918 H1N1V), SARS-associated coronavirus (SARS-CoV), Rift Valley fever virus (RVFV), and Andes virus (ANDV).

b. Taken Section F.4.3.3.

c. Concentrations and exposures are given in terms of colony forming units (CFU) for bacteria. For viruses, concentrations and exposures are given in terms of plaque forming units (PFU), median cell culture infective dose (CCID₅₀), or median mouse intracerebral lethal dose (MICLD₅₀).

d. Spores in a liquid suspension.

e. Two values are reported for RVFV with different units. The CCID₅₀ value is an order of magnitude greater because this measurement is more sensitive than the PFU measurement. The units of MICLD₅₀ also apply to the CCID₅₀ value.

As discussed in Section F.6.3.2.4, *F. tularensis* and *Y. pestis* might not be centrifuged in NEIDL, so retaining these pathogens in Table F.6-5 is potentially conservative for those pathogens. Also, as explained in Section F.6.3.2.4, the maximum working volume of these two pathogens is less than the 10 mL leakage assumed, so the exposures are scaled accordingly (i.e., a factors of 0.1 for *F. tularensis* and 0.5 for *Y. pestis* were used to adjust for the reduced volumes).

F.6.3.3.5 Summary

Table F.6-6 summarizes the results of the above analysis of the BSL-3 centrifuge aerosol release with partial respiratory protection.

Table F.6-6. Summary of results—BSL-3 centrifuge aerosol release with partial respiratory protection

Frequency category	Exposed group: category	Route of exposure	Pathogen ^a	Exposure range ^b
B (1 in 100 to 10,000 years)	Laboratory workers—full respiratory protection: MODERATE (0-3) ^c	<ul style="list-style-type: none"> Direct contact Ingestion Inhalation 	<i>B. anthracis</i> ^d	0–2 CFU ^d
			<i>F. tularensis</i>	0–2 CFU

a. *Bacillus anthracis* (*B. anthracis*), *Francisella tularensis* (*F. tularensis*), *Yersinia pestis* (*Y. pestis*), 1918 H1N1 influenza virus (1918 H1N1V), SARS-associated coronavirus (SARS-CoV), Rift Valley fever virus (RVFV), and Andes virus (ANDV).

b. Exposures are given in terms of colony forming units (CFU) per milliliter for bacteria. For viruses, exposures are given in terms of plaque forming units (PFU), median cell culture infective dose (CCID₅₀), or median mouse intracerebral lethal dose (MICLD₅₀).

c. Accounts for the one worker with only partial protection.

d. Spores

e. Two values are reported for RVFV with different units. The CCID₅₀ value is an order of magnitude greater because this measurement is more sensitive than the PFU measurement. The units of MICLD₅₀ also apply to the CCID₅₀ value.

F.6.3.4 BSL-4 Centrifuge Event Sequence with Partial Respiratory Protection

This event sequence is similar to the event sequence analyzed in Section F.6.3.3 with the exception that this event sequence occurs in a BSL-4 laboratory rather than in a BSL-3 laboratory. One piece totally encapsulating positive-pressure suits are required for BSL-4 laboratories, whereas PAPRs are required for BSL-3 laboratories. This event sequence is similar in most respects to the events analyzed for the BSL-3 laboratories, so the discussion below does not repeat the common features of the analysis addressed in Section F.6.3.3; it merely addresses the differences.

F.6.3.4.1 Event Sequence Description

This hypothetical scenario involves the aerosol release of a pathogen from a bench-top centrifuge and is representative of a variety of centrifuge event sequences that could occur in the NEIDL BSL-4 space.

This scenario is relevant for any pathogens that might be used in the BSL-4 space, which includes

1 pathogens requiring BSL-3 biocontainment precautions and pathogens requiring BSL-4 biocontainment
2 precautions because pathogens normally used in BSL-3 space might be used in the BSL-4 area. The
3 following paragraphs describe the initial conditions and the event sequence.

4
5 ***Initial Conditions***—The initial conditions of this event sequence include partial respiratory protection for
6 one or more laboratory workers. The respiratory protection for laboratory workers is a positive-pressure
7 suit in BSL-4 space as opposed to the PAPR used in BSL-3 space, which is the difference between this
8 event sequence and the event sequence described in Section F.6.3.3. The biocontainment function of the
9 positive-pressure suit is to supply uncontaminated air from a clean air source to the worker and to provide
10 protection from other contact with the pathogen under study.

11
12 Failures of positive-pressure suits do occur, and Section A.2 of Attachment A provides a summary of
13 several positive-pressure suit failures at biosafety laboratories. The potential failure modes considered
14 included the following (Smith and Edwards 2002):

- 15 • *Supply of contaminated air*—If an aerosol release occurs, the room air would be drawn into the
16 dedicated BSL-4 HVAC system, which includes double-HEPA filtration. The positive-pressure
17 suits have a dedicated HEPA-filtered air supply that is independent from the BSL-4 HVAC
18 system, so potentially contaminated room air cannot expose the workers. Therefore, a release
19 would need to exit the facility stack and be recycled back into the HVAC inlet to contaminate the
20 workers' breathing air. It is beyond reasonably foreseeable, frequency category D (1 in more than
21 1 million years), that the worker would be supplied contaminated air, and this possibility is not
22 considered further.
- 23 • *Loss of airflow*—Airflow to the positive-pressure suit could be reduced or lost because of such
24 problems as a crimped hose, hose or connector failure, or loss of air supply. The worker can hear
25 the air released from the hood vent during normal airflow, and this sound will be absent if a loss
26 of airflow occurs, thereby alerting the worker to the situation. The suits have a free air volume
27 sufficient for approximately 5 minutes of breathing and are equipped with a life support system
28 (an escape bottle air apparatus). Therefore, the worker has sufficient time to exit the room in case
29 of a total loss of air supply. This failure mode is not considered further because the worker would
30 detect the problem and exit the room without exposure.
- 31 • *Small leaks*—The most common mode of air-supplied positive-pressure personnel suit failure is
32 small leaks (Smith and Edwards 2002). Small suit leaks do not pose a risk to laboratory workers
33 because the air flows out of the suit at a tear, thereby preventing potentially contaminated air
34 from entering the suit and exposing the worker. Small leaks are not considered further.

- **Rupture**—The failure mechanism considered here is a severe suit rupture, for example where the umbilical air-supply line connects to the suit. The suit would promptly depressurize, the worker would be aware of the condition and would be expected to promptly exit the room by retreat to the chemical shower airlock. In the process of exiting, the worker could be exposed to some pathogen particles.

The role of each biocontainment feature for this event sequence, including the positive-pressure suits, is shown in Table F.6-7.

Table F.6-7. Exposed group protected by each biocontainment feature—BSL-4 centrifuge event sequence with partial respiratory protection

Exposure group	Admin. controls		Safety equipment							Facility	
	Procedures	Training	Container	Rotor	Centrifuge chamber ^a	BSC	PPE	PAPR	Positive-pressure suit	HVAC system	Sealed walls, floors, and ceilings
Laboratory worker	M ^b /P ^c	M/P	M ^e	M/P	M	- ^d	-	-	M	M	-
Facility worker	P	P	M	M/P	M	-	-	-	-	M	M
Public	P	P	M	M/P	M	-	-	-	-	M	M

a. Not all centrifuge chambers are aerosol-tight. Centrifuge chambers that are not aerosol-tight provide some mitigation while closed. Centrifuge lids provide no mitigation when open, so this is a minor mitigating effect.

b. Mitigative feature

c. Preventive feature

d. This biocontainment feature is not relevant for this event sequence or does not have a preventive or mitigative role for this exposed group.

e. The cells with cross-hatching indicate a biocontainment feature that is assumed to fail or have partial performance for this event sequence.

Event sequence description—This event sequence proceeds from the initial conditions in the same manner as the event sequence discussed in Section F.6.3.2. Unlike the event sequence discussed in Section F.6.3.3, the respiratory protection cannot reasonably be compromised before the release without being detected, so the positive-pressure suit rupture must occur concurrently with the centrifuge aerosol release.

F.6.3.4.2 Frequency

This event sequence involves the combination of a centrifuge aerosol release event sequence concurrent with the rupture of the positive-pressure suit for one laboratory worker. The centrifuge event frequency estimation in Section F.6.3.2.2, frequency category A (1 in 1 to 100 years), is also applicable for the centrifuge aerosol release portion of this event sequence.

A rupture of a positive-pressure suit large enough to cause it to lose pressure and fail to provide clean air to the worker is improbable. Section A.2 of Attachment A lists 3 suit failures that have occurred in biosafety laboratories. However, the three suit rupture incidents did not appear to result in the potential for exposure because the leakage was out of the suit. For the aerosol in the room to enter the positive-pressure suit, the suit would need to be breached and depressurized because, otherwise, the airflow will be out of the suit. A positive-pressure suit breach that depressurizes the suit would clearly be detected immediately by the worker and co-workers.

It is considered beyond reasonably foreseeable, frequency category D (1 in more than 1 million years), that an aerosol release from a centrifuge could occur because a worker exposure requires (1) an undetected aerosol release from a centrifuge, and (2) an undetected positive-pressure suit breach large enough to allow the worker to be exposed. Consistent with guidance (DOE 2002), this event is considered speculative and is not considered further.

F.6.3.4.3 Summary

This analysis did not identify any credible event sequences that result in pathogen exposure to a BSL-4 laboratory worker, facility worker, or the public as a result of an aerosol release from a centrifuge. Because no credible event sequences were identified, there are no exposures, as reported in Table F.6-8.

Table F.6-8. Summary of results—BSL-3 centrifuge aerosol release with partial respiratory protection

Frequency category	Exposed group: category	Route of exposure	Pathogen	Exposure range
D (1 in more than 1 million years))	Laboratory workers: NONE (0)	-- ^a	--	-
	Facility worker: NONE (0)	--	--	--
	Public: NONE (0)	--	-	--

a. The dash indicates analysis is not appropriate because exposure, if any, is speculative and would average much less than one particle.

F.6.3.5 Variability and Uncertainty

There are numerous variabilities and uncertainties that apply to the results presented in Sections F.6.3.2 through F.6.3.4. Table F.6-9 identifies the key variabilities and uncertainties, provides a discussion of each, and provides an estimate of the potential effect of each.

Table F.6-9. Summary of key variabilities and uncertainties

Variability/ uncertainty	Discussion	Potential factor ^a
Frequency category	As discussed previously, no data are available suitable for use in estimating the frequency of each event, so there is considerable uncertainty in these estimates. While the estimates are uncertain, they are also considered conservative (i.e., overstate the frequency) because the event sequences analyzed for the release involves multiple failures, and the events are assumed to be undetected/unreported. Such events are expected to be highly improbable given the NEIDL safety program.	Conservatism
Suspension concentration	The exposure calculations were performed using maximum suspension concentrations found in literature reviews and interviews. The applicability of these maximum concentrations to NEIDL operations is uncertain because of potential differences between NEIDL protocols and practices and those on which the literature is based. Because the estimates used for this analysis are expected to be conservative there is no reason to expect that NEIDL protocols will result in higher pathogen concentrations, and, in fact, BUMC personnel expect them to be lower.	Conservatism
Analysis of <i>Y. pestis</i> and <i>F. tularensis</i>	<i>Y. pestis</i> and <i>F. tularensis</i> are included in the analysis even though the SOPs do not include centrifugation of those pathogens. This conservatism is appropriate because of the potential that they might be centrifuged in the future and because this analysis is intended to envelope other aerosol-producing events in which those pathogens could be involved.	Conservatism (for frequency)
	The typical volumes of <i>F. tularensis</i> and <i>Y. pestis</i> are less than the 10 mL used for the experiments, but the experimental data are not available for smaller leakages. It was assumed that the aerosol concentrations would be scaled down proportionally according to their reduced leakage volumes.	Potential non-conservatism (maximum of 10x for <i>F. tularensis</i> and 2x for <i>Y. pestis</i>)
10 mL leakage	The analysis is based on a 10-mL leakage of a potentially larger total volume; however, the leakage could be greater or less than 10 mL for those pathogens that have more than a 10-mL volume. However, a larger leak is more likely to result in an imbalanced rotor that would ultimately result in the centrifuge being stopped either automatically by the centrifuge's imbalance control or manually by the laboratory worker, so larger leakages are less likely to occur and more likely to be detected. It is not known whether a larger leakage results in a larger release. Therefore, the frequency could be lower, but the airborne release might or might not be greater.	Unknown (potentially lower frequency and higher release)
SF	The SF is based on experimental data (Bennett and Parks 2006). These experimental results are the best available basis to estimate the exposure, but there is uncertainty associated with this SF. The SF could be different for the NEIDL because of differences in the centrifuge speed and rotor design. The SF used might be conservative or non-conservative.	Unknown

Variability/ uncertainty	Discussion	Potential factor ^a
	It is not known whether the SF is based solely on aerosol particles that are no larger than 10 µm. If the experiments used to determine the SF included particles larger than 10 µm, the SF is conservative and overstates the exposure.	Potential conservatism
LPF	A PAPR APF of 0.001 is used for the full respiratory protection case based on test data. HEPA tests generally reflect the minimum filtration efficiency, but might not reflect HEPA filters in their <i>as used</i> condition. Therefore, it is uncertain whether the APF of 0.001 is conservative or non-conservative for the full protection case.	Unknown
	A PAPR APF of 0.1 is used for the partial respiratory protection case. This estimate is not based on data, but is believed to be conservative. The procedures for testing the PAPR before use would detect most severe problems and a two order of magnitude reduction in filtration is very severe for an undetected failure.	Unknown conservatism
BR	The generally accepted and recommended breathing rate is used, but the actual breathing rate varies depending on the level of activity involved. Rather than the $3.33 \times 10^{-4} \text{ m}^3/\text{s}$ value used, the rate could range from an extreme of $1.25 \times 10^{-4} \text{ m}^3/\text{s}$ for sleep to $8.33 \times 10^{-4} \text{ m}^3/\text{s}$ for heavy exercise (DOE 2004a). There is some variability in this value, but it is relatively small compared to the other factors.	Relatively small variation
Number of workers exposed	It is possible for more than four people to be in the room at the time of the release, but that is expected to be an infrequent occurrence (BUMC 2009). If the number of people in the room were to exceed four, the number of people exposed would increase, but the frequency for such an event might decrease. Potential exposure of more than four workers is not expected to be a risk-dominant sequence.	Unknown
Location of workers	The location of the worker(s) relative to the point of release is highly variable and the resulting exposures for any given location are highly uncertain. The lowest end of the exposure range is clearly exposure to 0 organisms. No attempt was made to define locations of individuals or the extent of exposure at any given locations.	Unknown

a. The estimate provided in the analyses (Sections 3.1 and 3.2) would be multiplied by this value to obtain the new value. So a current value of 10 when multiplied by a potential factor of 10 would result in 100 and a current value of 10 when multiplied by a potential factor of 0.1 would result in 1. A factor of 0 means that the result could be 0.

As shown in Table F.6-9, numerous variabilities and uncertainties could affect the results of this analysis, some of which result in a conservative and some in a non-conservative bias. While the net effect of those variabilities and uncertainties is not known, the addition of an order of magnitude increase in the maximum exposure is expected to result in an overall conservative bias. Overall, the results of this analysis are judged to be conservative and an event of this type would likely result in lower exposures.

F.7 NEEDLESTICK EVENTS

F.7.1 Introduction

A needlestick is an inadvertent penetration of the skin by a syringe needle. If the needle contains any pathogenic material, a needlestick in a BSL-3 or BSL-4 laboratory could result in an LAI of a laboratory worker. The BMBL (CDC and NIH 2007) states (p. 12):

Investigations of LAIs have identified five principal routes of laboratory transmission. These are parenteral inoculations with syringe needles or other contaminated sharps, spills and splashes onto skin and mucous membranes, ingestion through mouth pipetting, animal bites and scratches, and inhalation exposures to infectious aerosols.

Accidental punctures⁵ (note: the term *puncture* is used in this document to generically cover percutaneous⁶ routes of exposure) by contaminated sharp objects such as needles or scalpels can expose workers to pathogens through the skin or mucous membranes and result in an infection. Sewell 1995 states, “accidental parenteral inoculation of infectious material is one of the leading causes of laboratory-associated infections. Nearly all microorganisms can produce an infection following penetration of the skin by contaminated needles, scalpels, or broken glass.”

Pedrosa and Cardoso 2011 reviewed 141 scientific articles published between 1930⁷ and 2008. Results relevant to this analysis include:

- “Of laboratory arboviral infections, 15.7% were acquired percutaneously.” Both Rift Valley fever virus (RVFV) and tick-borne encephalitis complex (Russian spring-summer encephalitis virus-Far Eastern type) (TBEV-FE) are arboviruses.
- “Of the 12 infections with viruses with preferential mucocutaneous transmission, seven occurred percutaneously.”

While changes in laboratory equipment and procedures have changed during this time period, the fact remains that punctures are a significant cause of LAIs.

Sewell 1995 also states:

The use of a syringe and needle is the most hazardous laboratory procedure. Infections associated with needles and syringes occur through three routes: (i) inhalation of aerosols, (ii) contamination of fingers and the environment, and (iii) direct inoculation...Direct inoculation of the worker from an accidental needlestick is a leading cause of infections by the blood-borne pathogens.

⁵ Puncture: to pierce with or as if with a pointed instrument or object; *puncture* the skin with a needle (www.dictionary.com)

⁶ Percutaneous: effected or performed through the skin (www.dictionary.com)

⁷ Though some of the articles published before circa 1980 might not be as rigorous or relevant as the more recent articles, the general statements quoted here are judged to still be valid.

Thus, an infection resulting from a puncture by a sharp object, specifically direct inoculation of the worker by a needlestick, has been selected as a representative LAI event to be analyzed for laboratory worker exposure.

This analysis relies on both generic and NEIDL-specific information. BMBL provides generic guidance for the biocontainment of pathogens in laboratories of this type. The BUMC Biosafety Manual, provides NEIDL-specific procedures.

It is reasonable to expect that the majority of the 13 pathogens evaluated could be used to inoculate animals; however, some pathogens are more likely to be used in syringes than others. Wild type SARS-associated coronavirus (SARS-CoV) and 1918 H1N1 influenza virus (1918H1N1V) are not expected to be used as injectable live inocula. However, it is possible that blood samples could be taken from animals infected with those pathogens using needle and syringe, and a needlestick would be possible in that case. If those viruses are used, the animal blood concentration is taken to be the same as the maximum working concentration. There is also a risk of exposure to SARS-CoV and 1918H1N1V via other sharp objects, and a needlestick scenario is used as a surrogate for all sharps exposure.

F.7.2 Methodology

F.7.2.1 Biocontainment Features

There are a number of biocontainment features associated with the NEIDL that can be grouped as administrative controls and safety equipment. The biocontainment features that are considered in this analysis include the following:

Administrative Controls:

- Procedures
- Training

Safety Equipment:

- Containers (including needles/syringes)
- PPE

The following paragraphs describe each of those biocontainment features as they relate to sharp objects in general and to needles in particular as they were used in the analysis of the needlestick event sequence.

1 *Procedures*—The BUMC Biosafety Manual (Appendix W) provides requirements for developing NEIDL
2 SOPs, which include safe handling of needles and other sharps. Controls specified by the Biosafety
3 Manual (BUMC 2011) include the following:

- 4 • Needles and syringes or other sharp instruments are restricted in the laboratory for use only when
5 there is no alternative, such as for parenteral injection, phlebotomy, or aspiration of fluids from
6 laboratory animals and diaphragm bottles.
- 7 • Plasticware should be substituted for glassware whenever possible.
- 8 • Only needle-locking syringes or disposable syringe-needle units (i.e., needle is integral to the
9 syringe) are used for injection or aspiration of infectious materials.
- 10 • Used disposable needles must not be bent, sheared, broken, recapped, removed from disposable
11 syringes, or otherwise manipulated by hand before disposal; rather, they must be carefully placed
12 in conveniently located puncture-resistant containers used for sharps disposal.
- 13 • Non-disposable sharps must be placed in a hard-walled container for transport to a processing
14 area for decontamination, preferably by autoclaving.
- 15 • Syringes that re-sheath the needle, needleless systems, and other safety devices are used when
16 appropriate.
- 17 • Broken glassware must not be handled directly by hand, but must be removed by mechanical
18 means, such as a brush and dustpan, tongs, or forceps.

19
20 While the BMBL quote above states, “Needles must not be...recapped,” recapping of needles sometimes
21 may be necessary. For example, recapping the needle is appropriate after the syringe and needle are
22 loaded with the inoculums that will later be injected into an animal.

23
24 29 CFR 1910.1030, *Bloodborne pathogens*, requires the use of engineering and work practice controls to
25 eliminate or minimize employee exposure to bloodborne pathogens. It also requires employers to keep a
26 sharps injury log for the recording of puncture injuries (i.e., injuries involving broken skin) from
27 contaminated sharps (29 CFR 1910.1030).

28
29 ***Training***—The training requirements for NEIDL laboratory workers are outlined in the BUMC Biosafety
30 Manual Appendix F for BSL-3 and Appendix G for BSL-4. The training program educates employees
31 about the hazards to which they might be exposed and instructs them on the proper protocols to be used
32 for safe operation of the NEIDL. An example of training might include not allowing needle guards to be
33 removed or recapped with the worker’s teeth.

Containers—Containers provide direct containment of pathogens and consist of tubes, bottles, syringes, flasks, or other types of containers. All containers for liquids used in the BSL-3 and BSL-4 will be resistant to breakage and sealed with either snap or screw caps.

PPE—The specific PPE used is dependent on the pathogen and activity involved but will always include protective clothing, including gloves.

In addition, the needles themselves can provide a mechanism for control against needlesticks. For example, safety syringes that automatically retract or re-shield the needle after use (e.g., no manual recapping is necessary) are available.

F.7.2.2 Extent of Exposure

The consequences of a needlestick involve not only the number of people potentially exposed, which is addressed in the previous section, but also the extent to which those people are exposed. Estimating the specific extent of exposure (e.g., the number of bacteria or virions received) is speculative for needlestick events because it could result in a broad range of pathogen exposures for the laboratory worker. The extent of exposure depends on such factors as the extent to which the needle penetrates the skin, whether pathogen is present in the syringe, the amount and concentration of pathogen present in the syringe, and whether the syringe plunger is depressed. If no pathogens are present, then the extent of exposure is zero. Conversely, if pathogen is present and the syringe plunger is depressed, the exposure could be very large.

To demonstrate that a very small amount of inocula can deliver a very large dose, Attachment B shows the amount of each pathogen that could be injected from a single drop. For example, a single drop of inocula with an SC of 1×10^6 CCID₅₀ would deliver an exposure of about 4,500 CCID₅₀. That supports the claim from Sewell above that, “Nearly all microorganisms can produce an infection following penetration of the skin by contaminated needled, scalpels, or broken glass.”

Instead of speculating on the extent of exposure, it is conservatively assumed that an infectious dose was administered for each needlestick event. This conservatism will result in an overestimate of the number of infections that result from needlestick events. The available data provide limited insight into the likely extent of exposure. Attachment B shows that of the 8 BSL-3 incidents for which detailed data are provided, one incident has been shown to have resulted in an infection, one has been shown to have resulted in no infection, and the balance (6 of 8) of the summaries give no information (e.g., the data only show *potential exposure* and the results indicate *investigation ongoing*).

F.7.3 Results

This section documents the selection and analysis of needlestick event sequences. Separate event sequences are selected and analyzed for the BSL-3 and BSL-4 pathogens.

F.7.3.1 Selection of Event Sequences

Factors that were considered in the selection of event sequences for analysis include the following:

- *Detection and Reporting*—Prompt detection and reporting of a needlestick event can maximize the effectiveness of medical intervention and, thus, potentially lower the likelihood that an initial exposure results in infection (and potentially lower the likelihood of related symptoms) to the worker, and lowers the likelihood of secondary transmissions to other workers or the public. Therefore, event sequences are analyzed both with and without prompt detection and reporting.
- *Type of Pathogen*—As stated previously, BSL-3 and BSL-4 activities will be addressed separately.

Thus, the needlestick event sequences selected for further analysis are as follows:

- BSL-3 needlestick with prompt worker detection and reporting—This event was selected to determine the potential risk at BSL-3 when proper protocols for detection and reporting are followed.
- BSL-3 needlestick without prompt worker detection and/or reporting—This event was selected to determine the potential risk at BSL-3 when proper protocols for detection and reporting are not followed.
- BSL-4 needlestick with prompt worker detection and reporting—This event was selected to determine the potential risk at BSL-4 when proper protocols for detection and reporting are followed.
- BSL-4 needlestick without prompt worker detection or reporting—This event was selected to determine the potential risk at BSL-4 when proper protocols for detection and reporting are not followed.

F.7.3.2 Needlestick in BSL-3 Laboratory with Prompt Detection and Reporting

F.7.3.2.1 Event Sequence Description

Initial Conditions—The conditions leading up to this event sequence are as follows:

- The pathogen suspension contains the maximum concentration for that pathogen that is expected to be used in NEIDL. Lower concentrations are expected to result in correspondingly lower exposures.
- As required, the laboratory workers in the room are wearing BSL-3 dedicated shoes, shoe covers, scrub suits with elastic cuffs, a back-fastening gown and double gloves (BUMC 2011), which are the minimum PPE required for all BSL-3 activities.

Other conditions such as the use of respiratory protection and the number of co-located workers in the laboratory are not important for this scenario as they do not influence the extent of exposure.

Initiating Events—Conditions that could initiate a needlestick event include the following:

- A laboratory worker being startled (e.g., by a co-worker, dropped container, animal)
- Inattention to detail
- Laboratory worker involuntary movement (e.g., sneeze)
- Erratic animal movement

Contributing Events and Conditions—The following events or conditions could influence the likelihood of the event, extent of exposure, and human effects, if any, on the laboratory worker:

- Pathogen present or not—If no pathogen is present, the exposure to the worker is zero. It is assumed that the pathogen is present in this needlestick scenario.
- Skin broken or not—If the needlestick does not penetrate the skin, the chances of an infection decrease considerably (assuming the skin is not already compromised by an existing cut or abrasion). It is assumed that the skin is penetrated for this needlestick scenario.
- Proper use of procedures—Procedures that are followed as written could reduce the frequency of events. It is assumed that procedures are properly implemented for this needlestick scenario.
- Proper availability, selection, and use of PPE—The proper use of PPE can effectively eliminate a variety of potential exposure events; however, the types of PPE available are not always capable of preventing all types of needlesticks given the nature of the work to be performed. For example, the use of metal mesh gloves could prevent punctures from contaminated sharps but might not

prevent a needlestick. Also the use of mesh gloves could make the handling of a syringe/needle unwieldy. It is assumed that PPE does not prevent this needlestick scenario.

- Immediate detection and reporting of potential mishaps and operational upsets—It is assumed that the needlestick is promptly detected and reported for this needlestick scenario.
- Prompt and appropriate medical intervention—It is assumed that appropriate medical intervention is taken for this scenario, which includes such actions as quarantine, as appropriate.

F.7.3.2.2 Frequency Category

The operational incident data (see Attachment C of this appendix and Appendix D) identifies incidents that have occurred at other BSL-3 and BSL-4 facilities and provide insights into the types of incidents that might occur at NEIDL. Section F.1.3 discusses the limitations of the data and explains why it is not suitable for use in developing quantitative estimates of the frequency for needlesticks.

BSL-3 operating experience in Attachment C showing 19 incidents from 2002 to 2010 (about 8 years) at facilities similar to the NEIDL. The number of entities registered with the CDC and USDA Select Agent Program maintaining BSL-3 laboratories increased from 191 in 2004 to 279 in 2008 (GAO 2009). That equates to about 0.01 needlestick incidents per year per facility (19 incidents divided by an average of about 235 facilities divided by 8 years). While this frequency estimate provides insight into the frequency, it may understate or overstate the real value for the following reasons:

- It may understate the historic frequency because incidents have historically been underreported because of fear of reprisal and the source of exposure for over 80 percent of laboratory related illnesses is not known (Harding and Byers 2006). (See Section F.1.3 for details.)
- This historic estimate may overstate the frequency because it may not reflect:
 - The historic decline in LAI rates have declined dramatically over time due to enhancements in biosafety procedures, primary biocontainment systems, personal protective equipment, and facilities engineering, as shown in Section D.1.1 of Appendix D.
 - The sharps safety practices at the NEIDL (see Section F.7.2.1) may significantly reduce the rate of exposures due to sharp objects, including syringe needles, and
 - The enhancements to the NEIDL culture of safety (see Section 2.1 of Chapter 2) may reduce the incident rate.

Therefore, BSL-3 needlesticks events are assigned to frequency category A (1 in 1 to 100 years). Based upon the discussion above, this assignment is considered conservative and an incident rate of greater than once per year is not expected.

F.7.3.2.3 Exposure Category

Because this analysis is limited to the point of primary exposure, exposure categories to facility workers and members of the public are not applicable. For laboratory workers, at most one worker will be exposed from a needlestick event. Therefore, an exposure category of LOW is chosen.

F.7.3.2.4 Extent of Exposure

As explained in Section 7.2.2, all needlesticks are conservatively assumed to result in an infectious exposure. Whether such a postulated event is reported promptly does not affect the laboratory worker's exposure to the likely infectious dose, only the ability for medical intervention to mitigate the possibility of infection to the worker and to prevent secondary exposures.

F.7.3.2.5 Summary

Table F.7-1 summarizes the results of the above analysis for a needlestick in a BSL-3 laboratory with prompt detection and reporting.

Table F.7-1. Summary of results—needlestick in BSL-3 laboratory with prompt detection and reporting

Frequency category	Exposure group category	Pathogen ^a	Exposure
A (1 in 1 to 100 years)	Laboratory workers: LOW (1)	<i>B. anthracis</i>	Infection assumed
		<i>F. tularensis</i>	Infection assumed
		<i>Y. pestis</i>	Infection assumed
		1918 H1N1V ^b	Infection assumed
		SARS-CoV ^b	Infection assumed
		RVFV	Infection assumed
		ANDV	Infection assumed
	Facility worker: NONE (0)	--	--
	Public: NONE (0)	--	--

a. *Bacillus anthracis* (*B. anthracis*), *Francisella tularensis* (*F. tularensis*), *Yersinia pestis* (*Y. pestis*), 1918 H1N1 influenza virus (1918 H1N1V), SARS-associated coronavirus (SARS-CoV), Rift Valley fever virus (RVFV), and Andes virus (ANDV).

b. SARS-associated coronavirus, and 1918 H1N1 influenza virus are not expected to be used as wild type inocula but are analyzed here for completeness. Additionally it is assumed that if these viruses are used, then the animal blood concentration is taken to be the same as the maximum working concentration

F.7.3.3 Needlestick in BSL-3 Laboratory without Prompt Detection and Reporting

F.7.3.3.1 Event Sequence Description

The event sequence is the same as described in Section F.7.3.2.1 for a BSL-3 needlestick with prompt reporting except for the following:

- Immediate reporting of potential mishaps and operational upsets is assumed not to occur for this scenario.
- Immediate reporting of symptoms that could be because of an LAI are assumed not to occur for this scenario.

This type of scenario could be representative of a worker who does not feel comfortable reporting the injury for fear of reprisal, believes it was a near-miss event that does not require reporting, or does not notice the needlestick, for example.

F.7.3.3.2 Frequency Category

The available operational experience in Attachment C for BSL-3 facilities indicates that all the events were promptly reported, which implies that the non-reporting rate may be less than about 5% (i.e., all of the 19 incidents were promptly reported). However, as discussed in Section F.3.1.2, there are limitations with the available data; one limitation is that unreported incidents are not included the data and are only likely to be included if an infection resulted later. The likelihood of a needlestick not being reported at the NEIDL is expected to be lower than the historic average for the following reasons:

- The BUMC worker must fail to perform as trained, which includes the requirement to report incidents promptly (BUMC 2011).
- The enhancements to the NEIDL culture of safety (see Section 2.1 of Chapter 2) should encourage reporting and minimize consideration of not reporting.
- The presence of two or more people (i.e., 2-person rule) in the laboratory will discourage any consideration of not reporting incidents.

As described previously in Section F.7.3.2.2, the frequency category for a reported needlestick has been conservatively assigned to frequency category A (1 in 1 to 100 years). The historic data discussed above indicate that the rate of non-reporting considerably lower (e.g., 5%). Therefore, undetected or unreported needlestick incidents are assigned to frequency category B (1 in 100 to 10,000 years) based on the historic data and the enhancements at the NEIDL.

F.7.3.3.3 Exposure Category

Because this analysis is limited to the point of primary exposure, exposure categories to facility workers and members of the public are not applicable. For laboratory workers, at most one worker will be exposed from a needlestick event. Therefore, an exposure category of LOW is chosen.

F.7.3.3.4 Extent of Exposure

As explained in Section F.7.2.2, all needlesticks are conservatively assumed to result in an infectious exposure. Whether such a postulated event is reported promptly does not affect the laboratory worker's exposure to the likely infectious dose, only the ability for medical intervention to mitigate the possibility of infection to the worker and to prevent secondary exposures.

F.7.3.3.5 Summary

Table F.7-2 summarizes the results of the above analysis for a needlestick in a BSL-3 laboratory without prompt detection or reporting.

Table F.7-2. Summary of results—needlestick in BSL-3 laboratory without prompt detection or reporting

Frequency category	Exposure group category	Pathogen ^a	Exposure range
B (1 in 100 to 10,000 years)	Laboratory workers: LOW (1)	<i>B. anthracis</i>	Infection assumed
		<i>F. tularensis</i>	Infection assumed
		<i>Y. pestis</i>	Infection assumed
		1918 H1N1V ^b	Infection assumed
		SARS-CoV ^b	Infection assumed
		RVFV	Infection assumed
		ANDV	Infection assumed
	Facility worker: NONE (0)	-	--
	Public: NONE (0)	--	-

a. *Bacillus anthracis* (*B. anthracis*), *Francisella tularensis* (*F. tularensis*), *Yersinia pestis* (*Y. pestis*), 1918 H1N1 influenza virus (1918 H1N1V), SARS-associated coronavirus (SARS-CoV), Rift Valley fever virus (RVFV), and Andes virus (ANDV).

b. SARS coronavirus, and 1918 H1N1 influenza virus are not expected to be used as wild type inocula, but are analyzed here for completeness. Additionally it is assumed that if these viruses are used, then the animal blood concentration is taken to be the same as the maximum working concentration.

F.7.3.4 Needlestick in BSL-4 Laboratory with Prompt Detection and Reporting

F.7.3.4.1 Event Sequence Description

Initial Conditions—The conditions leading up to this event sequence are as follows:

- The pathogen suspension contains the maximum concentration for that pathogen that is expected to be used in NEIDL. As required, the laboratory workers in the room are wearing BSL-4 positive-pressure suits and double gloves (BUMC 2011).

Other conditions such as the use of respiratory protection and the number of co-located workers in the laboratory are not relevant or applicable for this analysis because they do not influence the extent of exposure from this scenario.

Initiating Events and Contributing Events—Conditions that could initiate, prevent, and/or mitigate a needlestick event are similar to those presented in Section F.7.3.2.1 for BSL-3 and are not duplicated here.

F.7.3.4.2 Frequency Category

Background information (unreported incidents) for determining frequency category in both BSL-3 and BSL-4 facilities is presented in Section F.7.3.2.2 and is not duplicated here. Attachment C shows 5 BSL-4 operating experience incidents since 1976 at four different facilities. These five needlestick incidents in over 100 facility-years of operation (see Section D.2.2 of Appendix D) result in a rate of about 0.05 per year. In addition, Appendix D shows for a number of BSL-4 facilities, the following statistics:

- At the U.S. Army Medical Research Institute of Infectious Diseases, between 1972 and 2009, six reported events similar to the needlestick event being evaluated;
- At the CDC Special Pathogens Branch, between 1979 and 2009, one reported needlestick-type like event;
- At the National Institute for Communicable Diseases, between 1980 and 2003, no reported needlestick-type event;
- At the Southwest Foundation for Biomedical Research, between 2000 and 2009, no reported needlestick-type event; and
- At the University of Texas Medical Branch –Galveston, between 2004 and 2009, no reported needlestick-type event.

While this frequency estimate of 0.05 per year provides insight into the frequency, it may understate or overstate the real value for the following reasons:

- It may understate the historic frequency because incidents have historically been underreported because of fear of reprisal and the source of exposure for over 80 percent of laboratory related illnesses is not known (Harding and Byers 2006). (See Section F.1.3 for details.)
- This historic estimate may overstate the frequency because it may not reflect:
 - The historic decline in LAI rates have declined dramatically over time due to enhancements in biosafety procedures, primary biocontainment systems, personal protective equipment, and facilities engineering, as shown in Section D.1.1 of Appendix D.
 - The sharps safety practices at the NEIDL (see Section F.7.2.1) may significantly reduce the rate of exposures due to sharp objects, including syringe needles, and

- The enhancements to the NEIDL culture of safety (see Section 2.1 of Chapter 2) may reduce the incident rate.

Therefore, BSL-4 needlesticks events are assigned to frequency category A (1 in 1 to 100 years). Based upon the discussion above, this assignment is considered conservative and an incident rate of greater than once per year is not expected.

F.7.3.4.3 Exposure Category

Because this analysis is limited to the point of primary exposure, exposure categories to facility workers and members of the public are not applicable. For laboratory workers, at most one worker will be exposed from a needlestick event. Therefore, an exposure category of LOW is chosen.

F.7.3.4.4 Extent of Exposure

As explained in Section 7.2.2, all needlesticks are conservatively assumed to result in an infectious exposure. Whether such a postulated event is reported promptly does not affect the laboratory worker's exposure to the likely infectious dose, only the ability for medical intervention to mitigate the possibility of infection to the worker and to prevent secondary exposures.

F.7.3.4.5 Summary

Table F.7-3 summarizes the results of the above analysis for a needlestick in a BSL-4 laboratory with prompt detection and reporting.

Table F.7-3. Summary of results—needlestick in BSL-4 laboratory with prompt detection and reporting

Frequency category	Exposure group Category	Pathogen ^a	Exposure range
A (1 in 1 to 100 years)	Laboratory workers: LOW (1)	EBOV	Infection assumed
		MARV	Infection assumed
		LASV	Infection assumed
		JUNV	Infection assumed
		TBEV-FE	Infection assumed
		NIPV	Infection assumed
	Facility worker: NONE (0)	--	-
	Public: NONE (0)	--	--

a. Ebola virus (EBOV); Marburg virus (MARV); Lassa virus (LASV); Junin virus (JUNV); tick-borne encephalitis virus, Far Eastern sub-type, formerly known as tick-borne encephalitis complex (Russian spring-summer encephalitis virus) (TBEV-FE); and Nipah virus (NIPV).

F.7.3.5 Needlestick in BSL-4 Laboratory without Prompt Detection and Reporting

F.7.3.5.1 Event Sequence Description

The event sequence is the same as described in section F.7.3.2.1 for a BSL-3 needlestick with prompt reporting except for the following:

- Immediate reporting of potential mishaps and operational upsets (assumed not to occur for this scenario).
- Immediate reporting of symptoms that could be because of an LAI (assumed not to occur for this scenario).

This type of scenario could be representative of a worker who does not feel comfortable reporting the injury for fear of reprisal, believes it was a near-miss event that does not require reporting, or does not notice the needlestick, for example.

F.7.3.5.2 Frequency Category

As discussed in Section 7.3.3.2, the historic data imply that a small fraction (0.05) of the needlestick events go unreported and Attachment C of this appendix gives no indication of unreported needlesticks in BSL-4 facilities. As with BSL-3 (see Section 7.3.3.2) a BSL-4 needlestick event without prompt detection or reporting is assigned to frequency category B (1 in 100 to 10,000 years). This frequency category is considered appropriate or even conservative because: (1) the historic values likely overstate the value for current facilities due to enhanced practices, equipment, and facilities (see Section D.1.1 of Appendix D), (2) and the NEIDL sharps safety program (see Section F.7.2.1) and culture of safety enhancement program (see Section 2.1 of Chapter 2) are expected to reduce rates, and (3) the morbidity and mortality rates of the BSL-4 pathogens provides a greater incentive to report promptly.

F.7.3.5.3 Exposure Category

Because this analysis is limited to the point of primary exposure, exposure categories to facility workers and members of the public are not applicable. For laboratory workers, at most one worker will be exposed from a needlestick event. Therefore, an exposure category of LOW is chosen.

F.7.3.5.4 Extent of Exposure

As explained in Section F.7.2.2, all needlesticks are conservatively assumed to result in an infectious exposure. Whether such a postulated event is reported promptly does not affect the laboratory worker's exposure to the likely infectious dose, only the ability for medical intervention to mitigate the possibility of infection to the worker and to prevent secondary exposures.

F.7.3.5.5 Summary

Table F.7-4 summarizes the results of the above analysis for a needlestick in a BSL-4 laboratory without prompt detection and reporting.

Table F7-4. Summary of results—needlestick in BSL-4 laboratory without prompt detection or reporting

Frequency category	Exposure group category	Pathogen ^a	Exposure range
B (1 in 100 to 10,000 years)	Laboratory workers: LOW (1)	EBOV	Infection assumed
		MARV	Infection assumed
		LASV	Infection assumed
		JUNV	Infection assumed
		TBEV-FE	Infection assumed
		NIPV	Infection assumed
	Facility worker: NONE (0)	--	--
	Public: NONE (0)	--	--

a. Ebola virus (EBOV); Marburg virus (MARV); Lassa virus (LASV); Junín virus (JUNV); tick-borne encephalitis virus, Far Eastern sub-type, formerly known as tick-borne encephalitis complex (Russian spring-summer encephalitis virus) (TBEV-FE); and Nipah virus (NIPV).

F.7.3.6 Variability and Uncertainty

Numerous variabilities and uncertainties apply to the above sections. Table F.7-5 identifies the key variabilities and uncertainties, provides a discussion of each, and provides an estimate of the potential effects of each.

1

Table F.7-5. Summary of key variabilities and uncertainties

Variability/ uncertainty	Discussion	Potential factor
Frequency Categories	As discussed previously, needlesticks are a relatively common hazard in biocontainment laboratories. However, because of limitations in reporting and uncertainty in the outcomes of events, the frequency estimates are uncertain. That uncertainty is greater for unreported events for obvious reasons. However, on the basis of improving safety (procedures, equipment) and reporting practices, it is anticipated that the frequency categories estimated here will be conservative.	Potential conservatism
Working Concentration	The exposure calculations were performed using the maximum working concentrations as determined in TT-CP-001. Using any lower value than those maximum working concentrations will result in lower exposures to the laboratory worker.	Conservatism
	Because of the uncertain nature of biological activities, it is possible for concentrations to be higher than those assumed here. However, because the upper bound of values in the literature is used herein, it is expected that concentrations would not be much higher.	Potentially non-conservatism (factor undetermined)
SARS-CoV and 1918 H1N1V	SARS-CoV and 1918 H1N1V are not expected to be used as wild-type inocula but were included in this analysis for completeness. It was assumed that the animal blood concentration would equal the maximum working concentration.	Potential conservatism for frequencies
Extent of Exposure	Some needlesticks will involve syringes that are sterile and others will transfer almost no pathogen, therefore assuming an infectious dose is received is conservative. Also, the true infection rate might not be 100% even at relatively high doses.	Known conservatism
Inhalation and ingestion not analyzed	Only direct exposure because of a puncture was analyzed. It is believed that this is appropriate given the nature of needlesticks (i.e., any amount of pathogen available for inhalation or ingestion is negligible).	Potentially non-conservative, but negligible
Needlestick punctures skin	It is assumed that the needlestick punctures the skin and injects pathogen on contact. As stated in the analysis, double gloves are standard operating practice, so a needlestick could penetrate a glove but not the skin.	Conservatism

2

F.8 EARTHQUAKE EVENTS

F.8.1 Introduction

The NEIDL facility was designed and constructed in compliance with strict seismic criteria. Attachment D of this appendix provides an overview of the relevant design criteria and compliance of the NEIDL design with those criteria. As presented in Attachment D of this appendix, a few features of the NEIDL seismic design are as follows (BUMC 2008; Massachusetts 1997; and NIH 2005):

- The design criteria include compliance with
 - NIH Design Policy and Guidelines, November 2003 Edition (NIH 2003)
 - U.S. Department of Health and Human Services, CDC/NIH, Microbiological and Biomedical Laboratories(BMBL), 5th ed. (CDC and NIH 2007)
 - Massachusetts State Building Code (780 CMR); 6th ed. (Massachusetts 1997)
- The Massachusetts State Building Code establishes Seismic Hazard Exposure Groups and Seismic Performance Categories for buildings depending on the nature of their occupancy. NEIDL is classified as a Seismic Hazard Exposure Group II and is assigned to Seismic Performance Category C.
- As required by the Massachusetts State Building Code, the effective peak velocity-related acceleration and the effective peak acceleration are each 0.12g. For Seismic Performance Category C, the building structure must stay functional after a seismic event (Massachusetts 2009).
- While NEIDL is assigned to Seismic Performance Category C, it complies with Seismic Category D, which includes more stringent criteria. Category D facilities have essential functions that are required for post-earthquake recovery. In addition to the structure remaining intact, Category D facilities must also remain operational following a design basis earthquake.
- The BSL-4 suites are structurally separated from the adjoining floors. Such structural separation allows for movement in an earthquake, while maintaining structural integrity of the BSL-4 suites.
- BSL-4 suites have 12-inch-thick reinforced concrete walls with special epoxy covering that acts as a sealant.
- All fixtures for the BSL-4 suite were designed specifically for the facility, and are Underwriters Laboratories tested, to ensure that the facility retains its air pressurization.

F.8.2 Methodology

The risk associated with an event sequence is defined by the combination of its frequency of occurrence and the consequences of its occurrence (EPA 1987; DOE 2002). This section describes the methodology for determining the frequency and consequence for each event sequence.

F.8.2.1 Radial Grid

The level of exposure is dependent on the amount of pathogen released and how the pathogen is dispersed. Both the airborne dispersion factors and the number of people are site-specific, and they have been developed using the same radial (or polar) grid with sixteen 22.5°-sectors similar to the one shown in Figure F.8-1.

For this analysis, each annulus is 100-m wide, and the grid extends to a maximum radius of 1 km. While a radius of 1 km captures the majority of the impacts, the expected number of infections would be somewhat higher if the calculation were performed for a larger radius.

Figure F.8-1. Radial grid.

There are two competing factors associated with exposures at greater distance, namely, (1) a decrease in the exposure level as the concentration of the pathogen aerosol decreases with distance and (2) a tendency for the number of people per segment to increase because the area of each segment increases as the distance from the center increases. The maximum radius of 1 km (0.6 mile) was selected for several reasons:

- The 1-km radius is consistent with U.S. Nuclear Regulatory Commission recommendations for the NEPA environmental justice evaluation of proposed actions in cities (Nuclear Regulatory Commission 2003).
- The highest density of nonresidents surrounding the urban site is within 0.5 km of NEIDL and is included in the 1-km radius (see Section F.4).

- No high-population communities are just beyond the 1-km radius that would significantly affect the results at any of the sites (see Section F.4).
- The average exposure levels are extremely low at 1 km and would be even lower for greater distances. The MRF (total collapse) earthquake analysis (as shown later) estimates the average exposure level to be less than one one-thousandth (1/1,000) of a unit for all but one pathogen and less than one one-hundredth (1/100) of a unit for all pathogens at 1 km. The calculated exposures at even greater distances would result in even lower exposure levels.

There is limited data on the airborne spread of pathogens, but there is one incident that was considered. The 1979 *B. anthracis* incident in Sverdlovsk, Russia resulted in human infections to a distance of 4 km. However, that incident occurred in a weapons production facility with large quantities of spores released. U.S. biological weapons experts estimate the release to be in the range of one to ten kilograms (Wampler and Blanton 2001). Because the release involved a weaponized pathogen and because the release was many orders of magnitude greater than the entire inventory of NEIDL pathogens, the incident is not relevant to the decision to truncate the exposure calculations at 1 km. Therefore, the 1 km maximum radius is considered appropriate.

F.8.2.2 Atmospheric inactivation

After release from the stack, the pathogen aerosol would be transported and dispersed as a result of winds and meteorological conditions. Atmospheric conditions (e.g., sunlight) would inactivate some infectious particles over time; however, that effect might not be significant for the following reasons:

1. The time required for transport aerosol particles 1 km in the atmosphere is less than 4 minutes at a median wind speed of 5.1 m/second for the urban site (see Section F.5). The median half-life for all pathogens under optimum inactivation conditions is greater than 4 minutes for all pathogens and is 10 to 20 minutes for most pathogens (Bozzette 2011). Therefore, the inactivation is not a major factor for most pathogens under optimum conditions.
2. The earthquake could occur at any time of the day (including nighttime) or of the year (including winter). The half-lives under those unfavorable conditions range from 20 to more than 120 minutes (Bozzette 2011). Therefore, there is virtually no inactivation within 1 km under unfavorable conditions.

Because atmospheric inactivation has a small effect under optimum conditions and virtually no effect under unfavorable conditions (i.e., nighttime and winter), which is a majority of the year, atmospheric inactivation was conservatively not included in this analysis.

F.8.2.3 Airborne dispersion

The airborne dispersion from the point of release is also an essential input to determining the extent of exposure. Section F.5.2 provides the airborne dispersion factors for all three sites. The airborne dispersion factors are calculated for a segment of each annulus of the radial grid to a distance of 1 km. The computer code and parameters used to estimate the airborne dispersion are consistent with guidance (DOE 2002, DOE 2004a) and are addressed in Section F.5.2 of Appendix F. The input parameters for the analyses were the recommended or conservative values (i.e., overestimate aerosol concentrations). For example, wet deposition the dry deposition and building wake effect parameters were the recommended default values. Conservative parameters include the suppression of wet deposition, buoyant plume rise, building wake effect plume rise, and plume meander. The results of these dispersion analyses were compared with the results of other dispersion analyses and wind tunnel tests for NEIDL and were found to be in good agreement. In the case of the MRF (total collapse) earthquake, the assumption of a ground-level release is very conservative and compensates for uncertainties in the analyses. For example at the urban site, concentrations are over 200 times greater at the 30-m exclusion fence for a ground-level release than for an elevated release (see Table F.5.3-1 of Appendix F). See Section F.5 of Appendix F for additional details.

F.8.2.4 Analysis Guidance

DOE NEPA Guidance (DOE 2002) states,

The key to informative accident analyses is to develop realistic accident scenarios that address a reasonable range of event probabilities and consequences.

In addition to stressing realistic scenarios, DOE NEPA Guidance also notes that *bounding* (i.e., simplified and conservative) approaches may be used for accident analyses, and the bounding approaches might have several distinct advantages (DOE 2002):

...streamlining an analysis when there are many uncertainties and avoiding the need to prepare more realistic analyses when not warranted. Further, bounding analyses may be more defensible than more realistic approaches because they are unlikely to underestimate potential accident consequences.

1 Because of the lack of seismic risk information (e.g., seismic hazard curves and NEIDL fragility curves),
2 use of a bounding approach is used for this analysis. However, DOE NEPA Guidance cautions (DOE
3 2002),

4 On the other hand, bounding analyses may mask differences among alternatives and be
5 less informative about the potential need for mitigation. Also, excessive conservatism may
6 result in a misleading presentation of accident risks

7
8 Use of a bounding analysis overstates the risks, but it does *not* mask differences between the sites
9 because of the following:

- 10 • The same methodology is used for all sites so any conservative bias will be applied equally to all
11 sites.
- 12 • The major site differences are the differences in meteorology and population density. Those
13 differences are taken into account with site-specific data, so the site differences are not masked
14 but are accurately reflected in the analysis.

15
16 DOE NEPA Guidance (DOE 2002) states, “prevailing (median) meteorological conditions generally
17 should be used.” Therefore, median meteorological conditions for each site are used in these analyses.

18 19 **F.8.3 Results**

20 This section documents the earthquake event selection and the analysis results. The analysis was
21 performed separately for the BSL-3 and BSL-4 areas, although there are many similarities. The
22 variabilities and uncertainties associated with the analyses were also evaluated qualitatively.

23 24 **F.8.3.1 Scenario Selection**

25 Two earthquakes have been selected for analysis; an earthquake that results in totally facility collapse was
26 selected as the MRF event and a less severe but still beyond design basis (BDB) earthquake that results in
27 minor damage was also analyzed. The following sections discuss those events and the rationale for their
28 selection.

F.8.3.1.1 Maximum Reasonably Foreseeable Earthquake

The MRF event is defined as a reasonably foreseeable accident⁸ that results in consequences that are not exceeded by any other reasonably foreseeable event. For this analysis, the MRF event is defined on the basis of direct effects (i.e., pathogen release and direct exposure) on the general public. A severe earthquake has been selected as the MRF event because it:

- Has the potential to affect the entire facility inventory
- Has the potential to compromise all biocontainment features
- Can occur under any meteorological conditions
- Results in higher airborne concentrations than tornadoes and hurricanes, which result in much greater mixing, thereby resulting in much lower concentrations
- Can result in escape of animals (mammals and arthropods)
- Typically *bounds* other natural phenomena events (DOE-HDBK-3010)

F.8.3.1.2 Beyond Design Basis Earthquake

The role of the MRF event is to provide insight into the *worst-case* accident, which was requested by the courts. However, DOE NEPA Guidance (DOE 2002) provides the following caution:

...in many cases the acceleration forces associated with extremely rare earthquakes (e.g., frequencies of less than 10^{-6} per year) may be so great that destructive impacts unrelated to the proposed action or alternatives would overwhelm impacts associated with the proposed action or alternatives. Such an analysis would not be informative regarding the proposed action or alternatives because a decision maker would be unable to distinguish the consequences resulting from the proposed action or alternatives from the general destructive effects of the earthquake. Analyzing a higher frequency earthquake scenario, however, could be useful in making decisions about the proposed action and alternatives, such as whether a robust earthquake design or alternative location for a proposed facility is warranted.

DOE NEPA Guidance stresses the importance of realism in the analysis and the MRF (total collapse) earthquake is an extremely unlikely event. To put the risks associated with the MRF earthquake into perspective, an earthquake that is less severe and more likely than the MRF earthquake is also analyzed.

⁸ “Reasonably foreseeable” events include events that might which may have catastrophic consequences, even if their probability of occurrence is low, provided that the analysis of the impacts is supported by credible scientific evidence, is not based on pure conjecture, and is within the rule of reason. .” [Council on Environmental Quality (CEQ) NEPA Regulations, (40 CFR 1502.22)]

Earthquakes that are within the seismic design basis of the facility were not analyzed because the NEIDL structures, systems, and components were designed to perform their functions during and following design basis earthquakes, thereby not resulting in a loss of biological containment. A slightly beyond design basis (BDB) earthquake that is more likely than the MRF (total collapse) earthquake but still beyond the design basis and results in minor damage was selected for analysis. The BDB earthquake is postulated to be slightly beyond the design basis and to result in partially mitigated releases.

F.8.3.2 Beyond Design Basis Earthquake Affecting BSL-3

A BDB (minor damage) earthquake is an earthquake that slightly exceeds the mean seismic ground motion used for the earthquake-resistant design of structures, systems, and components. This section describes the event sequence, frequency category, exposure category, and extent of exposure resulting from a BDB earthquake that results in a partially mitigated the BSL-3 release.

F.8.3.2.1 Event Sequence Description

The initial conditions for the earthquake event sequence are as follows:

- There are no warnings of a potential seismic event and the facility is operating without forewarning of the earthquake.
- Any or all pathogen(s) could be in use in the facility at its typical volumes and maximum concentrations in a liquid suspension. The pathogen could be in one or more containers at the time of the earthquake.
- The facility contains infected animals (mammals and arthropods) at the time.

An earthquake is postulated to occur that involves the following events and conditions:

- The postulated BDB earthquake exceeds the seismic design basis of the NEIDL facility. The NEIDL facility has been demonstrated (Weidlinger 2005) to meet the requirements of the Massachusetts State Building Code (Massachusetts 1997). That code specifies an effective acceleration of 0.12 g (i.e., 0.12 times the acceleration of gravity, or $0.12 \times 32.2 \text{ ft/s}^2 = 3.86 \text{ ft/s}^2$). As discussed in Attachment E of this appendix, the Richter scale is a measure of the size of the earthquake and does not directly correspond to the effective acceleration at a location.
- While the postulated BDB earthquake exceeds the 0.12 g design basis, accelerations slightly beyond this level are not expected to result in extensive structural damage or collapse. The Massachusetts Building Code (Massachusetts 1997) states the following:

For ground motions larger than the design levels, the intent of 780 CMR 1612.0 is that there be a low likelihood of building collapse.

Therefore, a total loss of structural integrity would not be expected from the BDB earthquake.

- As a result of the earthquake, one or more containers of pathogens in liquid suspension falls and an airborne release results. Non-breakable containers will be used whenever possible (CDC and NIH 2007), so a broken container is not likely, but a container spill is possible. Containers are allowed to be opened only inside a BSC.
- While loss of structural integrity is not expected, there could be a compromise to other biocontainment features. (Note: There are no windows in the BSL-3 or BSL-4 exterior walls.) One of the more affecting potential consequences would be continued operation of the HVAC system with a partial compromise of the HEPA filtration system. That configuration could result in prompt release of the aerosol with a limited attenuation. A loss airflow is also possible, but that would result in a very gradual release and a lower public exposure, so that failure mode is not considered further.
- One or more laboratory workers are in the room at the time of the release and are wearing respiratory protection (i.e., PAPR for BSL-3), as required (BUMC 2010).
- Facility workers would promptly leave the facility and are assumed to remain at the exclusion fence line for the duration of any release.
- It is assumed that a fire does not result from the earthquake. A fire would inactivate most pathogens and would tend to loft releases over the population, so this assumption results in the highest potential consequences.
- Per guidance, this event occurs during median meteorological conditions (DOE 2002).
- Infected animals (mammals and arthropods) are not expected to escape from a BDB earthquake because there are many barriers to escape, including the cages, interlocking doors to the suits, doors to the floors, and doors to the building.

F.8.3.2.2 Frequency Category

For an exposure to result, a significant vulnerable pathogen inventory (e.g., the working stock) must be present, and it must be release by the BDB (minor damage) earthquake. A rigorous estimate of the frequency is not possible for this analysis because of a lack of information, but the frequency of a BDB earthquake is judged to be in frequency category C (one in 10,000 to 1 million years) for all three candidate sites. This frequency category selection is made because the NEIDL is design to continue to perform its essential functions following a 2-second (effectively the natural frequency of the building) 0.12 g earthquake (BUMC 2005). A 2-second, 0.12 g earthquake has an annual exceedance probability of less than 1×10^{-4} based on the U.S. Geological Survey (USGS) National Seismic Hazard Maps (see Attachment E of this appendix).

F.8.3.2.3 Exposure Category

The exposure category for the laboratory workers is HIGH because all people in all rooms have the potential to be exposed.

As explained in Section F.8.2, the HVAC system protects laboratory workers from potential exposure because of the directional airflow; however, workers who evacuate and assemble at the fence line could be exposed. The exposure category for the facility worker is HIGH.

The estimated exposure category for the public is expected to be LOW. Dispersion calculations indicate that pathogens could be transported beyond the 30-m exclusion zone but are unlikely to spread beyond 300 m. It is possible for pathogen particles to be spread beyond 300 m, but the concentrations would be so low that they would be a minimal risk to health.

F.8.3.2.4 Extent of Exposure

Airborne dispersion of the pathogen organisms can result in inhalation, ingestion, and direct contact routes of exposures. Inhalation exposures are calculated for the laboratory worker and the general public because that is the most likely route of exposure and there is very limited dose-response information for the other routes. The extent of exposure was calculated for the laboratory worker, facility worker, and public. The laboratory worker and facility worker exposures are site-independent because the same facility design and operations are assumed for all three sites. However, the public exposures are site-dependent and are calculated separately for each site.

F.8.3.2.4.1 Laboratory Worker Exposure

A series of experiments designed to mimic the potential event sequences in laboratories was conducted by the Health Protection Agency, an independent organization in the United Kingdom. The purpose of the experiments was “To quantify microbial aerosols generated by a series of laboratory accidents and to use these data in risk assessment.” (Bennett and Parks 2006) While the experiments were performed with *B. atrophaeus*, the experimental results are assumed to be applicable to the pathogens evaluated for NEIDL because (1) the aim of the experiments and the discussion in the report addresses microorganisms in a general sense rather than *B. atrophaeus* in particular, (2) the report does not specify any limitations on applicability, and (3) the smaller size of viruses provides reason to believe the results are applicable to viruses. In this analysis, the airborne pathogen concentration in the laboratory room is based on the experiment involving the drop of a 250-mL flask containing 50 mL of pathogen suspension. The

experiment is referred to as a *smashed flask*, implying that the flask was glass, while non-breakable containers will be used whenever possible in NEIDL (CDC and NIH 2007). While the smashed flask likely overestimates the release from a non-breakable container, it is possible that the non-breakable container is not sealed or that it is otherwise breach from a falling object. The general equation resulting from the experiments is presented below.

$$AC = SC \times SF \quad \text{[equation F.8-1]}$$

where

AC The aerosol concentration in a room (per m³)
 SC The suspension concentration (per mL)⁹
 SF The experimentally determined spray factor (mL/m³)

The above equation is based on the drop of a flask containing 50 mL of suspension, but the maximum working volume for the pathogens being evaluated ranges from 1 mL to 150 mL (see Section F.3). The aerosol concentration in the room is assumed to be proportional to the ratio of the maximum working volume (V_{max}) of the pathogen to the 50 mL used in the experiment. Therefore, AC_{room} is calculated as follows:

$$AC_{room} = SC \times SF \times (V_{max} / 50 \text{ mL}) \quad \text{[equation F.8-2]}$$

Using the same Rift Valley fever virus (RVFV) working stock with an SC of 1×10^9 CCID₅₀/mL with a typical volume of 150 mL (see Section F.3) provides in the following example results:

$$\begin{aligned} AC_{room} &= SC \times SF \times (V_{max} / 50 \text{ mL}) \\ &= (1 \times 10^9 \text{ CCID}_{50}/\text{mL}) \times (5.2 \times 10^{-7} \text{ mL}/\text{m}^3) \times (150 \text{ mL} / 50 \text{ mL}) \\ &= 1,600 \text{ CCID}_{50}/\text{m}^3 \end{aligned}$$

Table F.8-1 provides the AC_{room} values for all BSL-3 pathogens.

⁹ Suspension concentrations for bacteria are given in terms of colony forming units (CFU). Concentrations for viruses are given in various units, including plaque forming units (PFU), median cell culture infective doses (CCID₅₀), and median mouse intracerebral lethal doses (MICLD₅₀) per milliliter. Attachment C provides some background information on the methods and units associated with the concentration measurements.

Table F.8-1. BSL-3 room aerosol concentrations from a BDB earthquake

Pathogen ^a	BSL	SC (/mL) ^b	SF (mL/m ³) ^c	V _{max} (mL)	AC _{room} (/m ³) ^b
<i>B. anthracis</i> ^d	2/3	2.4 × 10 ⁸ CFU	5.2 × 10 ⁻⁷	50	120 CFU
<i>F. tularensis</i>	3	2.0 × 10 ⁹ CFU	5.2 × 10 ⁻⁷	1	21 CFU
<i>Y. pestis</i>	3	2.0 × 10 ⁷ CFU	5.2 × 10 ⁻⁷	5	1.0 CFU
1918H1N1V	3	1.0 × 10 ⁸ PFU	5.2 × 10 ⁻⁷	150	160 PFU
SARS-CoV	3	1.0 × 10 ⁷ PFU	5.2 × 10 ⁻⁷	150	16 PFU
RVFV ^e	3	1.0 × 10 ⁸ PFU	5.2 × 10 ⁻⁷	150	160 PFU
		1.0 × 10 ⁹ CCID ₅₀ or MICLD ₅₀	5.2 × 10 ⁻⁷	150	1,600 CCID ₅₀ or MICLD ₅₀
ANDV	3/4	1.0 × 10 ⁶ CCID ₅₀	5.2 × 10 ⁻⁷	150	1.6 CCID ₅₀

a. *Bacillus anthracis* (*B. anthracis*); *Francisella tularensis* (*F. tularensis*); *Yersinia pestis* (*Y. pestis*); 1918 H1N1 influenza virus (1918H1N1V); SARS-associated coronavirus (SARS-CoV); Rift Valley fever virus (RVFV); and Andes virus (ANDV).

b. Suspension concentrations and room aerosol concentrations are given in terms of colony forming units (CFU) for bacteria and plaque forming units (PFU), median cell culture infective dose (CCID₅₀), or median mouse intracerebral lethal dose (MICLD₅₀) for viruses. Section F.3.1.2 provides background information on the methods and units associated with the concentration measurements. Values are taken from the working inventory reported in Section F.3.

c. SF is based on a smashed flask containing 50 mL (Bennett and Parks 2006).

d. In spore form in suspension.

e. Two values are reported for RVFV with different units. The CCID₅₀ and MICLD₅₀ units are an order of magnitude greater because this measurement is more sensitive.

The worker's potential exposure is the airborne pathogen concentration in the air inhaled multiplied by the volume of air inhaled. It is conservatively assumed that all infectious particles inhaled are retained in the body. The pathogen concentration in the inhaled air is the airborne concentration in the room air multiplied by the fraction of aerosol particles that pass through the PAPR filter. The amount of air inhaled is the breathing rate times the effective duration of exposure. Therefore, the average exposure (i.e., the number of infectious particles a worker inhales) (EX) is equal to the aerosol concentration (AC, which is calculated in equation F.8-2) times the PAPR leak path factor (LPF) times the breathing rate (BR) multiplied by the duration of exposure (T).

$$EX = AC_{room} \times LPF \times BR \times T \quad [\text{equation F.8-3}]$$

where

LPF The leak path factor is the fraction of airborne particles that would leak past the confinement or filtration system. For this event sequence, the PAPRs will have an APF¹⁰ of 1,000 (29 CFR 1910.134 and NIH 2010), which is the inverse of the LPF of 0.001.

¹⁰ The APF is the workplace level of respiratory protection that a respirator or class of respirators is expected to provide to employees when the employer implements a continuing, effective respiratory protection program (which includes fit testing and proper training) as specified by this section (29 CFR 1910.134).

BR The breathing rate for the worker is assumed to be $3.33\text{E-}04 \text{ m}^3/\text{s}$ or $0.020 \text{ m}^3/\text{min}$ (DOE 2004a).

T The duration of exposure (T) is the breathing time at the peak concentration. The air exchange rate for NEIDL is at least eight air exchanges per hour (BUMC 2009a), which equates to an air exchange every 7.5 minutes $[(1 \text{ hr} / 8 \text{ exchanges}) \times 60 \text{ min/hr} = 7.5 \text{ min}]$. The concentration of aerosols in the room will be dependent on the airflow patterns in the room and the nature of the release. The majority of the aerosol would be removed after 1 air exchange (i.e., 7.5 minutes) and 90 percent would be removed after 2.3 air exchanges (i.e., $17.25 \text{ minutes} = 2.3 \times 7.5 \text{ minutes}$) (NIH 2008). A laboratory worker remaining in the area for approximately one hour with the concentration decreasing as the release is purged from the room is approximately the same as a 10-minute exposure at the peak concentration. The exposure is modeled as a 10-minute exposure at peak concentration.

The previous RVFV example that resulted in a AC_{room} value of $1,600 \text{ CCID}_{50}/\text{m}^3$ is used to as an example of the exposure level calculation:

$$\begin{aligned} EX &= AC_{\text{room}} \times LPF \times BR \times T \\ &= (1,600 \text{ CCID}_{50}/\text{m}^3) \times (0.001) \times (0.020 \text{ m}^3/\text{min}) \times (10 \text{ min}) \\ &= 0.3 \text{ CCID}_{50} \end{aligned}$$

An average exposure (*EX*) of less than 1 CCID_{50} indicates that although there might be instances where one or more CCID_{50} is inhaled, there might also be instances where zero CCID_{50} are inhaled, for an average inhalation of less than one. The exposure for all BSL-3 pathogens being evaluated are presented in Table F.8-2.

Table F.8-2. Calculated laboratory worker exposures for BSL-3 pathogens from a BDB earthquake.

Pathogen ^a	AC _{room} (/m ³) ^b	LPF	BR (m ³ /min)	T (min)	EX ^b
<i>B. anthracis</i> ^c	2.4 × 10 ⁸ CFU	0.001	0.020	10	0.02 CFU
<i>F. tularensis</i>	2.0 × 10 ⁹ CFU	0.001	0.020	10	0.004 CFU
<i>Y. pestis</i>	2.0 × 10 ⁷ CFU	0.001	0.020	10	0.0002 CFU
1918H1N1V	1.0 × 10 ⁸ PFU	0.001	0.020	10	0.03 PFU
SARS-CoV	1.0 × 10 ⁷ PFU	0.001	0.020	10	0.003 PFU
RVFV ^d	1.0 × 10 ⁸ PFU	0.001	0.020	10	0.03 PFU
	1.0 × 10 ⁹ CCID ₅₀ or MICLD ₅₀	0.001	0.020	10	0.3 CCID ₅₀ or MICLD ₅₀
ANDV	1.0 × 10 ⁶ CCID ₅₀	0.001	0.020	10	0.0003 CCID ₅₀

a. *Bacillus anthracis* (*B. anthracis*); *Francisella tularensis* (*F. tularensis*); *Yersinia pestis* (*Y. pestis*); 1918 H1N1 influenza virus (1918H1N1V); SARS-associated coronavirus (SARS-CoV); Rift Valley fever virus (RVFV); and Andes virus (ANDV).

b. Room aerosol concentrations and exposures are given in terms of colony forming units (CFU) for bacteria and plaque forming units (PFU), median cell culture infective dose (CCID₅₀), or median mouse intracerebral lethal dose (MICLD₅₀) for viruses. Section F.3.1.2 provides background information on the methods and units associated with the concentration measurements.

c. In spore form in suspension.

d. Two values are reported for RVFV with different units. The CCID₅₀ and MICLD₅₀ units are an order of magnitude greater because this measurement is more sensitive.

The laboratory worker exposures resulting from a BDB earthquake are approximately the same as the exposures resulting from the centrifuge release event (see Section F.6). For example, the highest exposure level is for RVFV where the BDB earthquake exposure is 0.3 CCID₅₀ and the centrifuge release event exposure is 9 CCID₅₀ (see Section F.6), which is a factor of thirty greater than the results above. The centrifuge release event is in frequency category A (1 in 1 to 100 years) and the BDB earthquake is in the frequency category C (1 in 10,000 to 1 million years). The number of infections and secondary transmissions is not calculated for laboratory worker for the following reasons:

- On the basis of the results in RA Chapter 9 for the centrifuge release, the frequency of a laboratory worker infection caused by a BDB earthquake is expected to be either in or on the cusp of the beyond reasonably foreseeable, frequency category D (1 in more than 1 million years). Events that are beyond reasonably foreseeable are dismissed from further consideration.
- The analysis would not provide additional insight into either laboratory worker or public risk because the risk associated with the centrifuge release event is much greater (nominally four orders of magnitude based on the frequency of the release sequence).

F.8.3.2.4.2 Facility Worker

Following an earthquake of this magnitude, it is expected that all facility workers would promptly exit the facility and intuitively move away from the building. However, any facility workers that would remain in the building would not be exposed to the aerosol release because the directional airflow of the HVAC system would keep the aerosol away from facility workers and direct it to the exhaust system.

For this analysis, it is assumed that facility workers exit the building promptly and congregate at the exclusion fenceline (at least 30 m from the NEIDL). A person at the exclusion fence is defined as the maximally exposed individual (MEI), i.e., the hypothetical person receiving the greatest exposure, so the MEI exposure will be used for laboratory workers. The MEI exposure is calculated in the public exposure section below. Approximately 300 workers at NEIDL are present about 25 percent of the year (about 50 weeks at 40 hours per week out of an 8,760 hour year), which results in an average worker population of 75 people. Because of the very low levels of exposure, a facility worker infection is considered to be in frequency category D (1 in more than 1 million years), which is considered beyond reasonably foreseeable and is dismissed from further consideration.

F.8.3.2.4.3 Public Exposure

Following an aerosol release inside a laboratory room, the HVAC system would purge aerosol from the room, filter out aerosol particles, and exhaust the air through the stack. Members of the general public could be exposed to aerosol particles that are not filtered out of the building exhaust. To determine the consequences of that potential exposure, it is necessary to know the number of people exposed and the level of their exposure. The number of people is provided in Section F.4. The level of exposure is dependent on the amount of pathogen released and how the pathogen is dispersed (i.e., the dispersion factor). Both the airborne dispersion factors and the number of people are site-specific and they have been developed using the same radial (or polar) grid with sixteen 22.5°-sectors similar to the one shown in Figure F.8-1.

The stack source term (ST_{stack}), which is the total amount of material released through the stack, is the total amount of aerosol generated times the fraction that is *not* removed by the HEPA filters before discharge through the stack. Assuming a uniform aerosol concentration, the total amount of pathogen released from a dropped flask is the aerosol concentration in the room (AC_{room}) times the volume of the room. The stack source term can be calculated as follows:

$$ST_{stack} = AC_{room} \times V_{room} \times LPF \quad (\text{equation F.8-4})$$

where

ST_{stack} The stack source term is the quantity of aerosol released out the stack. The units of the source term are the same as the units used to quantify pathogen concentration, which differs from pathogen to pathogen.

AC_{room} The aerosol concentration in the room is provided in Table F.8-1 above. The units of the source term are the same as the units used to quantify pathogen concentration, which differs from pathogen to pathogen.

V_{room} The volume of the room. Because the aerosol concentration is based on the experiments, this is the volume of the room in which the experiment was performed. The room in which the experiments were performed was 3 m × 3 m × 2 m (Bennett and Parks 2006), which is 18 m³.

LPF The leak path factor is the fraction of the aerosol that leaks out of the facility (i.e., through the HEPA filtration system).

Under normal conditions, the NEIDL BSL-3 HEPA filters are at least 99.97 percent efficient at removing airborne particles 0.3 µm in diameter with higher efficiencies for all other particle sizes (NIH 2008). Therefore, LPF for HEPA filters is 0.03 percent (i.e., 1–0.9997). However, following a BDB earthquake, it is possible for the HEPA filter efficiency to be reduced because of gasket or media leakage. Several seismic tests of HEPA filters have shown no deterioration in performance; however, actual earthquakes at the Lawrence Livermore National Laboratory (LLNL) indicate a potential increase in filter failures (LLNL 1994). The 1980 earthquake resulted in peak ground accelerations of 0.2 to 0.3 g at LLNL. Tests of 213 HEPA filters over the 12 months following the earthquake showed an increase of about 5 percent in the number of filters experienced leakage beyond the permissible 0.03 percent. Similar tests on 741 HEPA filters were performed following the 1989 earthquake and there was no increase in the number of filters failing the tests. The 1989 earthquake caused peak ground accelerations of 0.1 g at LLNL.

The 1980 earthquake peak ground acceleration of 0.2 to 0.3 g at LLNL was well beyond the NEIDL seismic design basis of 0.12 g, and the 1989 earthquake peak ground acceleration of 0.1 g was slightly less than the NEIDL seismic design basis. If the NEIDL HEPA filters performed as the LLNL filters, one would expect that a BDB earthquake with a peak ground acceleration of slightly greater than 0.12 g would result in between a 0 and 5 percent increase in filter failures. In addition to the number of filter failures, it is also important to consider the severity of the failures. The extent of leakage in the LLNL HEPA filters is not reported, which implies that the severity was not great because that information would have been available and it would be important. However, it was reported that “[n]o contamination was

detected following the earthquakes that would suggest transient releases from the filtration system” (LLNL 1994). On the basis of that experience, it is expected that there would be no or a very slight increase in leakage through the NEIDL HEPA filters as a result of a BDB earthquake. However, to ensure that potential impacts are not underestimated, it was assumed for this analysis that the leakage through the HEPA filters is increased an order of magnitude as a result of the BDB earthquake (i.e., from a leakage rate of 0.03 percent to a leakage rate of 0.3 percent). Therefore, an LPF of 0.3 percent will be used for the fraction of the aerosol in the room that would be released through the stack.

Using equation 3-4 and the RVFV AC_{room} from Table F.8-1 as an example produces the following results:

$$\begin{aligned} ST_{stack} &= AC_{room} \times V_{room} \times LPF \\ &= (1,600 \text{ CCID}_{50}/\text{m}^3) \times (18 \text{ m}^3) \times (0.003) \\ &= 86 \text{ CCID}_{50} \end{aligned}$$

Performing the calculation for all BSL-3 pathogens in Table F.8-1 produces the results presented in Table F.8-3. These results are applicable to all three sites because the facility design and operations are assumed to be the same at all sites.

Table F.8-3. Calculated stack source term for BSL-3 pathogens from a BDB earthquake

Pathogen ^a	AC_{room} (/m ³) ^b	V_{room} (m ³)	LPF	ST_{stack} ^b
<i>B. anthracis</i> ^c	120 CFU	18	0.003	7 CFU
<i>F. tularensis</i>	21 CFU	18	0.003	1 CFU
<i>Y. pestis</i>	1.0 CFU	18	0.003	0.06 CFU
1918H1N1V	160 PFU	18	0.003	8 PFU
SARS-CoV	16 PFU	18	0.003	0.8 PFU
RVFV ^d	160 PFU	18	0.003	8 PFU
	1,600 CCID ₅₀ or MICLD ₅₀	18	0.003	80 CCID ₅₀ or MICLD ₅₀
ANDV	1.6 CCID ₅₀	18	0.003	0.08 CCID ₅₀

a. *Bacillus anthracis* (*B. anthracis*); *Francisella tularensis* (*F. tularensis*); *Yersinia pestis* (*Y. pestis*); 1918 H1N1 influenza virus (1918H1N1V); SARS-associated coronavirus (SARS-CoV); Rift Valley fever virus (RVFV); and Andes virus (ANDV).

b. Room aerosol concentrations and stack source term are given in terms of colony forming units (CFU) for bacteria and plaque forming units (PFU), median cell culture infective dose (CCID₅₀), or median mouse intracerebral lethal dose (MICLD₅₀) for viruses. Section F.3.1.2 provides background information on the methods and units associated with the concentration measurements.

c. In spore form in suspension.

d. Two values are reported for RVFV with different units. The CCID₅₀ and MICLD₅₀ units are an order of magnitude greater because this measurement is more sensitive.

The inhalation exposure of a member of the public downwind from the release is calculated by the following formula, which is adapted from the airborne dispersion code guide by deleting the radiological factors that are not relevant here (DOE 2004a):

$$EX = (ST_{stack}) \times (\chi/Q) \times (BR) \quad (\text{equation F.8-5})$$

where

EX The inhalation exposure (*EX*) in to a person at that location. The units of the exposure are the same as the units used to quantify pathogen concentration, which differs from pathogen to pathogen.

ST_{stack} The stack source term is the quantity of aerosol released out the stack. The units of the source term are the same as the units used to quantify pathogen concentration, which differs from pathogen to pathogen.

χ/Q The downwind dilution factor (χ/Q) from atmospheric dispersion, which represents the time-integrated concentration at a specific downwind location that is normalized by the quantity released to the atmosphere, with typical units of s/m^3 . χ/Q is site-specific and changes with the distance from the point of release. Therefore, site and distance specific χ/Q values were developed in Section F.5. As discussed in Section F.8.2.7, the DOE guidance recommends, "...prevailing (median) meteorological conditions generally should be used." Therefore, median values are used in this analysis. The NEIDL stack is assumed to remain intact because structural failures are not expected until well beyond the design basis (see Section F.8.3.2.1).

BR The breathing rate (*BR*) of the individual exposed to the plume of released radiological material, with typical units of m^3/s . The recommended value for *BR* is $3.33 \times 10^{-4} \text{ m}^3/\text{s}$ (DOE 2004a), a value which applies for all three sites being evaluated.

Using the RVFV at 0.3 m for the MEI as an example results in the following:

$$\begin{aligned} EX &= (ST_{stack}) \times (\chi/Q) \times (BR) \\ &= (1,600 \text{ CCID}_{50}) \times (1.96 \times 10^{-5} \text{ s/m}^3) \times (3.33 \times 10^{-4} \text{ m}^3/\text{s}) \\ &= 5.5 \times 10^{-7} \text{ CCID}_{50} \end{aligned}$$

The average exposures were calculated for each annulus in the same manner shown above for an individual located at the midpoint of each segment. The χ/Q value for each annulus was based on the midpoint χ/Q , which was assumed to be the average of the values for the inner and outer radii. Using that average value for the midpoint χ/Q slightly underestimates the dispersion (i.e., overstates the exposure)

1 because a χ/Q versus distance plot is a concave curve. The midpoint χ/Q values are assumed to apply to
2 the entire segment even though the concentrations on either side of the plume centerline will be lower.
3 Use of the plume centerline values for the entire segment is another conservatism of this calculation.
4

5 Tables F.8-4a through F.8-4c are a composite of inputs and results for the urban, suburban, and rural sites.
6 The first four rows of each table present input values used for the calculation, including the BR and the
7 inner, outer, and midpoint χ/Q values for each annulus. The table also presents the exposures for each
8 pathogen for each annulus. The units for the exposure values are the same as the units for the ST_{stack}
9 values. The tables also present the average segment population for each annulus as calculated in Section
10 F.5. The exposure values are calculated for the plume centerline, which is the highest concentration in the
11 sector, so use of these exposure values for all people in the segment slightly overstates the risk.

F.8.3.2.5 Escaped Animals

The NEIDL could contain a number of infected animals (mammals and arthropods) at any time [see Section F.3.3.4). For an animal to escape the facility, it would need to escape from its enclosure, escape through interlocking laboratory doors, make its way to the ground floor through additional doors, and escape the building. That is highly unlikely for an earthquake slightly beyond the design basis. The potential impact of the infected escaped animals is analyzed in Chapter 7.

F.8.3.3 Beyond Design Basis Earthquake Affecting BSL-4

This section describes the event sequence, frequency category, exposure category, and extent of exposure resulting from a BDB (minor damage) earthquake that damages the BSL-4 areas of the facility. As explained in Section F.8.1.2, the BSL-4 area is isolated from the BSL-3 areas so an earthquake that fails the BSL-3 area might not fail the BSL-4 area. There are many similarities between the BSL-3 and the BSL-4 event sequences, but because of this BSL-4 isolation and because the pathogens that might be used are different, the BSL-3 and BSL-4 areas are analyzed separately.

F.8.3.3.1 Event Sequence Description

While the BSL-4 laboratories are isolated from the rest of the building, the seismic design information available (see Section F.8.1.2 and Attachment D) does not distinguish between the BSL-3 and BSL-4 areas when addressing the design criteria or seismic capacity. Therefore, there is no basis for distinguishing between the effects of a BDB earthquake on BSL-3 and BSL-4 areas, even though it is expected that the BSL-4 has a higher seismic capacity. Because there is no basis for distinguishing between the two areas, this event sequence is also assumed to fail all biocontainment features with the exception that BSL-4 requires positive-pressure suits for laboratory workers rather than PAPR. As a result, the BSL-3 discussion of the event sequence description (Section F.8.3.2.1) applies for the BSL-4 in its entirety and is not repeated here.

F.8.3.3.2 Frequency Category

The seismic capacity of the BSL-4 laboratories is expected to be greater than the seismic capacity of the BSL-3 laboratories; thus, the frequency should be lower than the frequency for the BSL-3 BDB earthquake. However, the BSL-4 has not been demonstrated to have a great capacity than the BSL-3 nor is the extent of this increased capacity known. Therefore, it is conservatively assumed that the seismic capacity of the BSL-4 laboratories is the same as the capacity of the BSL-3 laboratories and the discussion in Section F.8.3.2.2 and Attachment E are applied directly for the BSL-4 and are not repeated

here. As a result, the BSL-4 earthquake event sequence is placed in frequency category C (1 in 10,000 to 1 million years).

F.8.3.3.3 Exposure Category

The exposure category for the BSL-4 is comparable to the exposure category for the BSL-3, which is presented in Section F.8.3.2.3 and is not repeated here. The estimated exposure category for the laboratory worker is HIGH (more than 4), facility worker is HIGH, and public is LOW (30 to 300 m).

F.8.3.3.4 Extent of Exposure

F.8.3.3.4.1 Laboratory Worker

As discussed in the Section F.6.3.4, the positive-pressure suits provide clean external air to the BSL-4 laboratory workers so the laboratory workers in the room will not be exposed the aerosol released into the room. For an exposure to result, the following must all occur concurrently:

1. A BDB earthquake, which is assigned to the frequency category C (1 in 10,000 to 1 million years)
2. A large aerosol release in a room
3. A large breach in a positive-pressure suit in the specific room with the aerosol release
4. The laboratory worker with the breached suit remains in the room long enough to receive a significant exposure

The combination of all those events occurring is considered beyond reasonably foreseeable, frequency category D (1 in more than 1 million years), and the exposure for the BSL-4 laboratory worker is dismissed from further consideration.

F.8.3.3.4.2 Facility Worker

The BDB earthquake discussion for the BSL-3 also applies to the BSL-4 and is not repeated here.

Therefore, a facility worker infection is considered beyond reasonably foreseeable, frequency category D (1 in more than 1 million years), and is dismissed from further consideration.

F.8.3.3.4.3 Public

The same methodology used in Section F.8.3.2.4 is applied to the BSL-4 analysis as well because it is assumed that the release phenomena are the same. This methodology begins by estimating the aerosol concentration in the room, which uses equation (F.8-2) from Section F.8.3.2.4. Table F.8-5 provides the

details of the source term calculation for the BSL-4 laboratory. Table F.8-5 is applicable for all three sites because the facility and its operations are assumed to be the same for all 3 sites.

Table F.8-5. BSL-4 room aerosol concentrations from a BDB earthquake

Pathogen ^a	BSL	SC (/mL) ^b		SF (mL/m ³) ^c	V _{max} (mL)	AC _{room} (/m ³) ^b	
EBOV	4	5.0E+07	CCID ₅₀	5.2×10^{-7}	150	78	CCID ₅₀
MARV	4	1.0E+07	CCID ₅₀	5.2×10^{-7}	150	16	CCID ₅₀
LASV	4	1.0E+07	TCID ₅₀ or FFU (PFU)	5.2×10^{-7}	150	16	TCID ₅₀ or FFU (PFU)
JUNV	4	1.0E+07	PFU	5.2×10^{-7}	150	16	PFU
TBEV-FE	4	1.0E+08	MID50	5.2×10^{-7}	150	160	MID50
NIPV	4	2.0E+07	TCID ₅₀ or PFU	5.2×10^{-7}	150	31	TCID ₅₀ or PFU

a. Ebola virus (EBOV); Marburg virus (MARV); Lassa virus (LASV); Junín virus (JUNV); tick-borne encephalitis virus, Far Eastern sub-type, formerly known as tick-borne encephalitis complex (Russian spring-summer encephalitis virus) (TBEV-FE); and Nipah virus (NIPV).

b. Room aerosol concentrations and stack source term are given in terms of plaque forming units (PFU), median tissue culture infective dose (TCID₅₀), fluorescent focus units (FFU), median cell culture infective dose (CCID₅₀), or median mouse infective dose (MID₅₀).

c. SF is based on a *smashed flask* containing 50 mL (Bennett and Parks 2006).

Then, using equation F.8-4 from Section F.8.3.2.4.3 to calculate the stack source term (ST_{stack}) produces the results presented in Table F.8-6. The BSL-4 HVAC system has two HEPA filters in series rather than the single HEPA filter in the BSL-3 HVAC. As discussed in Section F.8.3.2.4.3, the filtration efficiency of each HEPA filter is assumed to be reduced by an order of magnitude (i.e., from a leakage rate of 0.0003 to a leakage rate of 0.003). Therefore, an LPF of 9×10^{-6} (i.e., 0.003×0.003) will be used for the fraction of the aerosol in the room that would be released through the stack.

Table F.8-6. Calculated stack source term for BSL-4 pathogens from a BDB earthquake

Pathogen ^a	AC _{room} (/m ³) ^b		V _{room} (m ³)	LPF	ST _{stack} ^b	
EBOV	78	CCID ₅₀	18	9×10^{-6}	0.01	CCID ₅₀
MARV	16	CCID ₅₀	18	9×10^{-6}	0.003	CCID ₅₀
LASV	16	TCID ₅₀ or FFU (PFU)	18	9×10^{-6}	0.003	TCID ₅₀ or FFU (PFU)
JUNV	16	PFU	18	9×10^{-6}	0.003	PFU
TBEV-FE	160	MID50	18	9×10^{-6}	0.03	MID50
NIPV	31	TCID ₅₀ or PFU	18	9×10^{-6}	0.005	TCID ₅₀ or PFU

a. Ebola virus (EBOV); Marburg virus (MARV); Lassa virus (LASV); Junín virus (JUNV); tick-borne encephalitis virus, Far Eastern sub-type, formerly known as tick-borne encephalitis complex (Russian spring-summer encephalitis virus) (TBEV-FE); and Nipah virus (NIPV).

b. Room aerosol concentrations and stack source term are given in terms of plaque forming units (PFU), median tissue culture infective dose (TCID₅₀), fluorescent focus units (FFU), median cell culture infective dose (CCID₅₀), or median mouse infective dose (MID₅₀).

As shown in Table F.8-6, all stack source term values are much less than 1 unit. That means that less than one unit of pathogen would be expected to be released from the MRF earthquake. As shown in Table F.8-4 for the BSL-3 impacts, the airborne dispersion will reduce exposures by at least three orders of magnitude. As a result, the average public exposures would be extremely small, and a significant exposure is considered beyond reasonably foreseeable, frequency category D (1 in more than 1 million years). Therefore, public exposures from a BDB earthquake are dismissed from further consideration.

F.8.3.3.5 Escaped Animals

The NEIDL might contain a number of infected animals (mammals and arthropods) at any time [see the NEIDL Inventory report (Tetra Tech 2011a)]. For an animal to escape the facility, it would need to escape from its enclosure, escape through interlocking laboratory doors, make its way to the ground floor through additional doors, and escape the building. That is highly unlikely for an earthquake slightly beyond the design basis. The potential impact of those infected escaped animals is analyzed in RA Chapter 7.

F.8.3.4 Maximum Reasonably Foreseeable Earthquake Affecting BSL-3

Consistent with Section F.8.2.7, a bounding analysis was performed for the earthquake event sequence. *American National Standard Categorization of Nuclear Facility Structures, Systems, and Components for Seismic Design*, (ANSI 2004) provides guidance specifically for analysis of earthquake events. That document is based on the methodology developed by DOE and is intended for facility design purposes; however, that methodology is frequently used in safety analyses and for environmental impact statements (EISs). The relevant guidance provided for the impact analysis includes the following recommendations:

1. “The unmitigated consequence analysis shall be performed considering only the inherent physical or chemical characteristics of the hazardous material and the energy sources for dispersing the material.”
2. The “...engineered mitigating features shall be assumed not to function unless the robustness of each mitigating feature can be demonstrated to survive the postulated event.”
3. ANSI/ANS-5.10-1998, *Airborne Release Fractions at Non-Reactor Nuclear Facilities* provides guidance concerning mechanisms for release of the hazardous material into the air or water and shall be used to support similar calculations required by this standard.” Because the document referred to is based on DOE-HDBK-3010 (DOE 2000) and because DOE-HDBK-3010 is more comprehensive, this analysis uses DOE-HDBK-3010 as its basis.
4. The “...consequence analysis shall strive to use mean values for the parameters related to material release, dispersal in the environment, and health consequences.”

In summary, this guidance results in development of bounding scenarios with the use of median factors when analyzing these bounding scenarios. This is an extremely severe scenario that is extremely unlikely to occur and whose consequences are highly unlikely to be exceeded.

The sections below describe the event sequence, frequency category, exposure category, and extent of exposure resulting from a MRF (total collapse) earthquake that severely damages the BSL-3.

F.8.3.4.1 Event Sequence Description

The initial conditions for the earthquake event sequence are as follows:

- There are no warnings of potential seismicity, and the facility is operating without forewarning of the earthquake.
- Any or all pathogen(s) could be in use in the facility at its typical volumes and maximum concentrations in a liquid suspension. The pathogen could be in one or more containers at the time of the earthquake.
- The facility contains infected animals (mammals and arthropods) at the time.

A severe earthquake is postulated to occur that involves the following events and conditions:

- The postulated severe earthquake exceeds the seismic capacity of the NEIDL facility. The NEIDL facility has been demonstrated (Weidlinger 2005) to meet the requirements of the Massachusetts State Building Code (Massachusetts 1997). That code requires design to an effective acceleration of 0.12 g (i.e., 0.12 times the acceleration of gravity, or $0.12 \times 32.2 \text{ ft/s}^2 = 3.86 \text{ ft/s}^2$). As discussed in Attachment E, the Richter scale is a measure of the size of the earthquake and does not directly correspond to the effective acceleration at a location.
- The postulated earthquake exceeds 0.12 g; however, the failure point for the NEIDL facility has not been determined. Therefore, the integrity of biocontainment features has not been demonstrated for the postulated earthquake, and the structure is assumed to fail. Consistent with the guidance provided in Section F.8.3.4 above, it is assumed that the biocontainment features do not provide biocontainment. Therefore, it is assumed that as a result of the severe earthquake, the NEIDL structure suffers a catastrophic failure, and all biocontainment is lost. Such a loss of biocontainment includes failure of the HVAC and its HEPA filtration and biocontainment provided by the facility walls. A total collapse of the facility would be the extreme case of this structural failure and a total loss of biocontainment.

- It is assumed that a fire does not result from the earthquake. A fire would inactivate most pathogens and would tend to loft releases over the population, so this assumption results in the highest potential consequences.
- As a result of falling debris from the earthquake, the container(s) of pathogens in liquid suspension are breached and released to the environment. Containers of frozen pathogen suspensions could be breached, but their release is minimal because they are initially frozen, and a large-scale, prompt release is unlikely; therefore, they are dismissed from further consideration for this analysis.
- Per guidance, this event occurs during median meteorological conditions.
- Infected animals (mammals and arthropods) could escape from the facility.

F.8.3.4.2 Frequency Category

A rigorous estimate of the frequency is not possible for this analysis because of a lack of information, but the frequency of an earthquake that causes failure of the NEIDL structure is judged to be in the frequency category C (1 in 10,000 to 1,000,000 years) for all three candidate sites. This selection is made because the NEIDL structure will continue to perform its functions following a 2-second shaking period, 0.12 g earthquake (BUMC 2005). A 2-second, 0.12 g earthquake has a return period in excess of 10,000 years or a frequency of less than 1×10^{-4} based on the USGS National Seismic Hazard Maps (see Attachment E).

F.8.3.4.3 Exposure Category

The exposure category for the laboratory workers is HIGH because all people in all rooms have the potential to be exposed.

The exposure category for the facility workers is HIGH because all people in the facility have the potential to be exposed.

The estimated exposure category for the public is expected to be MODERATE. Aerosol particles could be dispersed beyond 300 m, but concentrations would be extremely low beyond 3 km.

F.8.3.4.4 Extent of Exposure

The DOE NEPA Guidance (DOE 2002) provides the following guidance:

...in many cases the acceleration forces associated with extremely rare earthquakes (e.g., frequencies of less than 10^{-6} per year) may be so great that destructive impacts unrelated to the proposed action or alternatives would overwhelm impacts associated with the

1 proposed action or alternatives. Such an analysis would not be informative regarding the
2 proposed action or alternatives because a decision maker would be unable to distinguish
3 the consequences resulting from the proposed action or alternatives from the general
4 destructive effects of the earthquake.
5

6 This caution is certainly applicable for the MRF earthquake because of the low frequency of the event and
7 the extremely conservative assumptions used for the analyses. However, the exposures are estimated for
8 this event because the scenario provides insight into the maximum consequences that could reasonably be
9 expected from operation of the facility. Analysis of this extreme event also provides insight into potential
10 site differences.
11

12 **F.8.3.4.4.1 Laboratory Worker**

13 If a severe earthquake were to result in total structural failure of the NEIDL, it is unlikely that laboratory
14 workers would survive if they were in the BSL-3 laboratories. Estimation of exposures to workers in a
15 collapsed building provides no insight into worker risk from this event. Therefore, the laboratory workers
16 are assumed to have escaped the building and congregate at the NEIDL exclusion fence for the duration
17 of the release. In such a case, the laboratory workers are no different than any other facility worker and
18 are included in the following exposure estimate.
19

20 **F.8.3.4.4.2 Facility Worker**

21 If a severe earthquake were to result in total structural failure of the NEIDL, it is unlikely that facility
22 workers inside the facility would survive. Estimation of exposures to workers in a collapsed building
23 provides no insight into worker risk from this event. Therefore, the laboratory workers are assumed to be
24 at the NEIDL exclusion fence for the duration of the release, as described in Section F.8.3.2.4.2.
25

26 For this analysis, it is assumed that facility workers exit the building promptly and congregate at the
27 exclusion fenceline (at least 30 m from the NEIDL). A person at the exclusion fence is defined as the
28 MEI, so the MEI exposure will be used for laboratory workers. The MEI exposure is calculated in the
29 public exposure section below. Approximately 300 workers at NEIDL are present about 25 percent of the
30 year (about 50 weeks at 40 hours per week out of an 8,760 hour year), which results in an average worker
31 population of 75 people.
32

F.8.3.4.4.3 Public

Airborne dispersion of the pathogen organisms can result in inhalation, ingestion, and direct contact routes of exposures. Exposure due to puncture by contaminated sharp objects is also possible, especially for workers that might survive the event. The sections below provide the exposure estimates for the public, laboratory worker, and members of the public.

The source term (ST) is the amount of material released into the air to which a person can be exposed. *Airborne Release Fractions/Rates and Respirable Fractions for Nonreactor Nuclear Facilities*, DOE-HDBK-3010 (DOE 2000) equation (1-1) provides the typical formula for estimating the ST:

$$ST = (MAR) \times (DR) \times (ARF) \times (RF) \times (LPF) \quad \text{(equation F.8.3-6)}$$

where

- | | |
|------------|---|
| <i>ST</i> | The source term is the amount of respirable material, in organisms, released to the air. |
| <i>MAR</i> | The material at risk amount of pathogenic materials (e.F., the number of organisms) available to be acted on by a given physical stress. For this analysis, the MAR is the product of the suspension volume (V) times the SC. The maximum inventory is provided in the <i>Pathogen Inventory</i> (Tetra Tech 2011. The seed stock is not included in the MAR because it is generally a small fraction of the working stock (e.g., 2 mL versus 150 mL) and the frozen form has release fractions that are expected to be orders of magnitude lower. Excluding the frozen seed stock does not significantly affect the results. |
| <i>DR</i> | The damage ratio is the fraction of MAR affected by the conditions under evaluation. A DR of 1, the maximum value, means that the entire inventory is at risk. |
| <i>ARF</i> | The airborne release fraction is the coefficient used to estimate the amount of a material that is suspended in air and made available for airborne transport under a specific set of induced physical stresses. Attachment F provides the basis for selection of the ARF value. |
| <i>RF</i> | The respirable fraction is the fraction of airborne particles that can be transported through air and inhaled into the human respiratory system and is commonly assumed to include particles 10-µm Aerodynamic Equivalent Diameter (AED) and less. Attachment F provides the basis for selection of the RF value. |
| <i>LPF</i> | The Section F.8.2.7 methodology used here does not include mitigation by any biocontainment features that cannot be demonstrated to survive the event. Therefore, the analysis does not include consideration of the HVAC HEPA filtration system, |

sealed walls, or an elevated release. This analysis is based on a ground-level release. Assumption of a ground-level release is conservative (i.e., overestimates the exposure) because it results in less vertical mixing. While the LPF does not include any biocontainment features, even a totally collapsed building will provide some confinement. Structural debris is estimated to reduce the rate of release by a factor of 10 (DOE 2000), so the LPF is 0.1.

Substituting $V \times SC$ for MAR , the source term equation becomes

$$ST = [(V) \times (SC)] \times (DR) \times (ARF) \times (RF) \times (LPF) \quad (\text{equation 3-7})$$

Table F.8-7 provides the details of the source term calculation for all BSL-3 pathogens. Table F.8-7 is applicable for all three sites because the facility and its operations are assumed to be the same for all three sites. Using equation F.8-7 and the RVFV as an example, the calculation is as follows:

$$ST = (150 \text{ mL}) \times (1\text{E}+09 \text{ CCID}_{50}/\text{mL}) \times (1) \times (4\text{E}-05) \times (0.7) \times (1)$$

$$ST = 4.2\text{E}+06 \text{ CCID}_{50}$$

Table F.8-7. Calculated source term for BSL-3 pathogens from an MRF earthquake

Pathogen ^a	BSL ^b	V (mL) ^b	SC (/mL) ^b	DR ^b	ARF ^c	RF ^c	LPF ^d	ST ^e
<i>B. anthracis</i> ^e	2 / 3	50	2.4x10 ⁸ CFU ^e	1	4x10 ⁻⁵	0.7	0.1	3.4x10 ⁴ CFU ^e
<i>F. tularensis</i>	3	1	2.0X10 ⁹ CFU	1	4x10 ⁻⁵	0.7	0.1	5.6 x10 ³ CFU

a. *Bacillus anthracis* (*B. anthracis*); *Francisella tularensis* (*F. tularensis*); *Yersinia pestis* (*Y. pestis*); 1918 H1N1 influenza virus (1918H1N1V); SARS-associated coronavirus (SARS-CoV); Rift Valley fever virus (RVFV); and Andes virus (ANDV).

b. This value is taken from the working stock inventory in Section F.3.

c. The maximum value of 1 is used, which puts the entire inventory of that working stock at risk.

d. This is the mean ARF for a 3-m spill, as selected in Attachment F.

e. A value of 0.1 is used to account for the release reduction due to structural debris (DOE 2000).

f. In spore form in suspension.

After release to the air, the source term can be transported and dispersed as a result of winds and meteorological conditions. The inhalation exposure of a member of the public downwind from the release is calculated by equation F.8.3-5 (see Section F.8.3.2.4.3) (DOE 2004a):

$$EX = (ST) \times (\chi/Q) \times (BR)$$

As discussed in Section F.8.2.7, the DOE guidance recommends that, “prevailing (median) meteorological conditions generally should be used.” Therefore, median ground-level meteorological conditions are used in these analyses. The ground-level χ/Q values result in pathogen concentrations that are significantly greater (as much as 200 times greater at the nearest annulus) than the corresponding concentrations from the Base Case (i.e., an elevated release). The median meteorological conditions can be different at the various sites, so site-specific meteorological data are used to calculate exposures.

The DOE guidance for use of the MACCS2 code (DOE 2004a) notes that, “like all Gaussian models, MACCS2 is not well suited for modeling dispersion close to the source (less than 100 meters from the source).” While that limitation is noted, the downwind dilution factor is calculated for distances less than 100 m to account for the potentially higher concentrations. Section F.5 provides a comparison of the MACCS2 results with the wind tunnel tests and independent dispersion calculation results performed for NEIDL. That comparison showed that the MACCS2 results are very close to the other results and supports the reasonableness of its use in this analysis.

Tables F.8-8a through F.8-8c are a composite of inputs and results for the urban, suburban, and rural sites. The first four rows of each table present input values used for the calculation, including the BR and the inner, outer, and midpoint χ/Q values for each annulus. The tables also present the exposures for each pathogen for each annulus. The units for the exposure values are the same as the units for the ST values. The tables also present the average segment population for each annulus as calculated in Section F.4. The exposure values are calculated for the plume centerline, which is the highest concentration in the sector, so use of those exposure values for all people in the segment overstate the risk.

Table F.8-8a. Average public exposures to BSL-3 pathogens resulting from an MRF earthquake for the urban site

Section F.3 provides background information on the methods and units associated with the concentration measurements.

c. In spore form in suspension.

d. Two values are reported for RVFV with different units. The CCID₅₀ and MICLD₅₀ units are an order of magnitude greater because this measurement is more sensitive.

e. χ/Q values are the Ground Level values presented in Section F.5.

F.8.3.4.5 Escaped Animals

The NEIDL could contain a number of infected animals (mammals and arthropods) at any time. The earthquake could damage the enclosures, resulting in the potential escape of infected animals. The animals and the pathogen with which they might be infected are identified in Section F.3. The potential impact of those infected escaped animals is analyzed in RA Chapter 7.

F.8.3.5 Maximum Reasonably Foreseeable Earthquake Affecting BSL-4

The general approach describe in Section F.8.3.4 for the BSL-3 laboratories is also used for the BSL-4 laboratories and is not repeated here. This section describes the event sequence, frequency category, exposure category, and extent of exposure resulting from an earthquake that damages the BSL-4 areas of the facility.

F.8.3.5.1 Event Sequence Description

The seismic design information available (see Section F.8.1.2 and Attachment D of this appendix) does not distinguish between the BSL-3 and BSL-4 areas when addressing the design criteria or seismic capacity, so there is no basis for distinction of the two events, even though it is expected that the BSL-4 has a higher seismic capacity. Because there is no basis for distinguishing between the two areas, this event sequence is also assumed to fail all biocontainment features. As a result, the BSL-3 discussion of the event sequence description (Section F.8.3.4.1) applies for the BSL-4 in its entirety and is not repeated here.

F.8.3.5.2 Frequency Category

The seismic capacity of the BSL-4 laboratories is expected to be greater than the seismic capacity of the BSL-3 laboratories; thus, the frequency should be lower than the frequency for the BSL-3 MRF earthquake. However, the BSL-4 has not been demonstrated to have a great capacity than the BSL-3 nor is the extent of this increased capacity known. Therefore, it is conservatively assumed that the seismic capacity of the BSL-4 laboratories is the same as the capacity of the BSL-3 laboratories and the discussion in Section F.8.3.2.2 and Attachment E are applied directly for the BSL-4 and are not repeated here. As a result, the BSL-4 earthquake event sequence is placed in frequency category C (1 in 10,000 to 1 million years).

F.8.3.5.3 Exposure Category

The exposure category for the laboratory workers is HIGH because all people in all rooms have the potential to be exposed.

The exposure category for the facility workers is HIGH because all people in the facility have the potential to be exposed.

The estimated exposure category for the public is expected to be MODERATE. Aerosol particles could be dispersed beyond 300 m, but concentrations would be extremely low beyond 3 km.

F.8.3.5.4 Extent of Exposure

As discussed in Section F.8.3.4.4, DOE NEPA Guidance (DOE 2002) recommends caution when evaluating events like the MRF earthquake where the impacts with and without the proposed action are indistinguishable because of the magnitude of the unrelated impacts. However, the exposures are estimated for this event because this scenario provides insight into the maximum consequences that could reasonably be expected from operation of the facility. Analysis of this extreme event also provides insight into potential site differences.

F.8.3.5.4.1 Laboratory Worker

If a severe earthquake were to result in total structural failure of the NEIDL, it is unlikely that laboratory workers would survive if they were in the BSL-3 laboratories. Estimation of exposures to workers in a collapsed building provides no insight into worker risk from this event. Therefore, the laboratory workers are assumed to have escaped the building and congregate at the NEIDL exclusion fence for the duration of the release. In such a case, the laboratory workers are no different than any other facility worker and are included in the following exposure estimate.

F.8.3.5.4.2 Facility Worker

If a severe earthquake were to result in total structural failure of the NEIDL, it is unlikely that facility workers inside the facility would survive. Estimation of exposures to workers in a collapsed building provides no insight into worker risk from this event. Therefore, the laboratory workers are assumed to be located at the NEIDL exclusion fence for the duration of the release, as described in Section F.8.3.2.4.2.

For this analysis, it is assumed that facility workers exit the building promptly and congregate at the exclusion fenceline (at least 30 m from the NEIDL). A person located at the exclusion fence is defined as the MEI, so the MEI exposure will be used for laboratory workers. The MEI exposure is calculated in the public exposure section below. There are approximately 300 workers at NEIDL that are present about 25

percent of the year (about 50 weeks at 40 hours per week out of an 8,760 hour year), which results in an average worker population of 75 people.

F.8.3.5.4.3 Public

The calculation of public exposures for the BSL-4 affected release are performed using the same methodology described in Section F.8.3.4.4.3 (i.e., the equation F.8.3-7) with the only difference being the pathogens involved and their inventories. Table F.8-9 provides the source term for the BSL-4 event.

Table F.8-9. Calculated source term for BSL-4 pathogens from an MRF earthquake

Pathogen ^a	BSL ^b	V (mL) ^b	SC (/mL) ^{bc}	DR ^d	ARF ^e	RF ^e	LPF ^f	ST ^c
EBOV	4	150	5.0E+07 CCID ₅₀	1	4E-05	0.7	0.1	2.1E+04 CCID ₅₀

NIPV	4	150	2.0E+07 TCID ₅₀ or PFU	1	4E-05	0.7	0.1	8.4E+03 TCID ₅₀ or PFU

a. Ebola virus (EBOV); Marburg virus (MARV); Lassa virus (LASV); Junin virus (JUNV); tick-borne encephalitis virus, Far Eastern sub-type, formerly known as tick-borne encephalitis complex (Russian spring-summer encephalitis virus) (TBEV-FE); and Nipah virus (NIPV).

b. This value is taken from the working stock values of Section F.3.

c. Suspension concentrations and source term values are given in terms of plaque forming units (PFU), median tissue culture infective dose (TCID₅₀), fluorescent focus units (FFU), median cell culture infective dose (CCID₅₀), or median mouse infective dose (MID₅₀).

d. The maximum value of 1 is used, which puts the entire inventory of that working stock at risk.

e. This is the mean ARF and RF for a 3-m spill, as selected in Attachment F.

f. A value of 0.1 is used to account for the release reduction because of structural debris (DOE 2000).

Tables F.8-10a through F.8-10c are a composite of inputs and results for the urban, suburban, and rural sites. The first four rows of each table present input values used for the calculation, including the BR and the inner, outer, and midpoint χ/Q values for each annulus. The table also presents the exposures for each pathogen for each annulus. The units for the exposure values are the same as the units for the ST values. The tables also present the average segment population for each annulus as calculated in Section F.4. The exposure values are calculated for the plume centerline, which is the highest concentration in the sector, so use of those exposure values for all people in the segment overstate the risk.

Section F.3 provides background information on the methods and units associated with the concentration measurements.

c. χ/Q values are the Ground Level values presented in Section F.5.

F.8.3.5.5 Escaped Animals

The NEIDL might contain a number of infected animals (mammals and arthropods) at any time. The earthquake could damage the enclosures, resulting in the potential escape of infected animals. The animals and the pathogen with which they might be infected are identified in Section F.3. The potential impact of those infected escaped animals is analyzed in RA Chapter 7.

F.8.3.6 Variability and Uncertainty

Numerous variabilities and uncertainties apply to the results presented in Sections F.8.3.1 through F.8.3.5. Table F.8-11 identifies the key variabilities and uncertainties, provides a discussion of each, and provides an estimate of the potential effect of each.

Table F.8-11. Summary of key variabilities and uncertainties

Variability/ uncertainty	Discussion	Potential factor ^a
Frequency category	<i>BDB earthquake</i> —The design has been demonstrated by analysis to survive the 0.12 g event, but the maximum acceleration it can withstand or the extent of damage at any point beyond is uncertain. The BDB earthquake would have a frequency slightly below the frequency for the 0.12 g event.	Unknown
	<i>MRF earthquake</i> —A complete structural failure is highly unlikely at accelerations just beyond the design point, but the point at which complete structural failure occurs is not known, but failure is expected to be beyond 0.12 g.	Conservatism (potentially large)
MAR	The MAR was developed on the basis of typical volume and concentration expected according to literature reviews. At any time, not all pathogens will be used in active research. For those used in active research, the volumes will vary from volumes less than to perhaps 3-1/3 larger than the typical volume	Potential conservatism or non- conservatism (0x to 3-1/3x)
	The frozen seed stock was excluded from consideration because (1) it is almost always secured in freezers, which would impede release; and (2) the release fraction for frozen liquids is not provided or discussed in DOE-STD-3010 (DOE 2000), but it is expected to be orders of magnitude lower than the release fractions for liquids.	Slight non- conservatism
DR	The entire MAR is not likely to be involved in an earthquake release, but the exact DR is uncertain. Even in a catastrophic building failure, individual containers in a room might not be damaged or compromised and, if compromised, not all the material they contain will necessarily be released. DR actually ranges from 0 to 1.	Conservatism (0x to 1x)
Release phenomenon	<i>BDB earthquake</i> —The release is modeled as the release from a <i>smashed flask</i> . Because NEIDL requires use of non-breaking containers, this release mechanism is conservative.	Conservatism (potentially large)
	<i>MRF earthquake</i> —The release is modeled as a 3-m, free-fall spill. There are multiple different types of phenomena that could result, but this was selected because it results in a larger release than other expected phenomena (see Attachment F of this appendix). The actual phenomena that would occur are uncertain but are unlikely to result in a higher release.	Reasonable estimate

Final Supplementary Risk Assessment for the Boston University National Emerging Infectious Diseases Laboratories (NEIDL)

Variability/ uncertainty	Discussion	Potential factor ^a
ARF	<i>BDB</i> —The release factors are good estimates for the phenomena selected, so the conservatism is in the phenomena selection.	Reasonable estimate
	<i>MRF earthquake</i> —The release phenomenon selected is addressed above, and it largely determines the ARF. However, both bounding and mean values are available for the spill phenomena. The mean ARF was selected using the guidance for such analyses (ANSI 2004). Use of the bounding value would increase the release by a factor of 5 (4.00E-05 mean versus 2.00E-04 bounding per Attachment F of this appendix) if the bounding release value were used. The ARF is based on a 3-m, free-fall spill. A spill would likely be from a lower height, perhaps 1 m, which would reduce the potential energy to 1/3 and would reduce the ARF by an unknown amount.	Unknown
RF	<i>BDB earthquake</i> —The ARF and RF values are assumed to be integrated into one value in the Bennett and Parks (2006) data. The aerosol particle size is not reported.	Unknown
	<i>MRF earthquake</i> —The RF value was selected on the same basis used for the ARF. There is uncertainty in the actual RF, and it could even be pathogen dependent (e.g., the tendency of organisms to agglomerate can differ). The RF value paired with the bounding ARF is actually less than the value paired with the mean value (i.e., 0.7 versus 0.5 per Attachment F of this appendix). The RF is based on a 3-m, free-fall spill. A spill would likely be from a lower height, perhaps 1 m, which would reduce the potential energy to 1/3 and would reduce the RF by an unknown amount.	Unknown (potentially 0.7x)
LPF	<i>BDB earthquake</i> —The LLNL data (LLNL 1994), there was no observed release following the event. Therefore, use of the factor of 10 increase in the release for each HEPA filter, the estimates could be an order of magnitude high for each HEPA filter. Because the BSL-4 has two HEPA filters in series, it could be a factor of 100 high.	Conservatism (potentially 10x for BSL-3 and 100x for BSL-4)
	<i>MRF earthquake</i> —The LPF of 0.1 is based on structural debris. A large pile of debris, which would result from the catastrophic failure of a building the size of NEIDL with multiple internal walls, could result in a lower LPF.	Conservatism (potentially orders of magnitude)
X/Q	<i>Decay</i> —Pathogens exposed to the outdoor environment would be expected to undergo some biological decay (i.e., inactivation). The extent of this inactivation depends on the pathogen and the environmental conditions. Inactivation was not included in this analysis.	Conservatism (generally minor magnitude)
	<i>Washout and plume meander</i> —The airborne dispersion calculations did not include washout due to precipitation or plume meander, which would reduce exposures. These are both conservatisms, the magnitude of which is dependent on the conditions at the time.	Conservatism (unknown magnitude)
	<i>BDB earthquake</i> —The elevated release with median dispersion provides the expected results. Actual conditions could result in greater dispersion (lower concentrations) or less dispersion (greater concentrations).	Potentially conservative or non-conservative
	<i>MRF earthquake</i> —A ground-level release is assumed for this analysis consistent with the DOE guidance. An elevated release would result in a decrease in the concentration, especially at the very closest distances. If the building remains standing, which would be the case for all but the most severe failure case, this is a large conservatism. Concentrations resulting from an elevated release are distance dependent but can be 1 to 2 orders of magnitude lower for locations very close to the point of release (Tetra Tech 2011b).	Conservatism (0.01x to 1x)
	<i>MRF earthquake</i> —Median meteorology values were used, per DOE recommendation (DOE 2002). The concentrations would be about 9 times higher if the 95% conditions were used instead of the 50%. Use of the ground-level release values has a greater effect than use of 95% meteorology for locations near the point of release (Tetra Tech 2011b).	Potentially conservative or non-conservative

Variability/ uncertainty	Discussion	Potential factor ^a
	<i>MRF earthquake</i> - χ/Q was calculated via the MACCS2 computer code, which is a DOE-approved code for this type of analysis. Alternate codes would have provided different values. A direct comparison of the MACCS2 calculations with another code is not available, but a general comparison was performed and it is concluded that the results are very close (Tetra Tech 2011b).	unknown
BR	The generally accepted and recommended BR is used, but the BR varies depending on the level of activity involved. Rather than the 3.33×10^{-4} m ³ /s value used, the rate could range from 1.25×10^{-4} m ³ /s for sleep to 8.33×10^{-4} m ³ /s for heavy exercise (DOE 2004a). It could vary depending on the size, age, etc., of the person potentially exposed.	0.38x to 2.5x

a. The estimate provided in the analyses (Sections F.8.3.2 through F.8.3.5) would be multiplied by this value to obtain the new value. So a current value of 10 when multiplied by a potential factor of 10x would result in 100, and a current value of 10 when multiplied by a potential factor of 0.1x would result in 1. A 0x factor means that the result could be 0.

As shown in Table F.8-11, numerous variabilities and uncertainties could affect the results. Overall, the results of this analysis are judged to be conservative for the BDB (minor damage) earthquake and very conservative for the MRF (total collapse) earthquake (i.e., an event of that type would likely result in considerably lower exposures).

While the variabilities and uncertainties are potentially quite large, especially for the MRF earthquake, they do not invalidate the conclusions regarding site differences because the analyses are performed were the same for all three sites. Therefore, the variabilities and uncertainties would merely tend to shift the results for all three sites similarly.

F.9 AIRCRAFT CRASH

F.9.1 Introduction

An aircraft crash into the NEIDL is a postulated externally initiated accident scenario for the potential release of pathogens from the NEIDL facility to the public. This analysis demonstrates that the risk of an aircraft crash is bounded by the risk of other analyzed accident scenarios, namely the MRF (total collapse) earthquake event, and therefore does not necessitate a detailed analysis. Risk is a function of (1) the frequency of an adverse event and (2) the consequences of the adverse event. Thus, the frequency and consequence of a postulated aircraft crash scenario will be compared to that of the MRF earthquake.

This scenario involves an accidental aircraft crashing into the NEIDL facility resulting in an aerosol release of a pathogen and potentially exposing the public. Only the Boston site is analyzed because Boston Logan International Airport has a far more flights than the municipal airports nearby the two comparable sites and, therefore, a higher anticipated frequency for such an event. An aircraft crash

scenario initiated by a malevolent act is not specifically addressed by this section; however, the consequences of an aircraft crash initiated by a malevolent act would be comparable to the consequence addressed below.

F.9.2 Methodology

The DOE has detailed guidance for estimating the frequency of an aircraft crash probability at a given location, as opposed to crash frequencies on a per flight basis. The DOE guidance, *Accident Analysis for Aircraft Crash into Hazardous Facilities* (DOE-STD-3014-2006, DOE 2006), was used in this evaluation.

DOE 2006 uses a four-factor formula to estimate the annual aircraft crash frequency at a location. DOE 2006 cautions,

It should be noted that there is uncertainty associated with the frequency estimates produced using the four-factor formula, caused by the need to model complex physical processes using parameters that are based on limited historical data. Experience-based judgments have been made as needed to supplement historical data, introducing additional uncertainties. This standard does not provide a quantitative estimate of the uncertainties involved; rather, the mathematical formulations and supporting parameter estimates have been made so as to provide a reasonable point estimate of the frequency of aircraft crash impacts into specified facilities.

The estimates provided by the DOE guidance are considered adequate for this screening assessment. The four factors are (1) the number of aircraft operations; (2) the probability that an aircraft will crash; (3) given a crash, the probability that the aircraft will crash into a one square mile (mi²) area where a facility is located; and (4) the size of the facility. This is expressed mathematically as follows:

$$F = \sum_{i,j,k} N_{ijk} \times P_{ijk} \times f_{ijk}(x, y) \times A_{ij} \quad \text{[equation F.9-1]}$$

where

F	Estimated annual aircraft crash impact frequency for the facility of interest (number/year)
N_{ijk}	Annual number of site-specific airport operations (i.e., takeoffs, landings, in-flights) for each applicable summation parameter (number/year)
P_{ijk}	Aircraft crash rate per takeoff or landing for near-airport phases and per flight for the in-flight (non-airport) phase of operation for each applicable summation parameter
$f_{ijk}(x,y)$	Aircraft crash location conditional probability (per square mile) given a crash evaluated at the facility location for each applicable summation parameter

A_{ij}	Site-specific effective area for the facility of interest that includes skid and fly-in effective areas (square miles) for each applicable summation parameter, aircraft category or subcategory, and flight phase for military aviation
i	(index for flight phases): $i = 1, 2$, and 3 (takeoff, in-flight, and landing)
j	(index for aircraft category or subcategory): $j = 1, 2, \dots, 11$
k	(index for flight source): $k = 1, 2, \dots, k$ (there could be multiple runways, and non-airport operations)

F.9.3 Results

F.9.3.1 Frequency

An airport *operation* can include more than takeoffs and landings; for example, it can include such activities as an aircraft contacting the tower for a change of vector. For the purposes of this analysis, airport operations will be conservatively assumed to only mean takeoffs and landings (i.e., parameter $i = 1$ and 3 in the equation above). The definition of airport operations from DOE 2006 is, “As defined by the Federal Aviation Administration (FAA), the number of arrivals and departures from the airport at which the airport traffic control tower is located.” Therefore, in-flight (non-airport operations, parameter $i = 2$) are discussed later because they do not meet that definition.

F.9.3.1.1 Airport Operation Frequency Estimation

Each of the four factors in equation F.9-1 is discussed below for airport operations.

N_{ijk} (Number of airport operations)

Data for number of airport operations at the Boston Logan International Airport were obtained from the US. Department of Transportation Federal Aviation Administration’s Airport Master Record (FAA 2010). Data from that website states that a total of 208,494 operations involving air carriers, 113,175 operations involving air taxis, and 15,560 general aircraft operations occurred during the most recently reported 12 months (FAA 2010). The data do not discriminate between takeoffs and landings, so the conservative assumption that 50 percent of all operations are takeoffs and 50 percent are landings is used (DOE-STD-3014-2006, p. 40). That assumption results in “very conservative numbers because total operations include activities other than takeoff and landing, such as an aircraft contacting the tower for a change of vector” (DOE 2006). As stated above non-airport operations are not included here because they do not meet the definition of *airport operation*; the annual crash frequency of non-airport operations is discussed later in this document. The data included in the calculation for airport operations are in Table F.9-1.

Table F.9-1. Number of airport operations and crash rates

Aircraft operation	$\sum N_{ijk}$ (Number of operations per year)	P (Crash rate ^a)
Commercial aviation -air carrier (takeoff)	104,247	1.90×10^{-7}
Commercial aviation—air carrier landing)	104,247	2.80×10^{-7}
Commercial aviation—air taxi (takeoff)	56,587.5	1.00×10^{-6}
Commercial aviation—air taxi (landing)	56,587.5	2.30×10^{-6}
General aviation (takeoff)	7,780	1.10×10^{-5}
General Aviation (landing)	7,780	2.00×10^{-5}

a. Table B-1 of DOE STD 3014-2006 (p. B-3)

P_{ijk} (Aircraft Crash Rate per Takeoff, Landing, and In-flight)

For airport operations (takeoff and landing), the value of P, Crash rate, is taken from Table B-1 of DOE-STD-3014-2006 (p. B-2). Those values are shown in Table F.9-1.

A – Effective Area

The effective area is calculated using the methodology in Section B.4 of DOE-STD-3014-2006. Specifically, three equations are used:

$$A_{eff} = \text{Effective Fly-in Area plus Effective Skid Area} = A_f + A_s$$

$$A_f = (WS + R) \times H \cot \phi + 2 \times (L \times W \times WS) / R + L \times W$$

$$A_s = (WS + R) \times S$$

where

$R = (L^2 + W^2)^{0.5}$ = diagonal length of facility

L = Length of facility = 120 ft (Payne 2009)

W = Width of facility = 226 ft (Payne 2009)

$\cot \phi$ = Mean of the cotangent of the aircraft impact angle (Table B-17, of DOE-STD-3014-2006, p. B-29)

S = Mean aircraft skid distance (Table B-18, of DOE-STD-3014-2006, p. B-29)

WS = Aircraft wingspan (provided in Table B-16, of DOE-STD-3014-2006, p. B-28)

H = Facility height = 139 ft (Payne 2009)

The calculation of effective area for each aircraft type is given in Table F.9-2.

Table F.9-2. Effective area calculation

Variable	Commercial air carrier	Commercial air taxi	General aviation
WS (ft) ^a	98	59	50
L (ft)	120	120	120
W (ft)	226	226	226
H (ft)	139	139	139
R (ft)	255.88	255.88	255.88
cot (Φ)*	10.2	10.2	8.2
S (ft)*	1,440	1,440	60
A _f (mi ²)	1.97×10^{-2}	1.74×10^{-2}	1.39×10^{-2}
A _s (mi ²)	1.83×10^{-2}	1.63×10^{-2}	6.58×10^{-4}
A _{eff} (mi ²)	3.80×10^{-2}	3.37×10^{-2}	1.45×10^{-2}

a. From Tables B-16, B-17, and B-18, respectively, of DOE STD 3014-2006

$F_{ijk}(x,y)$ (Conditional Probability per Square Mile)

For airport operations, the conditional probabilities were taken from Tables B-2 through B-5 of DOE-STD-3014-2006 (p. B-12 to B-15). To use these tables, the standard specifies that the orthonormal distances (Cartesian distance in both the x and y directions) must be determined from the facility's closest point to the center of each runway. As described in the standard (p. B-4), the "x axis coincides with the extended runway centerline; the positive direction is the direction of flight. The y axis is perpendicular to the x axis with the positive direction created by a 90-degree counterclockwise rotation of the positive x axis." There are multiple runways at Boston Logan International Airport, but only four (4) different directions in which the various runways are oriented: 150°, 220°, 270°, and 320°. The runway number is "approximately one-tenth of the angle that the extended runway direction makes with magnetic north" (DOE 2006). Thus runways labeled 22 equates to 220°. Also note that runways can use multiple numbers: 4/22, equating to 40° and 220°; those are identical because they are 180° out of phase. The distance from the NEIDL facility to intersection of two runways was determined to be approximately as 3.75 miles at an angle of 59°.

DOE 2006 gives two relationships to determine x and y:

$$x = -R \cos(\Theta - \Phi)$$

and

$$y = R \sin(\Theta - \Phi)$$

where

R = distance from the facility (miles) = 3.75

Θ = bearing from the facility to the airport = 59°

Φ = runway bearing as an angle with respect to magnetic north (runway number times ten) = 150° , 220° , and 270°

Thus x and y are calculated for each runway, and the results are shown in Table F.9-3:

Table F.9-3. Distances from NEIDL to each Boston Logan runway

Φ (runway bearing, degrees)	x (miles)	y (miles)
150°	0.07	-3.75
220°	3.55	-1.22
270°	3.21	1.93
320°	0.59	3.70

Once the x and y direction distances were determined, Tables B-2 and B-5 of DOE-STD-3014-2006 were used to look up values of $F(x,y)$; results are shown in the tables below for each runway. By inspection runway 27 (270°) should yield the highest crash probabilities because it is the closest direction to the line from NEIDL to/from the airport. The results of Table F.9-1 are input into Tables F.9-4 through F.9-7, which provide confirm that runway yields the highest crash probabilities.

1

Table F.9-4. Aircraft crash frequency calculations for airport operations—Runway 15 (150°).

Aircraft operation	$\sum N_{ijk}$ (Number of operations per year)	P (Crash rate ^a)	X (Distance) (mi)	Y (Distance) (mi)	f(x,y) (Aircraft crash location probability ^b)	A _{eff} (Effective area [mi ²])	F (Impact frequency per year)
Commercial aviation—air carrier (takeoff)	104,247	1.90×10^{-7}	0.07	-3.75	4.50×10^{-5}	3.80×10^{-2}	3.39×10^{-8}
Commercial aviation—air carrier (landing)	104,247	2.80×10^{-7}	-0.07	3.75	$0.00 \times 10^{+0}$	3.80×10^{-2}	$0.00 \times 10^{+0}$

F.9.3.1.2 Non-Airport Operations Crash Frequency Estimation

Non-airport operations (e.g., in-flight, parameter i , from four factor formula = 2) crash frequency is also estimated using the four-factor formula, however the first three terms are combined into one term, $NPf(x,y)$, for the estimated number of crashes per square mile per year (mi^2/yr). This value is taken from Tables B-14 and B-15 of DOE-STD-3009-2006, depending on the type of aircraft operations, conservatively using the maximum values listed. To determine the impact frequency into the facility, one simply multiplies these values by the effective area discussed above. The calculation is shown in Table F.9-8 with the resulting total of 4.38×10^{-5} per year. It should be noted that general aviation flights by far dominate this non-airport risk. General aviation planes include small planes that are unlikely to penetrate the NEIDL walls.

Table F.9-8. Non-airport operations crash frequency calculations

Type of aircraft	$NPf(x,y)$ number of crashes per sq mile per year ^a	A_{eff} effective area (mi^2)	Non-airport crash frequency per year [$NPf(x,y) \times A_{eff}$]
Commercial aviation—air carrier	2.00×10^{-6}	3.80×10^{-2}	7.60×10^{-8}
Commercial aviation—air taxi	8.00×10^{-6}	3.37×10^{-2}	2.70×10^{-7}
General aviation	3.00×10^{-3}	1.45×10^{-2}	4.35×10^{-5}
Total crash frequency (per year)			4.38×10^{-5}

a. Maximum values from Tables B-14 and B-15 of DOE STD-3014-2006

F.9.3.1.3 Total Aircraft Crash Frequency

The resulting total estimated aircraft crash frequency is just the summation of the calculated frequencies for airport operations assuming all flights are associated with that runway plus non-airport operations. This is summarized for each of the runways in Table F.9-9 below:

Table F.9-9. Total annual crash frequency for each Boston Logan runway

Runway direction (degrees)	Total crash frequency for airport operations (/year)	Total crash frequency for non-airport operations (/year)	Total crash frequency (/year)
150°	2.06×10^{-6}	4.38×10^{-5}	4.6×10^{-5}
220°	1.24×10^{-5}	4.38×10^{-5}	5.6×10^{-5}
270°	1.40×10^{-5}	4.38×10^{-5}	5.8×10^{-5}
320°	1.22×10^{-6}	4.38×10^{-5}	4.5×10^{-5}

Thus, as expected, the largest contributor is runway 270 with a total crash frequency of approximately $6 \times 10^{-5}/yr$. The frequency of $6 \times 10^{-5}/yr$ (return period of ~16,700 years) places the aircraft crash into frequency category C (1 in 10,000 to 1 million years). However, that is the frequency of an aircraft crashing into NEIDL and it does not take into account the conditional probability of conditions that must

exist for a pathogen release to occur. For an aircraft crash to result in a pathogen release, the following conditions are necessary:

1. The aircraft crashing must have sufficient energy (speed and mass of a projectile) to penetrate the building. It is not known which aircraft would be capable of penetrating the walls of the building exterior and the laboratory walls (BSL-3 or BSL-4), but not all are likely to be capable of penetrating both walls. That is especially true of the general aviation flights, which dominate the frequency for non-airport operations, because they include small planes.
2. The angle of impact must be sufficiently perpendicular for penetration to result. Impacts at lower angles can result in the aircraft ricocheting off the building, or hitting with a grazing blow, without penetrating the interior laboratory spaces.
3. The impact must be at a location that results in a pathogen release. An aircraft impact into administrative areas is not likely to result in a pathogen release. The BSL-3 and BSL-4 areas compose 29 percent of the facility floor space (13 percent BSL-3 and 16 percent BSL-4) (BUMC 2008a). The laboratory rooms will contain pathogens in a releasable form (i.e., a liquid suspension) for only a fraction of the time. Rooms where pathogens are stored are not in an easily releasable form (i.e., frozen).

On the basis of the conditional probabilities, the frequency of an aircraft crash that results in a pathogen release is judged to be in frequency category C (1 in 10,000 to 1 million years), but it is in the low-frequency (high return period) end of that category. The MRF earthquake scenario is also in frequency category C (1 in 10,000 to 1 million years). However, given the multiple extreme conservative assumptions for the calculation of the aircraft crash frequency (e.g., all planes take off and land in the direction to/from NEIDL) and the conditional probabilities stated above, it is judged that that aircraft crash frequency is considered comparable to or lower than the MRF earthquake frequency.

F.9.3.2 Consequences

While a structural evaluation of aircraft crash per the guidance of DOE-STD-3014-2006 has not been performed, the consequences (i.e., the number and extent of potential exposures) to the public are qualitatively judged to be less than that of an MRF earthquake event for the following reasons:

1. The MRF earthquake event assumes total collapse of the NEIDL building [i.e., all available material at risk (MAR) has the potential to be release and appropriate release factors applied to the entire inventory]. An aircraft crashing into the building will likely only impact the immediate portion of the building that is involved at point of impact, and to a lesser degree, the surrounding areas. That means that only a portion of the available MAR has the potential to be released in a

1 crash. In the unlikely event of a total facility collapse after an aircraft collision (similar to that of
2 the September 11, 2001, terrorist strikes on the World Trade Center and the Pentagon) could
3 impact all the available MAR. In such a case, the amount of MAR impacted would be equal to,
4 but not exceed, that assumed in the MRF earthquake event.

- 5 2. An aircraft provides a considerable fuel source and an ignition potential when crashed into a
6 building, thus the potential of a fire exists. A fire would raise the local and surrounding
7 temperatures of the crash site (i.e., areas where MAR is impacted), thus inactivating the
8 pathogens before or during their release. An inactive pathogen presents no hazard to a public
9 receptor.
- 10 3. NEIDL rooms containing pathogens are in the interior of the facility and there is at least one
11 exterior wall plus one primary containment wall protecting the pathogens. Therefore, an aircraft
12 projectile would have to penetrate two walls to impact the pathogens and result in a potential
13 airborne release. In addition, the BSL-4 area is constructed as a box-within-a-box with interior
14 walls that are more robust than (and seismically independent from) the rest of the building
15 structure.
- 16 4. The BSL-3 and BSL-4 laboratories are several stories above ground level, so any release would
17 be an elevated release that would allow dilution as the plume is dispersed, while the MRF
18 earthquake scenario was analyzed on the basis of a ground-level release. Because a ground level
19 release will tend to result in higher concentrations in the respirable zones/altitudes than an
20 elevated release, the MRF earthquake scenario will tend to bound the aircraft crash scenario.

21
22 Therefore, the consequences of an aircraft crash are expected to be less than the consequence estimates
23 for the MRF earthquake.

24 25 **F.9.3.3 Summary**

26 Both the frequency and consequences of an aircraft crashing are shown to be less than or no greater than
27 the frequency and consequences of the MRF earthquake as analyzed. Therefore, the MRF earthquake
28 analysis is considered bounding for the aircraft crash and further detailed aircraft crash analysis is not
29 deemed to be necessary.

30
31 The frequency of an aircraft carrying live pathogens and resulting in a leak to the environment was
32 demonstrated to be less than the threshold of frequency category D (1 in more than 1 million years)
33 beyond reasonably foreseeable, and is dismissed from further evaluation.

ATTACHMENT A. SUMMARY OF INCIDENTS RELATED TO A CENTRIFUGE RELEASE

This attachment focuses on the historic incident data provided in Appendix D of the RA and provides a summary of the incidents relevant to this analysis. Incidents considered here include those associated with centrifuge aerosol releases, reduced PAPR performance, loss of positive-pressure suit confinement, and failure of ventilation systems.

A.1 Centrifuge Incidents

The RA (Appendix D) identifies four centrifuge-related incidents at BSL-3 facilities, which are summarized below. No centrifuge-related incidents are identified in the RA Appendix D for BSL-4 facilities.

1. Location: University of Texas Houston Health Science Center, Houston, Texas
Date: May 7, 2007
Research Agent: *Bacillus anthracis* (anthrax)
Description: Tube leakage occurred inside a centrifuge used for concentration of *B. anthracis* cells.
Results: Four people apparently were exposed to *B. anthracis*.
Action: Prophylaxis was refused. No infections resulted. Procedures were modified to require that centrifuge buckets be opened only within a BSC, and inspected and decontaminated after each use.
2. Location: University of Texas at Austin, Texas
Date: April 12, 2006
Research Agent: Recombinant Influenza A H3N2 virus, containing genes from strain H5N1 (avian influenza virus).
Description: A centrifuge secondary container lid broke during centrifugation of virus, causing the rotor to become unbalanced. The researcher noted loss of volume in one viral tube and, suspecting viral leakage, undertook decontamination of centrifuge, centrifuge tube, work area, adjacent equipment, and himself.
Results: A decision was made to treat the researcher empirically using Tamiflu[®] [Oseltamivir]. Secondary decontamination of laboratory room was undertaken the following day.

Action: Responsible officials maintain that it is unclear whether a leakage of virus occurred. However, their records show that proper decontamination protocol was not followed for the suspected leak.

3. Location: Medical University of Ohio, Toledo, Ohio

Date: September 30, 2005

Research Agent: *Coccidioides immitis*

Description: A student potentially was exposed to infectious aerosols from a broken vial inside a centrifuge.

Results: Medical evaluation was provided.

Action: The BSL-3 facility director, who was in charge of the *C. immitis* research, resigned as director and was replaced as animal and biosafety protocol principal investigator and as advisor to the student.

4. Location: New Haven, Connecticut

Date: August 8, 1994

Research Agent: Sabia virus¹¹

Description: A research virologist discovered a leaking vessel on opening a sealed aerosol biocontainment centrifuge rotor. Improper PPE was used, and the incident was not reported.

Results: Symptoms began 8 days afterward. Two days later, the infection was properly diagnosed.

Action: Antiviral therapy cured the nearly fatal infection. Two external committees strongly criticized the researcher and institution. The university agreed to implement all recommendations.

The above incident data can be summarized as follows:

- There have been four potential centrifuge-related release incidents in BSL-3 facilities and none in BSL-4 facilities.
- Three incidents resulted in potential exposure of one individual each, and one incident involved the exposure of four people.
- Only one of the incidents resulted in infection and only one individual was infected.

¹¹ Sabia virus, a BSL-4 virus, was not classified by BMBL 3rd edition regarding biocontainment precautions at the time of this incident

- Only one incident was undetected or unreported. This incident involved a failure to report the incident until after the researcher became ill.

A.2 Positive-Pressure Suit Incidents

Appendix D of the RA identifies three positive-pressure suit failure incidents in BSL-4 facilities. These incidents are identified below, along with the pathogens involved.

- Marburg virus—Separation of BSL-4 filter from suit.
- Marburg virus—V-shaped rip in a suit. Positive airflow inside the suit prevented contact with room air.
- Lassa virus—Brass connector on suit fell apart.

There is no indication that any of those incidents prevented the suits from providing the necessary protection, in fact one of the descriptions states that continued protection was provided.

A.3 PAPR Incidents

Two incidents related to PAPR are summarized below.

- Location: Medical College of Wisconsin

Date: July 28, 2010

Research Agent: *Mycobacterium tuberculosis*

Description: During activities, the worker backed into a doorway and bumped the power pack on the PAPR unit. The PAPR power was inadvertently turned off as a result.

Results: The worker noticed the air was not flowing into the hood and immediately turned the unit back on. It was estimated that the PAPR was not operating for a few seconds.

Action: No other actions were taken.
- Location: Medical College of Wisconsin

Date: October 6, 2010

Research Agent: Influenza A/Brevig Mission/1918

Description: The individual was centrifuging washed cells (i.e., cells contained in sealed cups inside the centrifuge) when the HEPA filter fell off the PAPR belt. It was

unknown whether the filter was loose for a prolonged period or was knocked off at that moment.

Results: The individual picked up the filter, reconnected it to the PAPR, and finished the work.

Action: The individual was given Tamiflu and quarantined but showed no symptoms.

A.4 Ventilation System Incidents

Six ventilation incidents at BSL-3 facilities were identified in Appendix D of the RA and are summarized below.

1. Location: Centers for Disease Control and Prevention, Atlanta, Georgia, Bldg 17

Date: July 11, 2008

Research Agent: Program pathogens included influenza virus, extensively drug-resistant *Mycobacterium tuberculosis*, and rabies virus.

Description: A bird caused a Georgia Power transformer to fail, knocking out electricity to BSL-3 biocontainment areas.

Results: Backup generators failed to start, leaving the laboratories without main electrical power for 75 minutes. CDC personnel did not attempt to override and start the backup generators. Negative directional airflow was not maintained.

Action: No exposures or infections were reported. Backup failure was determined to be due to removal of two generators from service for upgrades. Their absence caused a power fluctuation when main power was lost, resulting in shutdown of the entire backup generator system. The system was tested subsequently on July 21; CDC officials would not release results of the test. No further information was available.

2. Location: Centers for Disease Control and Prevention, Atlanta, Georgia, Building 18

Date: June 8, 2007

Research Agent: Not applicable

Description: A lightning strike knocked out electricity to BSL-3 and unoccupied BSL-4 biocontainment areas. Circuit breakers that should have remained engaged were tripped.

Results: Backup generators failed to start. Negative directional airflow was not maintained. A battery-powered system provided power to lights and doors for 15–20 minutes. No exposures or infections subsequently were reported.

Action: Changes to the design of the backup system were discussed and damage to the lightning protection equipment was repaired. It was later determined that a ground cable had been cut some time earlier, and prevented the circuit breakers from remaining engaged. CDC has declined to release documents relating to the incident.

3. Location: Centers for Disease Control and Prevention, Atlanta, Georgia, Building 18
- Date: May 2007
- Research Agent: Not applicable
- Description: Malfunction of the HVAC system pulled potentially contaminated air out of the BSL-3 biocontainment area and into a clean hallway.
- Results: Nine workers were tested for possible exposure to the bacterium and no infections were diagnosed.
- Action: The HVAC system was brought back into compliance. Duct tape was used to seal the door and remained in place as of June 2008. A self sealing door will be installed by April 2009.

4. Location: The University of North Carolina at Chapel Hill, Chapel Hill, North Carolina
- Date: March 19, 2005
- Research Agent: *Mycobacterium tuberculosis* (recombinant)
- Description: An exhaust fan servicing two BSCs and the general laboratory space failed. Audible alarms on the cabinets and air pressure monitors had been turned off.
- Results: Loss of primary and secondary biocontainment occurred.
- Action: A review of all BSL-3 laboratories was scheduled to identify renovation needs to ensure compliance with current design standards.

5. Location: University of Illinois at Chicago, Chicago, Illinois
- Date: September, 2004
- Research Agent: Not specified (redacted by IBC)
- Description: Both doors of the double door biocontainment entryway were propped open by laboratory staff while experiments were in progress.

1 Results: Infectious materials were not being handled at the time.

2 Action: Principal investigator was counseled and warned. Staff was retrained and
3 tested.

4
5 6. Location: Fort Detrick, Maryland

6 Date: April 1, 2002

7 April 20, 2002

8 Research Agent: *Bacillus anthracis* (anthrax)

9 Description: A researcher tested positive for exposure to anthrax spores, which were also
10 released into a locker room and adjacent hallway.
11 U.S. Army officials reported evidence of a second accidental release of
12 anthrax spores.

13 Results: No one was infected in either incident.

14 Action: The first incident involved a virulent strain. Test samples connected with the
15 second incident tested positive for the attenuated (vaccine) strain.

ATTACHMENT B. ESTIMATE OF THE AMOUNT OF PATHOGEN IN A DROP OF SUSPENSION

The purpose of this attachment is to get first order estimate as to the amount of pathogen toward which a worker could be exposed. It is first assumed that 1 molar saline-water is the solution used inside of a syringe. For purposes of this example analysis, a single drop is the basic unit used to determine how much pathogen could be injected into the worker. The laboratory worker could be exposed to multiple drops or a fraction of a drop, but a single drop is used as a foundation for this analysis. The effect of multiple drops or fractions of a drop can be calculated by extension, if desired.

A relationship for the mass of a drop of water hanging from the end of a tube is (Woodward)

$$W = 2 \times \pi \times r \times \gamma \quad \text{[equation B-1]}$$

where

W	weight of the drop (N) = $m \times g$
m	mass of water drop (kg)
g	acceleration due to gravity (9.8 m/s^2)
r	tube radius (m) = $0.5 \times \text{tube diameter}$
γ	surface tension (N/m)

Assuming room temperature is approximately 20°C (68°F), the surface tension of water is 7.28×10^{-2} N/m (The Engineering Toolbox). Jungwirth and Tobias (Figure 13c) show relationships of saline solutions relative to pure water for several salts. The general trend is a higher surface tension with increasing molarity, but the results are minor. For example, for one molar sodium chloride (NaCl), the surface tension increases approximately 1.5×10^{-3} N/m. Thus, the total surface tension is 7.43×10^{-2} N/M. Assuming a hypodermic needle that is 27 gauge (typical gauge for injecting mice), a nominal inner diameter of 0.19 mm (1.9×10^{-4} m) is used (WWW 3).

Solving equation B-1 for the mass of water in the drop gives the following:

$$m = 4.5 \times 10^{-6} \text{ kg} = 4.5 \times 10^{-3} \text{ grams}$$

Assuming a nominal density of water was assumed at 1 g/cc, this is equivalent to 4.5×10^{-3} cc or 4.5×10^{-3} mL (4.5 micro-liters). An exposure to 4.5×10^{-3} mL at a concentration of 1×10^6 CCID₅₀ results in an exposure to 4,500 CCID₅₀. Other pathogens have higher SCs so the exposure levels would be correspondingly higher.

ATTACHMENT C. SUMMARY OF INCIDENTS RELATED TO NEEDLESTICK

This attachment provides an overview of historic needlestick incidents at BSL-3 and BSL-4 facilities

BSL-3: Literature searches identified eight needlestick-related incidents at BSL-3 facilities, which are summarized below. In addition, NIH has supplied 11 other BSL-3 events from RDNA incidents (NIH RDNA 2010), which are summarized below in lesser detail.

1. Location: United States of America
Date: October 2002
Research Agent: West Nile virus, genus *Flavivirus* (WNV)
Description: A microbiologist working under BSL-3 conditions suffered a finger puncture from a hypodermic needle harboring WNV being harvested from infected mouse brain (Centers for Disease Control and Prevention, 2002 #16273).
Results: The wound was cleansed and bandaged. Serologic testing showed evidence of acute WNV infection. Mild symptoms developed and resolved.
Action: CDC determined that applicable handling and biocontainment protocols were followed.
2. Location: University of New Mexico, Albuquerque, New Mexico
Date: 2003
Research Agent: Redacted by IBC; likely was *Francisella tularensis*
Description: Puncture of thumb with hypodermic needle harboring spores to be used in mouse infections (University of New Mexico IBC, 2003 #4024) (Subcommittee on Oversight and Investigations, 2007 #16247).
Results: Worker received prophylactic treatment; no infection resulted.
Action: It was proposed that alternative methods for mouse inoculation be considered.
3. Location: University of Virginia
Date: April 11, 2007
Research Agent: *Francisella tularensis*
Description: Potential exposure—Needlestick with syringe that had been in contact with mice. Inoculated with select agent.
Results: Unknown
Action: No further information available.

4. Location: National Animal Disease Center
Date: July 2, 2007
Research Agent: *Brucella suis*
Description: Potential exposure—needlestick with syringe containing select agent during necropsy
Results: Unknown
Action: No further information available.
5. Location: The University of Chicago
Date: July 18, 2007
Research Agent: *Bacillus anthracis*
Description: Potential exposure—needlestick with syringe containing select agent during necropsy
Results: Unknown
Action: No further information available.
6. Location: Battelle Memorial Institute
Date: July 23, 2007
Research Agent: Avian influenza virus
Description: Potential exposure—needlestick with syringe containing select agent.
Results: USDA select agent, referred to APHIS
Action: No further information available.
7. Location: University of California, Davis
Date: July 27, 2007
Research Agent: *Brucella abortus*
Description: Potential exposure—needlestick with syringe containing select agent.
Results: Unknown
Action: No further information available.
8. Location: St. Louis University
Date: August 7, 2007
Research Agent: Monkeypox virus
Description: Potential exposure—needlestick with syringe containing select agent.

Results: Unknown
Action: No further information available.

Table C-1. External parenteral exposures in BSL-3

Institution	Date	Agent
Colorado State University	4/2/10	HIV
University of Rochester	1/20/10	Lentivirus
University of Texas—San Antonio	1/14/10	<i>Coccidioides</i> sp.
University of Massachusetts Medical School	11/5/09	<i>Mycobacterium tuberculosis</i>
Novartis	10/28/09	VEE and Sindbis
University of North Carolina Chapel Hill	11/13/08	Ross River virus
University of Texas—San Antonio	8/21/08	<i>Francisella tularensis</i>
University of Wisconsin—Madison	5/22/08	<i>Brucella</i> sp.
University of Colorado—Denver	4/16/08	<i>Mycobacterium tuberculosis</i>
St Louis University	4/4/08	Yellow Fever virus
University of Texas Health Science Center	9/21/07	<i>Bacillus anthracis</i>

Source: NIH RDNA 2010

BSL-4: There have been five needlestick related incidents in BSL-4 facilities, which are summarized below.

- Location: U.S. Army Medical Research Institute For Infectious Diseases (USAMRIID), Fort Detrick, Frederick, Maryland

Date: November, 1979

Research Agent: Lassa virus

Description: Accidental finger puncture with needle on a syringe loaded with Lassa virus.

Results: No illness or serological evidence for infection occurred

Action: Ribavirin and immune plasma were given. (This was an experimental therapy for monkeys under development at the Institute.)
- Location: U.S. Army Medical Research Institute For Infectious Diseases (USAMRIID), Fort Detrick, Frederick, Maryland

Date: February 18, 2004

Research Agent: Ebola virus

Description: A civilian scientist grazed her hand with a hypodermic needle that had been used to inject antibodies into Ebola virus-infected mice (Dishneau, 2004 #4037)(Subcommittee on Oversight and Investigations, 2007 #16247)

Results: Scientist was sequestered in the biosafety biocontainment care suite until it could be concluded that no infection ensued.

Action: No further information available.

3. Location: Vector Laboratory, Novosibirsk, Russia

Date: May 19, 2004

Research Agent: Ebola virus

Description: A researcher several days earlier had suffered an accidental finger stick with a hypodermic needle that contained the Zaire strain of Ebola virus. She was working with a guinea pig model of the infection at the time.

Results: The researcher died from Ebola infection on May 19.

Action: No further information available.

4. Location: Bernhard Nocht Institute for Tropical Medicine, Hamburg, Germany
(Enserink, 2009 #16252)

Date: March 12, 2009

Research Agent: Ebola virus

Description: A laboratory researcher wearing protective gloves experienced a needlestick from a syringe suspected to contain Ebola virus

Results: The researcher was quarantined in Hamburg University Hospital for observation. Treatment included use of the experimental Feldmann vaccine.

Action: The worker did not become ill. No further information concerning potential seroconversion. (McGroarty, 2009 #16253)

5. Location: CDC Special Pathogens Branch

Date: 2003 or earlier

Research Agent: Ebola virus, Zaire strain, mouse-adapted

Description: Needlestick to worker before setting up an inoculum with mouse-adapted Ebola virus

Results: No infection resulted

Action: No further information available

ATTACHMENT D. SUMMARY OF NEIDL DESIGN

This attachment presents excerpts from various design documents and summarizes the NEIDL design with respect to seismic, wind, blast effects, and security. The wind, blast, and security design information is potentially, but not necessarily, relevant to the earthquake analysis, but they are presented here to provide all potentially relevant design information for the earthquake event sequence analysis in one location.

D.1 General Design

The following excerpts apply to the general design of NEIDL:

1. “The NEIDL structure consists of a seven-story structural steel composite frame. The BSL-4 laboratory facility is contained in a concrete structure (referred to as the Containment Box) and is supported on level 2. The floors above the containment box will be used for various mechanical, BSL-2 and BSL-3 laboratories and office spaces.

In accordance with the basis of design report (BOD) for this project, the structural design is in compliance with the 6th edition of 780 CMR.” (Weidlinger 2005)

2. “The overall facility design and construction is in conformance with the applicable codes, including:

Code Compliance

- The NIH Design Policy and Guidelines; November 2003 Edition
- The U.S. Department of Health and Human Services, CDC/NIH, Biosafety In Microbiological and Biomedical Laboratories
- The Massachusetts State Building Code (780 CMR); 6th Edition (BMBL)” (BUMC 2008)

D.2 Seismic Design

The following excerpts apply specifically to the seismic design of NEIDL (Weidlinger 2005).

1. According to the Rolf Jensen & Associates, Inc., August 19, 2005, Code Compliance Report, the project was designed in accordance with the requirements of Use Group Classification B (Business) occupancy for laboratory and office areas. Per the report, this understanding is based on the use and storage of hazardous materials below allowable exempt quantities per control area. In addition, “materials in storage and in use in the BSL-4 areas are not classified as highly toxic,

as defined by MSBC 307.2, because they are biological in nature.” This use group classification translates to a Seismic user Group II (which corresponds to Seismic performance category C). A more stringent seismic performance category (Seismic Performance Category D) is also specified in 780 CMR which corresponds to User Group III. At the request of the project team, Weidlinger Associates, Inc. (WAI) performed an evaluation of the current containment box structural design when subjected to the seismic loads and deformation requirements of 780 CMR for seismic category D. In accordance with 780 CMR, WAI has performed a dynamic modal analysis and generated a new lateral load distribution for each level of the building. The modal analysis was based on the base shear value obtained from the equivalent lateral load procedure. The modal analysis is an alternate method to generate lateral loads that is known to yield more accurate results than the more conservative equivalent lateral load procedure (used in the current design for seismic category C). The structural design of the containment was then subjected to the new generated lateral loads and tested in accordance with the deformation requirements of Category D.

Based on the recently performed modal analysis, it is WAI’s conclusion that the design of the containment structure will not change if a Category D design were to be specified and that the current design meets the load and deflection criteria for this requirement.

2. The design and construction includes the following (BUMC 2008):
 - The NEIDL is designed according to Massachusetts Building Codes for Seismic Category D.
 - The BSL-4 suites are structurally separated from the adjoining floors. This structural separation allows for movement in the event of an earthquake, while maintaining structural integrity of the BSL-4 suites.
 - All fixtures for the BSL-4 suite designed specifically for the facility, and are Underwriters Laboratories (UL) tested, to ensure the facility retains its air pressurization.

ATTACHMENT E. ESTIMATE OF FREQUENCY

This attachment presents the basis for the frequency category assignment for an earthquake that would cause failure of the NEIDL structure. This attachment provides background information, summarizes the NEIDL design criteria, presents U.S. Geologic Survey (USGS) seismic hazard data, and estimates the frequency of an earthquake that could fail the NEIDL structure.

E.1 Introduction

Several different scales are used to measure characterize earthquakes. The Richter scale is a well-known measure of an earthquake's magnitude. The Richter scale is a logarithmic earthquake magnitude scale for measuring the size of the earthquake, it is not used to express damage or effect. Another measure of an earthquake is the Modified Mercalli (MM) intensity, which is a measure of the effect observed from the earthquake. Table E-1 below provides a comparison of the Richter and MM scales.

Table E-1. Richter magnitude and MM intensity earthquake measures

Richter magnitude	Typical maximum MM intensity
1.0–3.0 (Micro)	I
3.0–3.9 (Minor)	II–III
4.0–4.9 (Light)	IV–V
5.0–5.9 (Moderate)	VI–VII
6.0–6.9 (Strong)	VII–IX
7.0 and higher (Major or Great)	VIII or higher

Source: USGS 2010a

Table E-2 provides a description of each MM intensity level to provide some understanding of the effects.

Table E-2. Description of MM intensities

Level	Description
I	Not felt except by a very few under especially favorable conditions.
II	Felt only by a few persons at rest, especially on upper floors of buildings.
III	Felt quite noticeably by persons indoors, especially on upper floors of buildings. Many people do not recognize it as an earthquake. Standing motor cars might rock slightly. Vibrations similar to the passing of a truck. Duration estimated.
IV	Felt indoors by many, outdoors by few during the day. At night, some awakened. Dishes, windows, doors disturbed; walls make cracking sound. Sensation like heavy truck striking building. Standing motor cars rocked noticeably.
V	Felt by nearly everyone; many awakened. Some dishes, windows broken. Unstable objects overturned. Pendulum clocks might stop.
VI	Felt by all, many frightened. Some heavy furniture moved; a few instances of fallen plaster. Damage slight.
VII	Damage negligible in buildings of good design and construction; slight to moderate in well-built ordinary structures; considerable damage in poorly built or badly designed structures; some chimneys broken.

Level	Description
VIII	Damage slight in specially designed structures; considerable damage in ordinary substantial buildings with partial collapse. Damage great in poorly built structures. Fall of chimneys, factory stacks, columns, monuments, walls. Heavy furniture overturned.
IX	Damage considerable in specially designed structures; well-designed frame structures thrown out of plumb. Damage great in substantial buildings, with partial collapse. Buildings shifted off foundations.
X	Some well-built wooden structures destroyed; most masonry and frame structures destroyed with foundations. Rails bent.
XI	Few, if any (masonry) structures remain standing. Bridges destroyed. Rails bent greatly.
XII	Damage total. Lines of sight and level are distorted. Objects thrown into the air.

Source: USGS 2010a

The following is a USGS summary of earthquakes in Massachusetts (USGS 2010).

Nineteen earthquakes, intensity V or greater, have centered in Massachusetts. A number of other earthquakes were centered off the coast of Massachusetts and affected the eastern portion of the State. A shock in 1755 reached intensity VIII at Boston and was felt across the State. In addition, Massachusetts was affected by some of the more severe Canadian shocks plus the earthquake of 1929 that centered on Grand Banks of Newfoundland.

Table E-3 provides a list of the more significant earthquakes in Massachusetts.

Table E-3. Earthquakes in Massachusetts

Location	Date	MM intensity or Richter magnitude
Northern Cape Ann region, east of Newbury, Massachusetts	November 10, 1727	MM Intensity VII
Southern Cape Ann, Massachusetts region	June 14, 1744	MM Intensity VI
Cape Ann, Massachusetts	November 18, 1755	MM Intensity VIII (the largest earthquake recorded in Massachusetts)
Near the coast of Massachusetts	July 22, 2003	Richter Magnitude 3.6

The Richter magnitude and the MM intensity are not used when assessing a building's seismic capacity; instead, the spectral acceleration is used. The spectral acceleration is approximately the acceleration experienced by the building and accounts for the frequency of the shaking. The Richter magnitude and the MM intensity cannot be related to the spectral acceleration. So it is not possible to identify the largest historic spectral acceleration for Massachusetts.

E.2 NEIDL Design

The NEIDL was designed in accordance with the Massachusetts Building Code (Massachusetts 1997) which requires the following:

The effective peak velocity-related acceleration (A_v) and the effective peak acceleration (A_a) shall each be taken as 0.12g throughout Massachusetts for the purposes of seismic design in accordance with 780 CMR.

NEIDL was designed to withstand the 0.12 g acceleration (i.e., $0.12 \times 32.2 \text{ ft/s}^2 = 3.86 \text{ ft/s}^2$) (BUMC 2005). The fundamental period (essentially the inverse of the natural frequency) of the NEIDL structure is 1.866 seconds in the X direction and 1.964 seconds in the Y direction (BUMC 2005). An earthquake with a shaking period approximately equal to the fundamental period of the NEIDL structure, approximately 2 seconds, has the greatest potential to cause damage to the facility.

The Massachusetts Building Code (Massachusetts 1997) states the following:

For ground motions larger than the design levels, the intent of 780 CMR 1612.0 is that there be a low likelihood of building collapse.

In summary, the NEIDL structure is expected to withstand an earthquake with an acceleration of 0.12 g with a shaking period of approximately 2 seconds (approximately the natural frequency of the NEIDL structure) and for ground motions larger than the design levels, there is a low likelihood of a building collapse.

E.3 USGS Seismic Hazard Data

The USGS provides seismic hazard maps (USGS 2008), which report the spectral acceleration at various periods for portions of the country. Table E-4 below provides the spectral acceleration the corresponding likelihoods for 1 and 2 second shaking periods (i.e., the time between peak acceleration cycles). The data are applicable for northeastern Massachusetts, which includes the area surrounding the three candidate sites. The 2-second shaking period is quite close to the NEIDL fundamental periods of 1.866 and 1.964 seconds and is the period of greatest concern for NEIDL. Though the 1-second data are not important for this analysis because they are not close to the 2-second fundamental period of the NEIDL structure, they do provide insight into the shape of the curve, while the two data points from USGS maps for a 2-second period do not allow the shape of the curve to be determined. The footnotes below Table E-4 provide the identifiers listed on the USGS seismic hazard website (USGS 2008) for the specific maps from which the data were taken.

Table E-4. USGS Seismic Hazard Data

Likelihood	Spectral acceleration	
	1-second period	2-second period
10% in 50 years	0.02 to 0.03 g ^a	0.01 to 0.02 g ^b
5% in 50 years	0.04 to 0.06 g ^c	not available
2% in 50 years	0.06 to 0.08 g ^d	0.04 to 0.05 g ^e

- a. Conterminous U.S., 10% in 50 Years, 1.0 Second
- b. Conterminous U.S., 10% in 50 Years, 2.0 Seconds
- c. Conterminous U.S., 5% in 50 Years, 1.0 Second
- d. Conterminous U.S., 2% in 50 Years, 1.0 Second
- e. Conterminous U.S., 2% in 50 Years, 2.0 Seconds

Figure E-1 below provides a graph of the data in Table E-4 using the maximum spectral acceleration of each range (e.g., 0.03 g is used for the 0.02 to 0.03 g range). The likelihood values in Table E-4 (i.e., a percentage in 50 years) are presented as annual probability of exceedance values; so, the 10 percent in 50 years value is converted to an annual exceedance probability of 2×10^{-3} (i.e., $0.10 / 50$ years) and the 2 percent in 50 years value is converted to 4×10^{-4} (i.e., $0.02 / 50$ years). Dashed lines connect the points for each data set and are extrapolated beyond the end points in Figure E-1 to help visualize the potential extension. The three points for the 1-second shaking period data show that the relationship is not linear and that the curves bends downward, as shown by the three point for the 1-second shaking period curve. Figure E-1 also identifies the design basis for the NEIDL facility (i.e., 0.12 g spectral acceleration), which is the acceleration that NEIDL was designed to withstand without loss of function. Using a linear extrapolation, which is conservative, Figure E-1 shows that a 2-second 0.12 g spectral acceleration earthquake is expected to have an annual exceedance probability of about 1×10^{-5} .

Figure E-1. Chart of frequency and acceleration for 1- and 2-second shaking periods.

E.4 Frequency Category

On the basis of a visual examination of Figure E-1, a 2-second shaking period 0.12 g spectral acceleration earthquake is expected to have an annual exceedance probability of about 1×10^{-5} for NEIDL. Because NEIDL has been determined to remain functional after a 2-second 0.12 g earthquake, the frequency category for an earthquake that fails the NEIDL structure, either total or partial failure, is expected to have an annual exceedance probability of less than 1×10^{-5} . In the case of the MRF (total collapse) earthquake, Section E.2, the Massachusetts State Building Code (780 CMR) states that for ground motions larger than the design levels, there is a low likelihood of a building collapse. Therefore, an earthquake beyond the NEIDL design basis, either the BDB (minor damage) or the MRF (total collapse) earthquake, is assigned to frequency category C (1 in 10,000 to 1 million years).

E.5 Variability and Uncertainty

Numerous variabilities and uncertainties affect the results in Section E.3. Table E-5 identifies the key variabilities and uncertainties, provides a discussion of each, and provides an estimate of the potential effect of each.

Table E-5. Summary of key variabilities and uncertainties.

Variability/ uncertainty	Discussion	Potential effect
Seismic capacity of the NEIDL structure	<u>BSL-3 structure</u> -The structure has been analyzed and demonstrated to comply with the 0.12 g seismic requirement. It was also determined that the fundamental period is slightly under 2 seconds. (BUMC 2005) Therefore, the seismic capacity is expected to be somewhat beyond this level; however, there is always a some chance of failure at lower levels.	Expected conservatism
	<u>BSL-4 structure</u> -The BSL-4 structure is isolated from the BSL-3 structure and expected to have a greater seismic capacity than the BSL-3 areas, but this has not been demonstrate and the extent to which the BSL-4 capacity is greater is unknown.	Potentially large conservatism
Annual exceedance probability of a 2-second 0.12 g earthquake	<u>Interpretation of the USGS seismic hazard maps</u> -The maps show ranges of spectral accelerations and the highest acceleration of each range was used; therefore, this value may be conservative.	Potential conservatism
	<u>Linear extension of the curve generated from the USGS seismic hazard maps</u> -A linear extrapolation of the 1-second curve was used even though the 2-second curve demonstrates that the curve bends downward. Therefore, this is a conservative approach, but the magnitude of the conservatism cannot be determined.	Potential conservatism
Frequency category for the BDB earthquake	<u>BDB earthquake</u> -The frequency category of C was assigned based on the projected annual exceedance probability of 1×10^{-5} , which fall in the middle of frequency category C. However, it is possible that the frequency of an earthquake beyond the design basis or a conditional probability of structural failure at a lower acceleration is greater or lower than expected.	Potentially conservative or non-conservative
	<u>MRF earthquake</u> - The frequency category of C was assigned based on the projected annual exceedance probability of 1×10^{-5} , which fall in the middle of frequency category C. This is considered conservative because for ground motions larger than the design levels, there is a low likelihood of a building collapse (780 CMR).	Conservatism

As shown in Table E-5, there are a number of uncertainties and variabilities associated with the frequency category of the earthquake; however, the assignment of frequency category C (1 in 10,000 to 1 million years) is considered conservative and appropriate. A frequency category for the MRF earthquake is considered especially conservative because total collapse of the NEIDL structure is expected to require a much more severe earthquake, which would have a lower frequency.

**ATTACHMENT F. SELECTION OF AIRBORNE RELEASE AND RESPIRABLE
FRACTIONS FOR THE MAXIMUM REASONABLY FORESEEABLE
EARTHQUAKE**

Per the guidance provided in Section F.8.2, this analysis did not include confinement by any biocontainment features anticipated to be present at the NEIDL. The only limitation on the respirable airborne release is the initial form, quantity, and concentration of the pathogens and the selection of airborne release fractions and respirable fractions. To ensure the proper selection of airborne release and respirable fractions, a comprehensive review of potential values was performed. All airborne release and respirable fractions associated with liquids in Section 3.1 of *DOE Handbook –Airborne Release Fractions/Rates and Respirable Fractions for Nonreactor Nuclear Facilities* (DOE 2000) were reviewed and evaluated. Table F-1 lists all release phenomena associated with liquids, lists the airborne release fraction and respirable fraction, and provides a basis for selecting or not selecting the phenomena.

The phenomenon selected for analysis is a spill. This phenomenon was selected because

- A spill is likely to result from an earthquake, while the occurrences of other phenomena (e.g., explosive stress) are more speculative.
- The respirable airborne release fraction for a spill is comparable to or greater than the fraction for most other phenomenon.
- A spill does not involve high temperatures, which could inactivate most pathogens. The few phenomena that have a higher respirable airborne release involve high temperatures (e.g., boiling phenomenon).

Therefore, this analysis is performed on the basis of spill phenomena. Per the guidance discussed in Section 2, the median release fraction and respirable fraction is used. Therefore, the airborne release fraction used in this analysis is 4×10^{-5} and the respirable fraction is 0.7.

1

Table F-1. Basis for selection of release fractions

Release phenomena	Release/respirable fraction	Basis for selection or non-selection
Thermal stress		
Non-boiling	Mean = ARF^a 6E-7; RF ^b 1.0 Bounding = ARF 3E-5 / RF 1.0	This $ARF \times RF$ is less than the value for free-fall spill. In addition, given sufficient time the temperatures associated with near-boiling phenomena would inactivate most pathogens. Therefore, this phenomenon is dismissed from further consideration.
Boiling	Mean = ARF 1E-3; RF 1.0 Bounding = ARF 2E-3; RF 1.0	The $ARF \times RF$ is greater than the value for free-fall spill, but the temperatures that result in boiling will also inactivate most pathogens. There are no gas lines in the BSL-3 or BSL-4 rooms, so a severe fire is not expected. Therefore, this phenomenon is dismissed from further consideration.
Explosive stress		
Shock effect	Case-specific	Detonation phenomena require very specific conditions and are highly unlikely to occur. There are no gas lines in the BSL-3 or BSL-4 rooms, so there are no large fuel sources within the biocontainment spaces. Therefore, this phenomenon is dismissed from further consideration.
Blast effect	ARF 4E-3/hour (for duration of pulse)	Any blast effect would be a very short-duration spike (fractions of a second); therefore, this phenomenon is dismissed from further consideration.
High-pressure (200 psi) venting below the liquid surface level	Bounding = ARF 1E-3; RF 1.0	The pathogens are not stored in a pressurized configuration; therefore, this phenomenon is dismissed from further consideration.
Venting of low pressure liquids (< 0.35 MPa or 50 psi)	Bounding = ARF 5E-5; RF 0.8	This $ARF \times RF$ is less than the free-fall spill release factors (comparing bounding to bounding); therefore, this phenomenon is dismissed from further consideration.
Depressurization of liquid above boiling point	Bounding = ARF \leq 1E-2; RF \geq 0.6	Most pathogens would be inactivated at these superheated temperatures; therefore, this phenomenon is dismissed from further consideration.
Free-fall spill		
Aqueous solution^c	Mean = ARF 4E-5; RF 0.7 Bounding = ARF 2E-4; RF 0.5	This is for a spill from a height of 3 m, which is greater than the room height. This is the phenomena selected for use in the analyses.
Slurries	Mean = ARF 2E-5; RF 0.7 Bounding = ARF 5E-5; RF 0.8	This $ARF \times RF$ is less than the value for aqueous solution spills and the suspensions do not have 40% solid content; therefore, this phenomenon is dismissed from further consideration.
Viscous solutions	Mean = ARF 4E-5; RF 0.7 Bounding = ARF 2E-4; RF 0.5	This $ARF \times RF$ is less than the value for aqueous solution spills and the suspensions anticipated at the NEIDL are unlikely to be this viscous; therefore, so this phenomenon is dismissed from further consideration.
Aerodynamic entrainment and re-suspension		
Indoors, heterogeneous surface, low airspeeds	ARR 4E-7; hr; RF 1.0	This value is much lower than the aqueous, free-fall spill for any reasonably time period, so it is dismissed from further consideration.
Indoors, heterogeneous surface, covered with debris, static conditions	ARR 4E-8/hr; RF 1.0	This value is much lower than the aqueous free-fall spill for any reasonably time period, so it is dismissed from further consideration.

Release phenomena	Release/respirable fraction	Basis for selection or non-selection
Outdoors, higher wind-speeds (30 mph)	ARR 4E-6/hr; RF 1.0	This value for about 8 hours duration is equivalent to the aqueous free-fall spill. Wind speeds of this magnitude occur less than 1% of the time at the urban site and would result in much lower concentrations than could result from an earthquake. Therefore, this phenomenon is dismissed from further consideration.
Outdoors, higher wind-speeds (50 mph)	ARR 9E-5/hr; RF 1.0	This ARF × RF is somewhat greater than the value for aqueous free-fall spill, but this is far from typical meteorological conditions. DOE NEPA Guidance recommends use of typical meteorology and these conditions are extreme, which makes the event beyond reasonably foreseeable. This phenomenon is dismissed from further consideration.

- a. Airborne release fraction (ARF)
- b. Respirable fraction (RF)
- c. Release fractions for an aqueous free-fall spill were selected for the analysis.

5. Transportation Analysis

Chapter Highlights: Chapter 4 identified transportation mishaps as events warranting analysis. This chapter describes the analysis of public impacts associated with transportation of pathogen samples to and from the laboratory by truck and air. The public impacts analyzed are crash-related injuries and fatalities and potential exposure to pathogen releases as a result of truck and aircraft crashes.

This analysis has determined that crash-related injuries and fatalities are more likely than public exposure to infectious pathogens.

5.1 Introduction

NEIDL operations will include both incoming and outgoing shipments of infectious BSL-3 and BSL-4 pathogen samples throughout the life of the facility. In addition to pathogen samples, there is also the potential for infrequent shipment of specimens (e.g., blood, plasma, serum, tissue, urine, and respiratory secretions). These shipments may involve both the ground (truck) and mixed mode (combination of truck and air) transportation. This chapter addresses the public risks (i.e., frequency and consequences) to members of crash-related injuries and fatalities and a potential release of an infectious BSL-3 or BSL-4 pathogen resulting from a postulated transportation mishap. These risks are estimated for members of the public within the vicinity of the three sites being evaluated (i.e., the urban, suburban, and rural sites).

5.1.1 Transportation Analysis Guidance

No directly applicable guidance has been published that pertains to the analysis of accidents associated with transportation of infectious pathogens to and from the NEIDL. The National Research Council of the National Academies has observed this lack of guidance for facilities similar to NEIDL and concluded the following (NRC 2010):

U.S. Department of Energy's (DOE) recommendations for the preparation of EISs [(Environmental Impact Statements)] contain some of the most detailed explanations and guidelines for discussing human health impacts in an EIS. Although DOE's recommendations for analyzing human health effects are limited to exposure to radiation and chemicals, they also are relevant to pathogen exposures.

DOE provides detailed guidance for transportation analyses in *A Resource Handbook on DOE Transportation Risk Assessment* (DOE 2002). This guidance was written specifically for transportation of

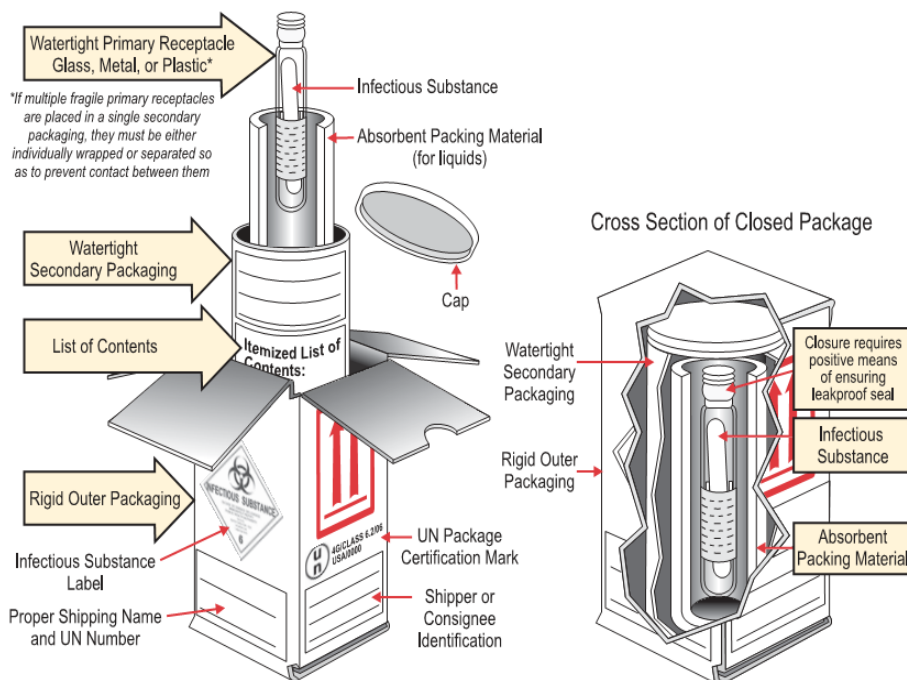

radioactive material, but the general methodology is applicable for any transportation analysis and was used to guide this analysis.

5.1.2 Packaging Requirements

U.S. Department of Transportation (DOT) Hazardous Material Regulations (49 CFR Parts 171-180) govern the transportation of infectious substances. The BSL-3 and BSL-4 pathogens addressed in this analysis are categorized as Class 6, Division 6.2 hazardous materials (i.e., biohazards) (49 CFR 173.134) subject to the Category A Infectious Substances packaging requirements in 49 CFR 173.196, *Category A infectious substances*. Category-A infectious substances must be triple-packed, which includes

- *A leakproof primary receptacle;*
- *A leakproof secondary packaging. If multiple fragile primary receptacles are placed in a single secondary packaging, they must be either wrapped individually or separated to prevent contact between them;*
- *A rigid outer packaging of adequate strength for its capacity, mass and intended use. The outer packaging must measure not less than 100 mm (3.9 inches) at its smallest overall external dimension. (49 CFR 173.196(a))*

An example of the triple-packaging required by 49 CFR 171.196 for infectious substance shipments is shown in Figure 5-1.

Note 1: The smallest external dimension of the outer packaging must not be less than 100 mm (3.9 inches)

Note 2: The primary receptacle or the secondary packaging must be capable of withstanding without leakage an internal pressure producing a pressure differential of not less than 95 kPa

Note 3: Follow package manufacturer's closure instructions

Figure 5-1: Example Packaging and Markings for Category-A Pathogens (DOT 2006)

DOT testing requirement for infectious substance packaging are provided in 49 CFR 178.609. Some of the requirements are dependent upon the materials of construction for the packaging. Assuming that the primary and secondary containers are constructed of plastic, which is expected to be the case for NEIDL, the requirements include the following:

- **Impact test:** Samples must be subjected to free-fall drops onto a rigid, non-resilient, flat, horizontal surface from a height of 9 m (30 ft) in various orientations with no leakage from the primary container. This drop test must be performed promptly after conditioning the container at -18°C (0°F).
- **Puncture test:** Samples must be subjected to steel rod puncture test with a 38 mm (1.5 in) diameter cylindrical steel rod. The mass for this test must be 7 kg (15 lb) or the mass of the sample, whichever is greater. The test must be conducted with a vertical free fall from a height of 1 m (3 ft). One sample must be placed on its base and a second sample must be placed in an orientation perpendicular to that used for the first. In each instance, the steel rod must be aimed to impact the primary receptacle(s). For a successful test, there must be no leakage from the primary receptacle(s) following each impact. (40 CFR 178.609)

5.1.3 Description of NEIDL Shipments

The likelihood and consequences of a transportation mishap are dependent upon the number of shipments, the packaging used, and other details of the shipments. This section describes the NEIDL shipments and identifies key assumptions for this analysis. The following assumptions have been accepted by NIH and Tetra Tech, based on information provided by BUMC (Murphy 2011).

While some shipments will be truck-only and others will be mixed mode (truck and air), all shipments will arrive at or depart from the NEIDL via trucks. While all NEIDL shipments must comply with the DOT regulations addressed in Section 5.1.2, BUMC imposes additional shipment requirements. The following sections provide descriptions that apply to all shipments, as well as those that are unique to truck and air portions of shipments.

Pathogen configuration: Bacteria may be shipped in a liquid, frozen, or solid form (e.g., agar in a tube). For this analysis, all bacteria are assumed to be shipped in a liquid suspension, such as a 10–15% glycerol (aqueous) at ambient temperature. The liquid form is assumed here for bacteria because this form is more vulnerable to release, which is a conservative assumption (i.e., tends to over-estimate the risk). If bacteria are shipped in solid form, the consequences of any packaging breach will be lower because a solid form (e.g., agar in a tube or frozen liquid) will have lower release fractions.

Viruses will be shipped in a tissue culture broth after harvesting and it is likely that they will be shipped in a frozen form. A frozen sample will have a lower release fraction than a liquid, so releases could be higher if viruses are shipped in liquid form. This analysis considers both the liquid and the frozen forms.

Specimen (e.g., blood, plasma, serum, tissue, urine, and respiratory secretions) shipments are not expected to be frequent but could occur. The specimens may be shipped in various forms, but are assumed to all be in a liquid suspension since that is the most releasable form.

Pathogen concentration: Bacteria and virus sample concentrations are expected to be comparable to the master/seed/working-stock concentrations identified in Appendix F, Section F.3.

If specimen shipments do occur, the pathogen concentrations will generally be less than or approximately the same as the seed stock concentrations; but in some cases the pathogen concentrations in specimens could exceed those in the seed stock by an order of magnitude.

Pathogens per shipment: A shipment may contain multiple strains of a pathogen and/or multiple infectious pathogens. All known strains of a pathogen could potentially be included in a single shipment.

Primary container: The DOT-compliant primary (inner-most) containers for sample shipments to and from NEIDL are assumed to be sealed, shatter-resistant 2-ml containers similar to the one shown in Figure 5-2. Experience at similar facilities confirms that 2-ml tubes are the typically used for shipments. This example container is made of polypropylene with an approximate length of 50 mm and a diameter of about 11 mm. This container has a screw cap, which will be reinforced with adhesive tape in accordance with 49 CFR 173.196(b)(1). Containers of this type are extremely robust and can withstand forces associated with accelerations of 20,000 g (g is the acceleration of gravity). (Sarstedt 2011)

Figure 5-2: Example Primary Container (Sarstedt 2011)

Secondary container: The DOT-compliant secondary container serves multiple functions: it contains absorbent material that will absorb all of the liquid potentially leaking from the primary container, provides a leak-proof secondary container, shields the primary container from external forces, and, when multiple primary containers are shipped in the same secondary container, includes a means of separating primary containers from each other. Either the primary or the secondary container must be capable of withstanding an internal pressure of at least 95 kPa (approximately 14 psi) without leaking. (10 CFR 173.196)

Tertiary container: The DOT-compliant rigid, tertiary packaging must be at least 100 mm (4 in) in its smallest external dimension. Substances shipped frozen must carry the refrigerant outside the secondary container. If dry ice is used to keep the infectious pathogen frozen, then the packaging must permit the release of carbon dioxide gas. (10 CFR 173.196).

Over-pack case: The DOT-compliant triple packaging will be placed in a “non-crushable,” liquid-tight, solid container for an added layer of safety (Murphy 2011). A Pelican™ 0370, 24” Cube Case, shown in Figure 5-3, meets these criteria and is used as the basis for this analysis. The case is watertight,

1 “crushproof,” and dust proof. The Pelican™ case has an open cell with an O-ring seal between the lid and
2 the base and is equipped with a pressure-equalization valve, so it is not air-tight with respect to internal
3 pressurization. The case has been independently tested for vibration, low temperature, dry heat, impact,
4 dust, and water immersion and has been found to meet various international specifications (Pelican 2011);
5 however, the crush-resistance of the case is not known, as discussed below. Use of the over-pack case is
6 above and beyond the requirements of 49 CFR, so any crush protection provided by the case is an
7 additional defense-in-depth layer of protection.

8
9 **Figure 5-3: Pelican™ Case**

10 Number of shipments: The number of shipments in any given year will vary throughout the course of the
11 facility’s lifetime; however, 50 shipments per year are expected on average. Of these shipments, the
12 majority (about 95%) of shipments will involve BSL-3 pathogens, the majority (about 90%) will involve
13 non-Select Agents, and the majority (about 90%) will be shipments to the NEIDL. Based on BUMC
14 policy, all shipments to or from locations in the USA are assumed to be made via truck transport. It is
15 assumed that the majority (i.e., 90%) will be truck-only shipments because of the commitment to use
16 trucks for shipments within the USA and Canada. Table 5-1 provides the assumed number of shipments
17 of each type. (Murphy 2011)

Table 5-1: Assumed Number of Annual Shipments by Transportation Mode

Mode of Transport	BSL-3 Pathogens	BSL-4 Pathogens	Total
Truck-only	42	3	45
Truck-Air	4	1	5
Total	46	4	50

All air segments of the shipments are assumed to be to/from Boston Logan International Airport for each of the three sites.

Truck carrier: Shipments will be made via carriers specializing in expedited, increased-security shipping services accustomed to handling Division 6.2, Category A hazardous materials. BUMC will require these carriers to provide exclusive-use vehicles (i.e., vehicles that do not contain cargo from any other shipper) (Murphy 2011). FedEx Custom Critical is one example of a carrier that may be used. The shipping agent (i.e., the shipper) would fully comply with all of the provisions of the federal and international regulations and requirements for transportation.

Vehicle: Shipments will be made via a “large truck” (Murphy 2011) with an enclosed cargo box. “Large trucks,” which are defined by DOT as trucks with a gross vehicle weight rating (GVWR) of greater than 10,000 lbs. Large trucks can either be single-unit or combination vehicles. A single-unit truck has the engine, cab, drive train, and cargo area on one chassis. A combination truck is a truck tractor pulling any number of trailers or a straight truck pulling at least one trailer. Because the NEIDL packages are small (approximately a 2-ft cube) and light (less than 100 lb), a single-unit truck would likely be used rather than a much larger combination truck. An example of a single-unit large truck includes trucks based on a Ford Super Duty 350/450/550/650/750/800 chassis (DOT 2010a).

Loading: The over-pack case would be secured to the middle of the truck bed away from the walls (Murphy 2011), thereby protecting it from impacts with the walls or from other vehicles that may impact the walls in a collision.

Global positioning system (GPS) tracking: Shippers must have the ability to provide GPS tracking of packages or vehicles as determined appropriate and approved by BUMC. In addition, the over-pack case will include a BU-monitored GPS tracking device (Murphy 2011). GPS tracking provides for detection of interruptions in transit, thereby enhancing the opportunity to support emergency response, including guidance to the responders.

Driver: Trained, professional drivers dedicated to these shipments will operate the cargo vehicles. Drivers will be HAZMAT trained.

Transfer to other BUMC facilities: Transfer of infectious BSL-3 pathogens between the NEIDL and other BUMC facilities will be performed with the same triple-packaging and over-pack case requirements imposed on external shipments; however, BUMC courier services may be used rather than commercial carriers. There are no other BSL-4 facilities at BUMC, so there can be no transfers of BSL-4 pathogens to other BUMC facilities.

5.1.4 Department of the Army Packaging Testing

Triple-packaged containers similar to those required for all Category A pathogen shipments were tested by the Department of the Army in the 1960s (DOA 1969). The tests were conducted to support development of packaging regulations and consisted of a series of drops from heights of 500 and 1,000 feet with varying packaging configurations including glass and plastic bottles. These drop heights (i.e., 500 and 1,000 ft) are well beyond the 30-ft (9-m) drop test requirements for triple-packaging (49 CFR 178.609). The bottles were over-packed in two outer containers (metal and fiberboard) with either cotton or vermiculite as packaging between the containers. The packages were dropped onto soil, concrete, and macadam surfaces. The purpose of the tests was to determine which packaging configurations could survive such drops. Despite the extreme test conditions, half of the packaging configurations did not leak after the 500-ft drop and a third did not leak after the 1,000-ft drop. In addition, the Department of the Army report states that “containers similar to those tested in May 1961 later withstood the crash of a C-119 aircraft at 138 miles per hour” into a concrete wall. (DOA 1969)

The packages tested by the DOA differ in several important respects from the packages used for shipping pathogens to NEIDL. The effects of these differences are discussed below:

The primary container volumes in the DOA tests ranged from 450 ml to 1,300 ml, while the NEIDL primary containers are expected to be 2-ml tubes. The 2-ml tubes have much less mass, so the impact loads would be much smaller than those used in the DOA tests. In addition to the lower impact loads, the 2-ml containers will tend to have greater strength-to-weight ratio.

The plastic primary containers in the DOA tests were made of polyethylene while the containers expected to be used for NEIDL are made of polypropylene. Polyethylene is softer and not as strong as polypropylene, so the NEIDL containers are less likely to eject caps or breach. Also, the caps are required to be sealed with adhesive tape.

The DOA tests did not include the over-pack case, which is required for infectious BSL-3 and BSL-4 pathogen shipments to or from NEIDL (Murphy 2011). The shell and foam liner of the case would absorb and distribute much of the impact loads.

Based on the partial survival of the DOA packages, the NEIDL packaging (a 2-ml vial triple packaged plus the over-pack case) are expected to survive both the 500-ft and 1,000-ft DOA drop tests, as well as the aircraft crash test, without leakage from the primary container.

5.1.5 Hypothetical Accident Conditions

Triple packaging must pass the requirement of 49 CFR 173.196, Section G.1.2; however, this does not ensure that the packaging will survive all potential accident conditions. The requirements for testing of Type B radioactive material shipping containers are provided in 10 CFR 71.73 and are intended to simulate hypothetical accident conditions. These tests go beyond the requirements of 49 CFR 173.196. While the NEIDL packaging is not required to comply with them, the requirements of 10 CFR 71.73 do provide insight into the type of severe hypothetical conditions that may occur and their potential to breach the packaging. These tests include consideration of fire, impact loads, puncture, and crush loads on the package. The following paragraphs identify the 10 CFR 71.73 testing requirements and discuss expected performance of NEIDL packages for each test to provide some insights into the survivability of the NEIDL packaging.

Free drop: This test consists of a free drop of the package from a height of 9 m (30 ft) onto a flat, essentially unyielding, horizontal surface striking in an orientation that is expected to produce the maximum damage. This test addresses the survivability of the package for the hypothetical impact loads. This 10 CFR 71.71 requirement is equivalent to the requirement for packaging of infectious substances (i.e., 49 CFR 173.196), as discussed in Section 1.2. The over-pack case may or may not be damaged in the test, but the case will distribute and absorb much of the impact load. The NEIDL packaging is expected to pass this test because the triple-packaging must pass the equivalent 49 CFR 173.196 test and the over-pack case will likely enhance its ability to withstand the free drop.

Crush: This test consists of the drop of a 500-kg (1,100-lb) plate that has a cross section of 1 m (40 in) by 1 m (40 in) from a height of 9 m (30 ft) onto the package. This test is not required for all radioactive material packages but would be required for containers that are the size of the NEIDL package. The over-pack case is unlikely to survive this test without extensive damage. The survivability of the primary container depends upon the amount of dynamic energy absorbed by the over-pack case and the extent to which the case distributes the load. The static load resulting from this test would average less than 1

pound per square inch, which is not likely to breach the primary container. While the survival of the primary container from the dynamic loading of this test is unknown, any aerosol or liquid release is unlikely because the over-pack foam liner would compress around the inner packaging and prevent any leakage. Therefore, the NEIDL packaging may be breached, but any release would be unlikely.

Puncture: This test consists of the free drop of a package 1 m (40 in) in the position of maximum expected damage onto the upper end of a 15-cm (6-in) diameter bar. The size of the bar is smaller in the 49 CFR 178.609 test, so the triple packaging is expected to survive this test. The over-pack case may or may not survive this test.

Thermal: This test consists of a fully engulfing fire with a flame temperature of at least 800°C (1,475°F) for 30 minutes. The NEIDL packaging would not withstand this test; however, this test is not relevant for infectious pathogen shipments because the pathogens would be inactivated at temperatures much lower than these. Thus, the public nor the environment would be at risk to infectious pathogens. In addition, the plastic over-pack case and its foam lining would likely melt and encapsulate the primary container.

Immersion: The package must be subjected to water pressures of 150 kPa (21.7 lb/in²) gauge, which is equivalent to immersion in 15 m (50 ft) of water. 49 CFR 173.196 requires a test for water spray that simulates rainfall, but does not require a similar test for packaging of infectious substances. The primary or secondary container is required to withstand an internal pressure of 95 kPa (approximately 14 psi), which is about 60% of this criterion. The 2-ml primary containers are expected to survive this test based on their ability to withstand 20,000 g of acceleration (see Section G.1.3.1).

Based upon the 10 CFR 71.73 criteria for severe hypothetical accident conditions, free drop, puncture, immersion, and thermal conditions are of minimal concern for NEIDL package survival. The greatest concern for the primary container is a crushing load (e.g., the truck rolls over onto the package). However, the foam lining of the over-pack case would confine any release from a pure crushing load. Therefore, the only postulated loads that can result in a significant release are a series of loads that first eject the triple-package from the over-pack case and then crush the triple packaging.

5.2 Methodology

Truck and aircraft crash rates were necessary inputs for this analysis. The following sections identify the truck and aircraft crash data sources used for this analysis and provide the basis for their selection. The population for which impacts were considered is also described.

5.2.1 Truck-Crash Data

Crash rates for large trucks have been declining significantly over the past two decades. Figure 5-4 shows the injury and fatality rates for single unit large trucks over the past two decades. Over that period, the injury rate has decreased by 60%, and the fatality rate has decreased by 40% (DOT 2010); therefore, use of older crash data (e.g., the data provided in the DOE transportation analysis guide) would overstate the risk. The most recent report that contains data on injuries and fatalities related to large trucks is the *Large Truck and Bus Crash Facts – 2008*, published by the U.S. Department of Transportation, Federal Motor Carrier Safety Administration (DOT 2010), and is used as the basis for this analysis. While the 2008 data are the most recent detailed dataset, an overview of the 2009 data shows the trend of decreasing accident rates has continued with an 18% decrease in injury rate and a 20% decrease in fatality rate from 2008 to 2009 (DOT 2011). Therefore, use of the most recent detailed dataset (i.e., the 2008 data) is appropriate and is expected to be slightly conservative for future NEIDL shipments.

Figure 5-4: Historic Injury and Fatality Rates (DOT 2011, Table 14 and 17)

In addition to containing the most recent detailed data, *Large Truck and Bus Crash Facts – 2008* was selected because it consolidates the results of four databases into a single document and provides a data quality review function on the data from the various sources.

5.2.2 Aircraft-Crash Data

The guidance provided in *Accident Analysis for Aircraft Crash into Hazardous Facilities*, DOE STD 3014-2006 (DOE 2006) is used as the basis for this analysis of aircraft crash. Infectious pathogens are assumed to be transported via certified commercial air carrier (i.e., a plane with 30 seats or more or a maximum payload of 3,401 kg [7,500 lb] or more).

5.2.3 Population

This analysis addresses the impacts on the population within 10 km of the three sites being evaluated (urban, suburban, and rural). This 10 km distance is consistent with the distance used for the environmental justice analysis (see Chapter 10) and is greater than the distance recommended by the U.S. Nuclear Regulatory Commission to define the vicinity of a site for environmental justice purposes (Nuclear Regulatory Commission 2003). The population within 10 km is reported in Appendix F, Section F.4.

5.3 Results

Consistent with the recommendations of the DOE transportation analysis guidance (DOE 2002), this section estimates both the crash-related risks (e.g., injuries and fatalities from directly resulting from the crash) and the pathogen-related risks (potential exposure from released pathogens) of NEIDL shipments. Additionally, the analysis estimates the pathogen-related risks of potential crashes of aircraft carrying NEIDL shipments.

5.3.1 Crash-Related Risks

The following sections address the crash-related risk to members of the public near each of the three sites from the truck portion of shipments, specifically injuries and fatalities that result directly from the potential crashes.

5.3.1.1 Crash-Related Injuries

The 2008 injury rate for single-unit large trucks is 46.9 injuries per 100 million vehicle miles traveled (2.91×10^{-7} fatalities per km) (DOT 2010). The distance traveled within 10 km of the facility is assumed to be 20 km per shipment because the truck must travel both to and from the facility. Table 5-2 provides the estimate for the frequency and period for injuries associated with BSL-3 and BSL-4 shipments. Crash-related injuries include those involving occupants of the other vehicle, non-occupant members of the public, and occupants of the truck.

Table 5-2: Estimate of Crash Injuries within 10 km of the Facility Due to NEIDL Truck Shipments

Parameter	BSL-3 Shipments	BSL-4 Shipments
Shipments per year ^a	46	4
Distance traveled (km/yr) ^b	920	80
Injury rate (injuries/km) ^c	2.91×10^{-7}	2.91×10^{-7}
Frequency of injuries (injuries/yr) ^d	2.7×10^{-4}	2.3×10^{-5}
Period (yrs) between injuries ^e	3,700	43,000

^a The number of shipments are based on Section 5.1.

^b Distance traveled within 10 km of the facility is assumed to be 20 km to account for arrival and departure.

^c Source: 2008 value from Table 17 of DOT 2010 (converted to km).

^d The average frequency equals the distance traveled times the injury rate.

^e The average period between injuries is the reciprocal of the average frequency of injuries.

5.3.1.2 Crash-Related Fatalities

The 2008 fatality rate for single-unit large trucks is 1.38 fatalities per 100 million vehicle miles traveled (8.57×10^{-9} fatalities per km) (DOT 2010). Similar to crash-related injuries (above), the distance traveled within 10 km of the facility is assumed to be 20 km per shipment because the truck must travel both to and from the facility. Table 5-3 provides the estimate for the frequency and period between fatalities for BSL-3 and BSL-4 shipments. Crash-related fatalities include those involving occupants of the other vehicle, non-occupant members of the public, and occupants of the truck.

Table 5-3: Estimate of Crash Fatalities within 10 km Due to NEIDL Truck Shipments

Parameter	BSL-3 Shipments	BSL-4 Shipments
Shipments per year ^a	46	4
Distance traveled (km/yr) ^b	920	80
Fatality rate (fatalities/km) ^c	8.57×10^{-9}	8.57×10^{-9}
Frequency of fatalities (fatalities/yr) ^d	7.9×10^{-6}	6.9×10^{-7}
Period (yrs) between fatalities ^e	130,000	1,500,000

^a The number of shipments are based on Section 5.1.

^b Distance traveled within 10 km of the facility is assumed to be 20 km to account for arrival and departure.

^c Source: 2008 value from Table 14 of DOT 2010 (converted to km).

^d The average frequency equals the distance traveled times the fatality rate.

^e The average period between fatalities is the reciprocal of the average frequency of fatalities.

5.3.2 Likelihood of Pathogen Release for Truck Transport

This section estimates the pathogen-related risk to the public associated with NEIDL shipments. The section begins with the consideration of various event types and then estimates the frequency and consequence of such events.

5.3.2.1 Events Considered

Multiple preventive and mitigative biocontainment features protect the shipper and the public from potential release of infectious pathogens during transport (see Section 5.1.3); however, there are also

multiple mechanisms for compromise of one or more of these features. The DOE transportation analysis guidance (DOE 2002) focuses solely on vehicle crashes and does not address non-crash releases. For completeness, this section considers both crash and non-crash pathogen releases. The non-crash events may either be initiated by actions prior to transport (e.g., placing dry ice inside a sealed container) or during transport. Therefore, this section addresses events that can occur prior to transport, non-crash events during transport, and crash events. The discussion applies intra-campus shipments (i.e., between the NEIDL and another BUMC laboratory) with the exception that BUMC vehicles would be used rather than a commercial carrier.

Pathogen Shipping Experience

Two potential pathogen release incidents during shipping are identified in Appendix D. In one incident, a shipment included two vials with no caps and a third vial with a loose cap. This incident resulted in possible laboratory worker exposures. In the other incident, a container burst due to improper packaging of dry ice. One or more shipping employees were potentially exposed, but the risk of infection was characterized as low.

5.3.2.1.1 Release Due to Events Prior to Transport

Two types of events— errors in the preparation of the package for shipment and errors in the loading of the package into the truck—are considered below:

Package Preparation Errors

Events prior to transport (e.g., in the preparation of samples for shipment) may result in the compromise of one or more of the biocontainment features. The following paragraphs discuss events that have the potential to compromise each of the biocontainment features. Most of these events only have the potential for a liquid release and have limited potential for a significant aerosol release. It should be noted that many of the shipments will originate at other laboratories and it may be difficult for BUMC to control the procedures and training used by those laboratories; however, all shippers must comply with the packaging requirements of DOT.

Primary container: The innermost container could fail to provide containment as a result of either personnel error or a faulty container. Personnel could fail to place caps on all vials, to appropriately tighten the cap (either under or over tightening), to appropriately tape the cap, or to use the correct cap (e.g., use a cap with a different thread pitch). Procedures and personnel training at the shipping laboratory have the potential to reduce the likelihood of such failures. A faulty container (e.g., cracked container or leaky cap) could also cause a leak.

Absorbent material: For liquids, absorbent material sufficient to absorb the entire volume of liquid must be placed between the primary and secondary containers (10 CFR 173.196). In the event of a leak from

1 the primary container, this absorbent material should absorb the leakage and limit any release. Personnel
2 could fail to place any absorbent or a sufficient absorbent into the secondary container. Additionally, even
3 if sufficient absorbent is present, a pool of liquid could accumulate at the bottom of the secondary
4 container; however, such a pool of liquid would be contained by the secondary container.

5 Secondary container: The leak-proof secondary container could fail to provide containment as a result of
6 either personnel error or a faulty container. Personnel could fail to install the cap, use the wrong cap (e.g.,
7 one with a different thread pitch), or fail to appropriately tighten the cap (either under or over tightening).
8 Procedures and personnel training at the shipping facility will reduce the likelihood of such failures. A
9 faulty container (e.g., cracked container or leaky cap) could also cause a leak.

10 When frozen samples are shipped, they are typically kept frozen with dry ice, which is required to be
11 positioned outside the secondary container (49 CFR 173.196). If dry ice is inadvertently placed inside the
12 sealed secondary container, the secondary container will become pressurized as the dry ice sublimates,
13 leading to over-pressurization and breach of the container. Over-pressurization is not credible for intra-
14 campus shipments because of the short time periods involved. This pressurization is also unlikely to
15 breach the primary container, which is expected to be able to withstand higher pressures because (1) the
16 secondary container would experience tensile stresses while the primary container would experience
17 compressive stresses and the compressive strength of plastics is generally greater than the tensile strength,
18 and (2) the surface area of the primary container is much less so the forces are much smaller on the
19 primary container.

20 Over-pack foam lining: The containment features of the over-pack case include the foam lining and the
21 watertight shell. The open-cell foam core can absorb many times more liquid than the liquid volume
22 contained within the triple-packaging. In addition, the foam would provide a degree of “filtration” for any
23 aerosol released. The foam would continue to perform these absorbing and “filtration” roles even if worn
24 or damaged by normal use.

25 Over-pack shell: The plastic shell of the over-pack case has a liquid-tight molded bottom that contains
26 any liquids not absorbed by the foam lining. The O-ring sealed lid would impede any liquid or aerosol
27 release, but the case is not air-tight for internal pressurization because of the pressure equalization valve.

28 Summary: Multiple personnel errors and/or equipment failures prior to shipment would be required for a
29 liquid or aerosol release due to a failure of the primary container, secondary container, over-pack foam
30 core, and over-pack shell. While potential human errors or equipment defects/failures can fail each of
31 these barriers, no common-causes (i.e., single events that fail multiple barriers) prior to shipment were

identified. No published data exists on which to base an estimate of frequency of a release due to events prior to transport (one incident is identified in the text box of Section 5.3.2.1, but the number of shipments is not known); nevertheless, a release caused by such events is highly unlikely. Furthermore, events of this type are very low energy events, including the over-pressuring of the secondary container, so there is a high likelihood that the over-pack case would confine any release. Therefore, this type of event is dismissed from further consideration.

Package Loading Errors

A NEIDL package could be breached prior to transport if it is inadvertently left on the driveway and the truck drives over it. In order for this event to occur, several failures and conditions must exist:

The requirement to secure the over-pack case to the middle of the bed must be violated in order for the NEIDL package to be left in the path of the truck.

1. The driver and the laboratory personnel must overlook the hazard. The large over-pack case (approximately a 2-foot cube) is less likely to be overlooked than the triple-packaging, which is only required to be larger than 100 mm (4 in).
2. The NEIDL over-pack case is (approximately a 2-foot cube) would tend to slide because the case is probably higher than the middle of the tire; however, it is possible that an obstruction would prevent the case from sliding and allow it to be crushed.

The driver would need to fail to be alerted by the sound of the case either scooting on the pavement or beginning to be crushed and stop the vehicle.

No data have estimated the frequency of this event, which is highly dependent upon a failure to implement the NEIDL protocol for securing the case to the middle of the truck bed. However, in the event that all of these failures and conditions occurred and the primary container is breached, then the multiple layers of packaging, especially the foam lining, would confine any release. Therefore, this scenario is not considered further.

5.3.2.1.2 Package Drops from the Truck during Transport

A package could topple from the truck onto the roadway and be crushed by another vehicle. In order for this event to occur, the following sequence of events must transpire:

- Shipper fails to secure the NEIDL package in the middle of the vehicle: Though required by BUMC procedures (see Section 5.1.3.2), personnel could neglect to secure the package properly.

- 1 • Shipper fails to close the cargo door on the truck: An unsecured package cannot topple from the
2 cargo bed unless the cargo door is open. It is possible that the driver neglects to properly close the
3 cargo door, which may then fully open in transit.
- 4 • Package drops from the truck: An unsecured package in a cargo bed with an open door would not
5 necessarily drop from the truck. Severe braking might exert enough force on the package to cause
6 it to slide, but it would slide to the front of the bed rather than to the back. However, bumps in the
7 roadway could cause an unsecured package to bounce to the rear of the bed and fall from the
8 truck if the cargo door is open.
- 9 • Another vehicle crushes the package: If a NEIDL package falls onto the highway, the over-pack
10 case will absorb most of the dynamic energy and the tippable-packaging is expected to remain
11 intact. However, if the package is struck by another vehicle, the NEIDL package could be
12 crushed. Because of its size (a 2-ft cube), the package would likely be noticed and evasive action
13 would be attempted by other vehicles, but they may not be successful. If an automobile were to
14 strike the 24-in over-pack case, the over-pack case might be deflected out of the pathway rather
15 than being crushed (automobile bumpers are typically 16–20 in from the highway). A large truck
16 bumper would not necessarily deflect the over-pack case and the case could be crushed. The GPS
17 tracking ensures that the package is not left on or beside the roadway for prolonged time periods.

18 This scenario requires multiple personnel errors (failure to secure and failure to close the cargo door) and
19 chance events (toppling from the truck and being crushed). This scenario is unlikely because it requires a
20 series of unrelated events and these events are not likely to occur within 10 km radius of the laboratory.
21 This scenario is not considered further.

22 **5.3.2.1.3 Crash Events During Transport**

23 The term “crash” is used by the National Highway Traffic Safety Administration (NHTSA) to include
24 both collision and non-collision events. Collision events include those involving a motor vehicle and
25 fixed objects (poles, walls, barriers, bridge supports, etc.) and those involving a motor vehicle and non-
26 fixed objects (pedestrians, animals, pedal cyclists, other motor vehicles, etc). Non-collision events include
27 a single vehicle that catches fire, a single vehicle that runs off the roadway and is immersed in water,
28 injuries due to shifting cargo, and damages due to pavement irregularities. (DOT 2010a)

29 Crash events are analyzed here because (1) they are foreseeable, highly energetic events capable of failing
30 all biocontainment barriers concurrently with the potential of causing an aerosol release of a pathogen; (2)

the DOE transportation analysis guidance (DOE 2002) recommends that they be analyzed; and (3) estimates of their frequency can be made because of the availability of truck-crash data.

5.3.2.2 Frequency of Releases Due to Truck Crashes

The DOE transportation analysis guidance (DOE 2002) provides severity categories for truck accidents involving radioactive materials, as well as the fraction of occurrences for each severity category. Unfortunately, those severity categories were developed for the massive casks used to transport radioactive materials and are not applicable to the low-mass, energy absorbing NEIDL packages. Therefore, alternate approaches were used to relate the crash severity to package failure. The frequency for pathogen release events was estimated based on two approaches: (1) crashes that involve an occupant fatality since the NEIDL packages are far more robust than a human, and (2) identification of the types of crashes that are most likely to involve crushing forces capable of breaching all layers of packaging. Though not directly relevant to NEIDL shipments, data on the frequency of Class 6 hazardous material releases during crashes is also presented to provide a frame of reference.

5.3.2.2.1 Frequency Based on Occupant-Fatal Crashes

The primary containers have a high strength-to-weight ratio and are surrounded with energy absorbing and liquid absorbing material. As discussed in Section 5.1.5, only severe truck crashes involving crushing forces have the potential to breach the packaging. There are no analytical or test estimates of the forces necessary to breach the NEIDL packaging nor are there data on the fraction of crashes that involve such forces, so the likelihood of a NEIDL package breach from a crash cannot be estimated directly. However, the packaging is clearly able to survive forces more severe than the human occupants can survive. Therefore, this analysis uses occupant-fatal (i.e., an occupant of the truck), single-unit, large truck crashes as a means of estimating the rate of NEIDL package breach and pathogen release. Crashes that are fatal to occupants of the other vehicle or to non-occupants do not provide any indication of the forces that would be exerted on the NEIDL package and are not considered in this calculation.

The occupant-fatal, single-unit, large truck crash rate is 2.44×10^{-9} /mile (205 occupant fatalities in 83.9 billion miles) or 1.52×10^{-9} /km, which is the rate used for this analysis (DOT 2010). Table 5-4 provides the frequency calculation for occupant-fatal crashes. The NEIDL package is able to withstand much greater forces than the occupant, so the pathogen release frequency is expected to be less than this frequency.

Table 5-4: Estimate of the Frequency of Pathogen Releases within 10 km Based on Occupant-Fatal, Single-Unit, Large Truck Crashes

Parameter	BSL-3	BSL-4
Occupant-fatal crash rate for single-unit trucks (/km) ^a	1.52×10^{-9}	1.52×10^{-9}
Annual truck shipments (/yr) ^b	46	4
Distance per shipment (km) ^c	10	10
Total distance per year (km/yr) ^d	460	40
Frequency (/yr) of pathogen release events ^e	7.0×10^{-7}	6.1×10^{-8}
Period (yrs) between pathogen release events ^f	1.4×10^6	1.6×10^7

^a Source: Table 17, DOT 2010.

^b The number of shipments per year are based on Section 5.1.

^c Distance traveled per shipment is assumed to be 10 km per within the 10 km radius.

^d Total distance per year is the product of the number of shipments per year times the distance per shipment.

^e The frequency equals the distance traveled times the occupant-fatal crash rate.

^f The period between events is the reciprocal of the frequency.

5.3.2.2.2 Frequency Based on the Types of Occupant-Fatal Crash

Impact loads due to collisions with other vehicles and objects may result in fatalities and severe damage to the vehicle but are unlikely to breach the primary container secured in the over-pack case secured in the middle of the bed (see Section 5.1.5). Therefore, crashes that have the potential to involve large crushing loads are considered the most likely crashes to breach the NEIDL packaging. A review of the most harmful event characteristics of truck accidents (Table 53, DOT 2010) identified only two categories of accidents that are judged to have the potential to result in the types of crushing forces necessary to breach all layers of packaging: namely, (1) overturns (rollover) and (2) collisions involving trains. Events that were dismissed include collisions (with vehicles in transport, fixed objects, pedestrians, pedal-cycles, other objects and animals), jackknives, and fire/explosions. Severe rollovers could fail the truck's cargo box, crush the NEIDL packaging, and eject the triple-package from the over-pack case, which leaves the primary container vulnerable to further crushing. Train collisions also have the potential to breach the NEIDL package because they can involve multiple severe crushing and shear forces. Rollover and train collision crashes are addressed below.

Rate of rollovers: Rollovers are defined by DOT as any rotation of 90° or more (DOT 2010a). The fraction of fatal, large-truck crashes in which rollover is the most harmful event is 7.0% (Table 53, DOT 2010); however, this value is likely to overstate the number of rollovers that have the potential to breach the NEIDL packaging for the following reasons:

This 7% includes 90° rollovers, which are likely to be a large percentage of the rollovers. A 90° rollover does not have the potential to crush the NEIDL package (a 180° rollover is required to crush the package). Therefore, 7% is a conservative value for the fraction of crashes that can breach all layers of the packaging.

1 This value reflects all large trucks, both single-unit and combination trucks. Compared to single-unit
2 trucks, combination trucks tend to have a higher center of gravity, which is a prime factor in rollovers. In
3 addition, the absence of any significant cargo load in the NEIDL shipments also creates a lower center of
4 gravity. Therefore, this factor would tend to make the 7% factor conservative for a single-unit large truck
5 with a very light load.

6 This value reflects all fatalities (truck occupant and as well as other vehicle occupants and non-
7 occupants). It is not known whether the more severe truck damage crashes (i.e., those involving a truck-
8 occupant fatality) would tend to have a higher or lower fraction of rollovers than all fatal large truck
9 crashes. Rollover is the most harmful event in 9.8% of injury crashes and 1.3% of the property-damage-
10 only crashes (DOT 2010). If this factor is non-conservative, the conservatism of the previous two factors
11 is judged to more than compensate.

12 Based upon the above rationale, the 7% rollover fraction was used for this analysis as the approximate
13 rate of greater than 90° rollovers for single-unit large trucks in severe crashes where an occupant of the
14 truck is killed.

15 *Rate of train collisions:* A collision with a train is the most harmful event for 0.3% of all fatal, large-truck
16 crashes. As with the rollover rate, the train collision rate is not directly applicable for this analysis for the
17 following reasons:

18 The “cattle catcher” at the front of the train would tend to prevent a truck from being pulled under the
19 train and crushed. The impact loads may be fatal to the occupant and severely damage the truck, but the
20 crash is unlikely to compromise the packaging. From this perspective, the 0.3% value is likely a
21 conservative value.

22 The driver of a vehicle may exit before the collision, so crashes that are non-fatal may still have the
23 potential of breaching the packaging. The train collision rate for injury crashes and property-damage-only
24 crashes are 0.2% and 0.1%, respectively (DOT 2010).

25 The 0.3% value reflects both single-unit and combination trucks collisions. It is assumed that the rates are
26 not significantly different for single-unit and combination large trucks.

27 Based upon the above rationale, the 0.3% fraction was used for this analysis as the approximate rate of
28 collisions with a train for single-unit large trucks in severe crashes where an occupant of the truck is
29 killed.

As discussed above, it is expected that, on average, crashes that have the potential to breach all packaging will also result in a truck occupant fatality and that the loads that have the greatest potential to breach the packaging are crushing loads, such as those associated with rollovers or train collisions. The crash rate for truck occupant fatalities is $1.52 \times 10^{-9}/\text{km}$ (see Section 5.3.2.2.1). The discussion above shows the fraction of fatal crashes that involve rollover is 7.0% and the fraction that involves train collisions is 0.3%. The most likely crashes to breach the NEIDL package are occupant-fatal truck crashes where the most harmful events are rollovers or train collisions, and the frequency of a pathogen release is estimated in Table 5-5.

Table 5-5: Estimate of the Frequency of Pathogen Release Crashes within 10 km Due to Occupant-Fatal Rollover and Train Collision Crashes for NEIDL Shipments

Parameter	BSL-3	BSL-4
Frequency of occupant-fatal crashes (/yr) (from Table 5-4)	7.0×10^{-7}	6.1×10^{-8}
Period (yrs) between occupant-fatal crashes (from Table 5-4)	1.4×10^6	1.6×10^7
Fraction of crashes that involve rollover or train collision ^a	7.3%	7.3%
Frequency of pathogen release events (/yr)^b	5.1×10^{-8}	4.4×10^{-9}
Period (yrs) between pathogen release event^c	2.0×10^7	2.3×10^8

^a Source: Table 53, DOT 2010.

^b Value is 7.3% of the frequency of occupant-fatal crashes.

^c The period between events is the reciprocal of the frequency of pathogen release events.

5.3.2.2.3 Comparison with Historic Release Data

The DOT report (DOT 2010) contains data on truck crashes, including data on the number of hazardous material releases that have occurred as a result. However, those data are not directly relevant for NEIDL shipments for the following reasons:

- The data include all Class 6 hazardous materials: The DOT data are presented for “poisonous and infectious substance,” effectively Class 6 hazardous materials as defined by 49 CFR 173. Class 6 hazardous materials include Division 6.1 (poisonous materials) and Division 6.2 (infectious materials). Division 6.1 includes chemicals transported in relatively large quantities (e.g., acids and gasoline additives) with different packaging requirements than Division 6.2 materials. Because larger containers routinely have a lower strength-to-weight ratio than smaller containers, Division 6.1 materials are likely to be more vulnerable to release than Division 6.2 materials in crashes. In addition, the NEIDL shipments evaluated are Division 6.2, Category A materials, which have more stringent packaging requirements than Division 6.2, Category B materials. Because the Division 6.2, Category A shipments materials have more robust packaging than the other Class 6 materials, they are less likely to involve releases as a result of crashes and, therefore, these data are likely to overestimate the frequency for release crashes.

2. Unique NEIDL shipment requirements: NEIDL shipments are likely to have lower frequencies of releases because the BUMC shipping requirements (see Section 5.1.3) go well beyond those required for Division 6.2, Category A shipments. The additional requirements for NEIDL shipments includes the following:

The required over-pack case protects the triple-package from impact loads.

The requirement that the over-pack case be secured to the middle of the truck bed reduces the chance that the package is ejected from the vehicle and crushed.

The exclusive-use vehicles eliminate the potential for other cargo to topple onto and crush the NEIDL package.

As a result, NEIDL shipments are expected to have a much lower rate of releases from crashes than other Division 6.2, Category A shipments.

Therefore, the average rate for crashes resulting in release of Class 6 hazardous material is expected to be greater than the rate for NEIDL shipments and the conservatism is judged to be in excess of an order of magnitude.

As stated previously, humans are more vulnerable in a crash than the NEIDL package, so the rate of fatal occupant crashes is considered to be an upper bound on the rate of release-causing crashes for NEIDL shipments. DOT reports that in 2008, one fatal crash (fatality in either vehicle) involving “poisonous and infectious substances” (i.e., Class 6 hazardous materials) occurred and did not result in a release (DOT 2010). DOT also reports that there were 11 nonfatal crashes involving “poisonous and infectious substances” (i.e., Class 6 hazardous materials) where the outcome is known, and there was a release in only one of those crashes (DOT 2010). The DOT data on Class 6 hazardous material releases provide only limited insight into the rate of release from NEIDL packages; however, the DOT data do support the expectation that NEIDL packages are likely to survive crashes that do not involve truck-occupant fatalities since the less robust Class 6 packaging survived in 11 of the 12 non-fatal crashes and the one fatal crash.

5.3.3 Likelihood of Pathogen Release from Air Transport

As discussed in Section 5.1.3, pathogen shipments may include air transport. Because BUMC policy requires ground transport for shipments to/from locations in the USA and Canada (Murphy 2011), any air transport would be to or from foreign locations. Foreign shipments are likely to be made through the

1 Boston Logan International Airport for all three sites being evaluated. If an aircraft carrying a NEIDL
2 pathogen crashes on takeoff or landing, there is a potential for a release and this analysis estimates the
3 likelihood of such an event. The potential for a NEIDL package being dropped from the aircraft during
4 takeoff or landing is not considered because the packaging is expected to survive such drops (see Section
5 5.1.4).

6 The guidance provided in *Accident Analysis for Aircraft Crash into Hazardous Facilities*, DOE STD
7 3014-2006 (DOE 2006) is used as the basis for the rate of aircraft crashes on takeoff and landing. The
8 infectious pathogen is assumed to be transported via a certified commercial air carrier (i.e., a plane with
9 30 seats or more or a maximum payload of 3,401 kg [7,500 lb] or more). The crash rate for certified
10 commercial air carrier is 1.9×10^{-7} for takeoffs and 2.8×10^{-7} for landings. The crash rate for these
11 specific aircraft while in flight over the rural and suburban sites much lower and are not addressed. (DOE
12 2006)

13 An aircraft crash does not necessarily result in an infectious pathogen release. Based on the Army tests
14 results discussed in Section 5.1.4, the NEIDL package is expected to survive drops from both 500-ft and
15 1,000-ft, as well as an aircraft crash into a concrete wall without leakage from the primary container (see
16 Section 5.1.4). While the NEIDL packages themselves have not been tested for aircraft crash survival, it
17 is conservatively judged that the conditional probability of pathogen leakage given an aircraft crash is less
18 than 10% because: (1) packaging used in the 1960s tests survived a plane crash into a concrete wall; (2)
19 the triple-packaging used for NEIDL shipments will be more robust than the packaging used in the 1960s
20 test (the 2-mL vials are much more resistant to breaching); and (3) the over-pack case for NEIDL
21 shipments protects the triple-packaging from impacts. Table 5-6 provides the estimated likelihood of a
22 pathogen release due to an aircraft crash.

Table 5-6: Estimate of the Likelihood of a Pathogen Release from the Takeoff or Landing Crash of Aircraft Carrying a NEIDL Pathogen

Parameter	BSL-3	BSL-4
Crash rate for commercial aviation - air carrier (takeoff) ^a	1.9×10^{-7}	1.9×10^{-7}
Crash rate for commercial aviation - air carrier (landing) ^a	2.8×10^{-7}	2.8×10^{-7}
Number of takeoffs per year ^b	2	0
Number of landings per year ^b	2	1
Conditional probability of release given a crash	0.1	0.1
Frequency of pathogen release events (/yr)^c	9.4×10^{-8}	2.8×10^{-8}
Period (yrs) between pathogen release event^d	1.1×10^7	3.6×10^7

^a Source: Table B-1, page B-3, of DOE STD 3014-2006 (DOE 2006).

^b From Table 5-1 in Section 5.1.

^c The frequency of pathogen release is the sum of the crash rate times the number of events for takeoff and landing crashes, times the conditional probability of a release given a crash.

^d The period is the reciprocal of the frequency.

5.3.4 Consequences of a Potential Pathogen Release

If an infectious pathogen release were to occur, the public or responders at the scene of the truck or aircraft crash could be exposed to the release. The DOE transportation analysis guidance (DOE 2002) recommends use of a “sliding scale” where “the preparer should analyze issues and impacts with the amount of detail that is commensurate with their importance.” The frequency of a pathogen release from either truck or air transport is very low (i.e., less than 1 in 1 million years), so per the guidance, detailed consequence analyses are not warranted. Consistent with this guidance, detailed analyses of exposures in close proximity were not performed, but a qualitative analysis is provided.

The maximum reasonably foreseeable release earthquake estimated the average exposures to each of the 13 pathogens evaluated for a person 30 m from a ground-level release (see Appendix F, Section F.8.3.4). Exposures to people 30 m or more from the point of a transportation release can be approximated by scaling the earthquake results on the basis of the smaller volumes associated with transportation. It is reasonable to use the maximum reasonably foreseeable release earthquake exposure calculations because they (1) are based on meteorological and terrain conditions appropriate for each of the three sites; (2) did not include any mitigative features; and (3) were based on a ground-level release, which would be consistent with a truck or aircraft crash. While reasonable, this scaling approach is likely to be conservative (i.e., overestimate the exposures) because (1) virus samples are likely to be shipped in frozen form (see Section 5.1.3), which has a lower release fraction than the liquid form used for the earthquake analyses; and (2) the small vials and over-pack foam associated with transportation are likely to provide a degree of confinement even if breached.

The pathogen with the highest exposure levels and the greatest probability of infections for the maximum reasonably foreseeable release earthquake was Rift Valley fever virus (RVFV). The RVFV volume was assumed to be 150 ml for the earthquake. The transportation packages contain duplicate samples in 2 ml vials which would be only partially full (approximately half full). There may be multiple strains of a given virus in a given shipment. It is assumed here that the transportation volume is 8 ml of liquid, which would be the equivalent of duplicate samples for 4 strains of a given virus, which is likely to be greater than the number of strains in the average shipment. The exposure levels would scale approximately proportionally to the volume, so the 8 ml release would result in exposures that are about 5.3% of the value for the maximum reasonably foreseeable release earthquake. The earthquake average RVFV exposures at a distance of 30 m from the point of release and the associated base case probability of infections occurring at that distance or greater are presented in Table 5-7 for each of the three sites. Table 5-7 also presents the scaled transportation exposures and the corresponding probability of infection for each of the three sites. As shown, the greatest probability of infection given a transportation release is 0.093 (i.e., 9.3%) at the urban site. The exposure and probability of one or more infection is lower for all other pathogens.

Table 5-7: Transportation RVFV Exposures and Probabilities of Infection Given Exposure

Parameter	Earthquake	Transportation
Urban site:		
Exposure at 30 m (CCID ₅₀ or MICLD ₅₀)	0.66 ^a	0.035 ^b
Probability of one or more infections in the population given exposure ^d	0.84 ^c	0.093
Suburban site:		
Exposure at 30 m (CCID ₅₀ or MICLD ₅₀)	2.4 ^a	0.13 ^b
Probability of one or more infections in the population given exposure ^d	0.038 ^c	2.1 x 10 ⁻³
Rural site:		
Exposure at 30 (CCID ₅₀ or MICLD ₅₀)	3.1 ^a	0.17 ^b
Probability of one or more infections in the population given exposure ^d	0.019 ^c	1.1 x 10 ⁻³

^a These values were taken from Table 4-13 of Chapter 4.

^b These values are 5.3% of the corresponding value for the earthquake.

^c These values are taken from Tables 5-3-14a, -16a, and -17a of Chapter 8, respectively, for the urban, suburban, and rural sites.

^d Probabilities are one or more infection are for the population 30 m to 1,000 m from the point of release.

In the event of a prompt pathogen aerosol release to the atmosphere due to a transportation crash, the aerosol would likely be transported 30 m in less than ½ minute (the 95th percentile wind speed is 1.5 m/sec at all three sites, as shown in Appendix F, Section F.5.3.2). First responders and potential Good Samaritans are unlikely to arrive at the scene within ½ minute and are unlikely to be exposed to a prompt release. The cargo bed may retain an aerosol release, but Good Samaritans would have no reason to search the cargo bed because it would not contain crash victims. The packaging is required to have the appropriate DOT labeling to warn first responders and Good Samaritans of the risk associated with

handling of the packaging, so a liquid leaking from the package is unlikely to result in contamination exposures. In the event of a crash and package breach, responders can be identified, contacted, and appropriate medical action taken, but that is less certain in the case of a Good Samaritan. Although not likely, the potential for public exposure due to a transportation accident cannot be ruled out.

5.3.5 Variability and Uncertainty

Numerous factors result in variability and uncertainty associated with the above analyses. Table 5-8 identifies the key factors responsible for variability and uncertainty and provides a qualitative assessment of their potential impact on the results.

Table 5-8: Evaluation of Variability and Uncertainty

Variability/ uncertainty	Discussion	Potential effect ^a
Number of truck shipments	The number of truck shipments is based on conservative projections by BUMC, which were confirmed from NIH. The number of shipments could be somewhat greater or less than these estimates. The likelihood of truck-related injuries and fatalities and pathogen releases would be affected proportional to the change in the number of shipments.	Minor conservatism or non-conservatism, which would not affect conclusions
Distance traveled per truck shipment	The analysis is based on a travel distance of 10 km within a 10-km radius of the laboratory. The actual distance traveled could be somewhat greater, depending upon the route taken. The frequency of crash-related injuries/fatalities and pathogen releases would scale proportionally. The potential non-conservatism is expected to be small (e.g., 10%).	Potential non-conservatism
Number of air shipments	The number of air shipments is based on the BUMC policy of using truck transport for shipments within the USA and Canada. The number of shipments could be somewhat greater or less than these estimates. The likelihood of air-related pathogen releases would be affected proportionally.	Minor conservatism or non-conservatism, which would not affect conclusions
Use of over-pack case	It is assumed that all NEIDL shipments will include use of the over-pack case. If the case is not used, the triple-package is much more vulnerable.	Highly non-conservative, if the over-pack case is not used
Use of exclusive-use truck	If the shipment is not exclusive-use, then other cargo could topple onto the NEIDL package and crush it.	Non-conservatism, if other cargo shipped concurrently
Package secured to the middle of the truck bed	If the package is not secured, it is more likely to drop from the truck if the cargo door is left open. If the package is next to the outer edge of the bed, it is more vulnerable to being punctured.	Non-conservatism, if this requirement is not implemented
Single-unit truck	Use of a light truck could increase the likelihood of crushing loads and the accident rates would differ.	Unknown effect, if lighter trucks are used
Single-unit-truck injury rate	The injury rates have declined 60% over the past two decades, so the rates are likely conservative. If the rate continues to decline at this pace, then the injury estimate would be overestimated by about 60% over the facility lifetime of 50 years.	Conservatism (potentially 1.6x over facility lifetime)
Single-unit-truck fatality rate	The fatality rates have declined 40% over the past two decades, so the rates are likely conservative. If the rate continues to decline at this pace, then the fatality estimate would be overestimated by about 40% over the facility lifetime of 50 years	Conservatism (potentially 1.4x over facility lifetime)

Variability/ uncertainty	Discussion	Potential effect ^a
Use of occupant-fatal crash rate for release rate	The NEIDL package is likely to survive many of the occupant-fatal crashes, so this assumption is likely conservative. It is not possible to estimate the degree of conservatism.	Conservatism, unknown extent
Use of rollover and train-collision rate for release rate	The NEIDL package is likely to survive many of the occupant-fatal rollovers and train collisions; however, there may be other types of crashes that result in the package being ejected and crushed. It is not possible to determine whether this assumption is conservative or non-conservative.	Unknown
Use of single crash rates	The crash frequency and severity is likely to be different for different types of roadways (e.g., city streets, country roads, and interstate highways). DOT 2010 does not provide the necessary crash rates for different road types and is a compilation that accounts for the total distance of each type, the vehicle used of each type, and the crash rate for each type. The differences are not expected to change the conclusions.	Unknown
Use of overall crash rates	The crash rates used for this analysis (i.e., DOT 2010) are national average values and specific rates for different types of roadway for these types of crashes are not available. There are certainly differences in the rates for different roadways such as rural versus urban roadways, single-lane versus interstate roadways, and high-speed versus low-speed roadways. Use of the average rates is likely to be conservative for low-speed roadway segments near the sites because the severity of low-speed crashes would be much lower. Use of the average rates may be non-conservative for high-speed non-divided roadways. Overall, the average rates provide reasonable estimates for this analysis and more specific rates are unlikely to alter the conclusions.	Potentially conservative for some roadways and potentially non-conservative for other roadways
Sample volume	The total volume of the samples for a pathogen is assumed to be 8 ml, which accounts for shipment of 4 strains of the virus (duplicate 2 ml vials that are half full). For cases where only one strain is shipped, this value is conservative by a factor of 4.	Expected conservatism of up to 4x for consequences
Sample concentration	The sample concentrations are assumed to be the same as the maximum master/seed/working-stock values. Since these are maximum concentrations, it is expected that they overestimate the actual concentrations, but it is possible that concentrations may occasionally exceed these values. If the estimated concentration is exceeded, the extent of exposure could increase proportionally to this increase.	Likely conservatism but potential non-conservatism, unknown magnitude
Virus samples assumed to be liquid form	The consequence scaling is based on the samples being liquid suspensions. The viruses are expected to be frozen, which results in a lower release fraction. There is a large conservatism of unknown magnitude.	Conservatism, unknown magnitude

^a This is a qualitative indication of the direction and magnitude of the conservative or non-conservative effect of this factor on risk. Quantitative effects are noted where possible.

While there are many variabilities and uncertainties associated with these calculations, the frequency and consequence estimates are judged to be conservative overall. It is not possible to estimate the degree of

this conservatism. As noted in Table 5-8, the results of this analysis are based specifically on the NEIDL shipping protocol as defined in Section 5.1.3. Changes to those protocols may invalidate these results.

5.3.6 Conclusions

The previous sections estimated the likelihood of crash-injuries, crash-fatalities, and pathogen release due to truck and aircraft crashes. As discussed in Section 5.3.5, there is a large variability and uncertainty associated with these estimates. As discussed in Section 4.1.2.2.4 of Chapter 4, this RA uses frequency categories to address these uncertainties when they cannot be addressed quantitatively. Table 5-9 presents the frequency categories associated with each event for BSL-3 shipments and BSL-4 shipments.

Table 5-9: Frequency Category for Transportation Impacts with 10 km of the Laboratory

Event	Frequency category	
	BSL-3	BSL-4
Crash-related injuries (including the public and driver of the truck)	⊙	○
Crash-related fatalities (including the public and driver of the truck)	○	.
Public infections due to the crash of a truck carrying NEIDL pathogens	.	.
Public infections due to the crash of an aircraft carrying NEIDL pathogens	.	.

Frequency categories: ● = A (1 in 1 to 100 years) ⊙ = B (1 in 100 to 10,000 years)
 ○ = C (1 in 10,000 to 1,000,000 years) · = D (1 in > 1 million years)

The conclusion of this transportation analysis can be summarized as follows:

- Crash-related injuries and fatalities from NEIDL shipments are more likely than pathogen-related infections or fatalities in the public. A crash-related injury due to truck or air transport of NEIDL pathogens has an estimated frequency of one in 100 to 10,000 years and a crash-related fatality has an estimated frequency of one in 10,000 to 1 million years. An infectious pathogen release from a truck or aircraft crash resulting in an infection has an estimated frequency of one in more than 1 million years, which is considered beyond reasonably foreseeable.
- In the event of an infectious pathogen release from a transportation crash, the exposure levels are expected to be no greater than 5% of the exposures resulting from the maximum reasonably foreseeable release earthquake. The probability of one or more infections from a pathogen release due to a transportation crash is also smaller than the probability for the maximum reasonably foreseeable release earthquake.

These conclusions are valid for all three sites being evaluated (i.e., urban, suburban, and rural), since it is assumed the protocols followed for pathogen shipments would be similar for all sites.

G. TRANSPORTATION ANALYSIS

G.1 INTRODUCTION

NEIDL operations will include incoming and outgoing shipments of infectious pathogen samples during the life of the facility. Those infectious pathogen shipments could involve both truck and air modes of transportation. This analysis addresses the potential risks (i.e., frequency and consequences) to members of the public because of a loss of an infectious pathogen release resulting from a transportation accident. The risks associated with both truck and air shipment of infectious pathogens are estimated for members of the public in the vicinity of the three sites being evaluated (i.e., the urban, suburban, and rural sites).

G.1.1 Transportation Analysis Guidance

There is no directly applicable guidance pertaining to the analysis of accidents associated with transportation of infectious pathogens to the NEIDL. The NRC has observed the lack of guidance for facilities similar to NEIDL and concluded the following (NRC 2010):

U.S. Department of Energy's (DOE) recommendations for the preparation of EISs contain some of the most detailed explanations and guidelines for discussing human health impacts in an EIS.

Although DOE's recommendations for analyzing human health effects are limited to exposure to radiation and chemicals, they also are relevant to pathogen exposures.

DOE provides detailed guidance for transportation analyses in *A Resource Handbook on DOE Transportation Risk Assessment* (DOE 2002). The DOE transportation analysis guidance was written specifically for transportation of radioactive material, but the general methodology and some of the data are applicable for any transportation analysis and were used to guide this analysis.

G.1.2 Packaging Requirements

The DOT Hazardous Material Regulations (49 CFR Parts 171-180) govern the transportation of infectious substances. The BSL-3 and BSL-4 pathogens being evaluated for NEIDL are classified as Category A Infectious Substances. The packaging requirements for those pathogens are provided in 10 CFR 173.196, *Category A infectious substances*. Category A infectious substances must be triple-packed, which includes the following [49 CFR 171.196(a)]:

- A leak-proof primary receptacle.
- A leak-proof secondary packaging. If multiple fragile primary receptacles are placed in a single secondary packaging, they must be either wrapped individually or separated to prevent contact between them.

- A rigid outer packaging of adequate strength for its capacity, mass and intended use. The outer packaging must measure not less than 100 mm (3.9 inches) at its smallest overall external dimension.

An example of the triple-packaging required by 49 CFR 171.196 for infectious substance shipments is shown in Figure G-1.

Note 1: The smallest external dimension of the outer packaging must not be less than 100 mm (3.9 inches)
Note 2: The primary receptacle or the secondary packaging must be capable of withstanding without leakage an internal pressure producing a pressure differential of not less than 95 kPa
Note 3: Follow package manufacturer's closure instructions

Source: DOT 2006

Figure G-1. Example packaging and markings for category A pathogens.

DOT testing requirement for infectious substance packaging are provided in 49 CFR 178.609. Some of the requirements are dependent on the materials of construction for the packaging. Assuming that the primary and secondary containers are constructed of plastic, which is expected to be the case for NEIDL, the requirements are as follows (summarized from 40 CFR 178.609):

- *Impact test*—Samples must be subjected to free-fall drops onto a rigid, non-resilient, flat, horizontal surface from a height of 9 m (30 feet) in various orientations with no leakage from the primary container. This drop test must be performed promptly after conditioning the container at –18 °C (0 °F).
- *Puncture test*—Samples must be subjected to steel rod puncture test with a 38 mm (1.5 inches) diameter cylindrical steel rod. The mass for this test must be 7 kg (15 pounds) or the mass of the sample, whichever is greater. The test must be conducted with a vertical free fall from a height of 1 m (3 feet). One sample must be placed on its base and a second sample must be placed in an orientation perpendicular to that used for the first. In each instance, the steel rod must be aimed to impact the primary receptacle(s). For a successful test, there must be no leakage from the primary receptacle(s) following each impact.

G.1.3 Description of NEIDL Shipments

The likelihood and consequences of a transportation mishap are dependent on details of the shipment. All NEIDL shipments must comply with the DOT regulations addressed in Section G.1.2; however, additional shipment details are important to this analysis. The following paragraphs describe those details, some of which apply to all shipments and some of which apply to only truck or air shipments. The descriptions apply to all BSL-3 and BSL-4 shipments to or from NEIDL.

G.1.3.1 All Shipments

Pathogen configuration—Bacteria could be shipped in a liquid, frozen, or solid form (e.g., agar in a tube). For this analysis, all bacteria are assumed to be shipped in a liquid suspension, such as a 10–15 percent glycerol (aqueous) at ambient temperature. The liquid form is assumed here for bacteria because that form is more vulnerable to release, which is a conservative assumption (i.e., tends to overestimate the risk). If bacteria are shipped in solid form, the consequences of any packaging breach would be lower because a solid form (e.g., agar in a tube or frozen liquid) would have lower release fractions.

Viruses will be sent shipped in a tissue culture broth after harvesting, and it is likely that they will be shipped in a frozen form. A frozen sample would have a lower release fraction than a liquid, so releases could be higher if viruses are shipped in liquid form. This analysis considers both the liquid and the frozen forms.

Pathogens per shipment—Only one infectious pathogen sample is assumed to be included in each shipment, which is expected to be the case. The analysis is not particularly sensitive to that assumption

1 because synergistic effects from concurrent exposure to multiple infectious pathogens are considered
2 minimal.

3 *Primary container*—The DOT-compliant primary (innermost) containers for shipments to and from
4 NEIDL are assumed to be sealed, shatter-resistant, 2-mL containers similar to the one shown in Figure G-
5 2. Experience at similar facilities indicates that 2-mL tubes are typically used for shipments. The example
6 container is made of polypropylene with an approximate length of 50 mm and a diameter of about 11 mm.
7 The container has a screw cap, which will be reinforced with adhesive tape. Containers of this type are
8 extremely robust and can withstand forces associated with accelerations of 20,000 g (Sarstedt 2011).

9
10 Source: Sarstedt 2011

11 **Figure G-2. Example primary container.**

12 *Secondary container*—The DOT-compliant secondary container serves multiple functions: it contains
13 absorbent material that will absorb liquids potentially leaking from the primary container, provides a leak-
14 proof secondary container, shields the primary container from external forces, and, when multiple primary
15 containers are shipped in the same secondary container, includes a means of separating primary
16 containers from each other. Either the primary or the secondary container must be capable of withstanding
17 an internal pressure of 95 kPa (approximately 14 psi) without leaking (10 CFR 173.196).

18 *Tertiary container*—The DOT-compliant rigid, tertiary packaging must be at least 100 mm (4 in) in its
19 smallest external dimension. Substances shipped frozen must carry the refrigerant outside the secondary
20 container. If dry ice is used to keep the infectious pathogen frozen, the packaging must permit the release
21 of carbon dioxide gas (10 CFR 173.196).

1 *Over-packing*—The DOT-compliant triple packaging will be placed in a non-crushable, liquid-tight, solid
2 container for an added layer of safety (Robbins 2011). A Pelican™ 0370, 24-inch Cube Case meets that
3 requirement and is shown in Figure G-3. The Pelican case provides an additional measure of safety
4 beyond those provided by the packaging required by the DOT regulations. The Pelican case has been
5 independently tested for vibration, low temperature, dry heat, impact, dust, and water immersion and
6 found to meet various international specifications (Pelican 2011); however, the capacity of the case to
7 withstand crushing loads is not known.

8
9 **Figure G-3. Pelican case**

G.1.3.2 Truck Shipments

Carrier—Shipments will be made via carriers specializing in expedited, increased security shipping services accustomed to handling Category A hazardous materials. Those carriers will provide exclusive-use vehicles (i.e., vehicles that do not contain cargo from any other shipper) (Robbins 2011). The shipping agent (i.e., the shipper) would fully comply with all the provisions of the federal and international regulations and requirements for transportation.

Vehicle—It is assumed that shipments will be made via a large truck (e.g., 10,000 lbs. or larger) with an enclosed bed (Robins 2011).

Loading—The over-pack is then secured to the middle of the truck bed away from the walls (Robins 2011), thereby, protecting it from impacts with the walls or from other vehicles that could impact the walls in a collision.

Global positioning system (GPS) tracking—Shippers must have the ability to provide GPS tracking of packages or vehicles as determined appropriate and approved by Boston University Medical Center (BUMC) (Robins 2011). GPS tracking provides for prompt detection of potential mishaps, thereby ensuring for prompt emergency response and plus the opportunity to provide emergency responders with important guidance.

Number of shipments—Per BUMC policy, all shipments to or from locations in the United States will be made via truck whenever feasible. For this analysis, it is assumed an average of one truck shipment per year to the NEIDL would occur for each of the 13 pathogens, for a total of 13 truck shipments (Robbins 2011).

In addition to solely truck shipments, there could also be air shipments of infectious pathogens to or from NEIDL. Those air shipments would include a truck-based component that delivers the package from (or to) Boston Logan International Airport to the laboratory. For this analysis it is assumed that there would be one incoming and one outgoing air shipment each year, so there would be two truck shipments between Boston Logan International Airport and each of the three sites (Robbins 2011).

Origin and destination of shipments—Most infectious pathogen shipments are expected to originate at Bethesda, Maryland; Frederick, Maryland, Hamilton, Montana, and Atlanta, GA Georgia. The number of shipments from each location is not known and is not an important factor for this analysis.

Driver—Trained professional drivers dedicated to the shipment will operate the cargo vehicles.

G.1.3.3 Air Shipments

Number of shipments—Per BUMC policy, all shipments to or from locations in the United States will be made via truck where feasible; however, there is a potential for air-based shipments to or from the NEIDL. For this analysis, it is assumed that an average of one ground shipment per year to and one from the NEIDL will occur (Robins 2011). For this analysis, it is assumed the shipment could involve any of the 13 pathogens.

Origin and destination of shipments—The air-based shipments were assumed have Boston Logan International Airport their origin or destination when evaluating each of the three sites.

G.1.4 Department of the Army Packaging Testing

Triple-packaged systems similar to required for all Category A pathogen shipments were tested by the Department of the Army (DOA) in the 1960s (DOA 1969). The tests consisted of a series of drop-tests from heights of 500 and 1,000 ft with varying packaging configurations including glass and plastic bottles. The drop heights (i.e., 500 and 1,000 ft) are well beyond the 30-ft (9-m) drop test requirements (49 CFR 178.609). The bottles were over-packed in two outer containers (metal and fiberboard) with either cotton or vermiculite as packaging between the containers. The packages were dropped onto soil, concrete, and macadam surfaces. The purpose of the tests was to determine which packaging configurations could survive such drops. Despite the extreme test conditions, several of the packaging configurations resulting in one or more of the three nested containers remaining leak-tight. In addition, the DOA report states that “containers similar to those tested in May 1961 later withstood the crash of a C-119 aircraft at 138 miles per hour” into a concrete wall (DOA 1969).

Two of the packaging systems tested had plastic primary containers with metal secondary containers, different packing materials (cotton and vermiculite), and different outer containers (metal and fiberboard). Both of those systems passed the 500-ft drop onto soil and one passed the 1,000-ft test onto soil. The packages tested by DOA differ in several important respects from the packages used for shipping pathogens to NEIDL but the test can be used to gain insight into the survivability of NEIDL packages:

- The primary container volumes in the DOA tests ranged from 450 to 1,300 mL, while the NEIDL primary containers are expected to be 2-mL tubes. The 2-mL tubes have much less mass, so the impact loads would be much smaller than those used in the DOA tests. In addition to the lower impact loads, the 2-mL containers will tend to have greater strength-to-weight ratio.
- The plastic primary containers in the DOA tests were made of polyethylene, while the containers expected to be used for NEIDL are made of polypropylene. Polyethylene is softer and not as

strong as polypropylene, so the NEIDL containers are less likely to eject caps or breach.

- The Pelican case provides a large margin of safety for the packages. The shell and foam liner of the case would absorb and distribute much of the impact loads.

On the basis of the partial survival of the DOA packages, it is expected that the NEIDL packaging (triple packaging plus non-crushable liquid tight solid container) would survive both the 500-ft and 1,000-ft DOA drop tests, as well as the aircraft crash test without leakage from the primary container.

G.2 METHODOLOGY

The infectious pathogen release frequency is dependent on the truck or aircraft crash frequency and the conditional probability that a package will breach in a crash. The conditional probability of a breach in a crash is dependent on the ability of the package to withstand the conditions that could be associated with a severe crash. A qualitative assessment of the ability to withstand a severe crash is presented below. In addition, the methodology used to estimate the frequency of a release is presented below.

G.2.1 Testing Requirements for Severe Hypothetical Accidents

The triple-packaging must pass the requirement of 49 CFR 173.196, as discussed in Section G.1.2, however, that does not ensure that the packaging will survive all potential accident conditions. The requirements for testing of Type B radioactive material shipping containers are provided in 10 CFR 71.73 are intended to simulate the conditions of severe hypothetical conditions and those test go beyond the requirements of 49 CFR 173.196. While the NEIDL packaging is not required to comply with them, the requirements of 10 CFR 71.73 do provide insight into the type of severe hypothetical conditions that could occur. Those tests include consideration of fire, impact loads, puncture, and crushing loads on the package. The following paragraphs identify the 10 CFR 71.73 testing requirements and discuss expected performance of NEIDL packages for each test to provide some insights into the survivability of the NEIDL packaging.

Free drop—This test consists of a free drop of the package from a height of 9 m (30 ft) onto a flat, essentially unyielding, horizontal surface striking in an orientation that is expected to produce the maximum damage. This 10 CFR 71.71 requirement is equivalent to the requirement for packaging of infectious substances (i.e., 49 CFR 173.196), as discussed in Section 1.2. The Pelican case might or might not be damaged in the test, but the case will distribute and absorb much of the impact load. The NEIDL packaging is expected to pass this test because the triple-packaging must pass the equivalent 49 CFR 173.196 test and the Pelican case will likely enhance its ability to withstand the free drop.

Crush—This test consists of dropping a 500-kg (1,100-lb) plate with a cross-section of 1 m (40 in) by 1 m (40 in) from a height of 9 m (30) onto the package. This test is not required for all radioactive material packages but would be required for containers that are the size of the NEIDL package. The Pelican case is unlikely to survive the test without extensive damage. The survivability of the primary container depends on the amount of dynamic energy absorbed by the Pelican case and the extent to which the case distributes the static load. While the survival of the primary container is unknown, it is unlikely that any aerosol or liquid would be released from the test because the Pelican case foam liner would compress around the inner packaging and prevent any leakage. Therefore, the NEIDL packaging could be breached but there might not be any release.

Puncture—This test consists of free dropping a package 1 m (40 in) in the position of maximum expected damage onto the upper end of a 15-cm (6-in) diameter bar. The size of the bar is smaller in the 49 CFR 173.198 test, so the triple packaging is expected to survive this test. The Pelican case might or might not survive this test.

Thermal—This test consists of a fully engulfing fire with a flame temperature of at least 800 °C (1,475 °F) for 30 minutes. The NEIDL packaging would not withstand the test; however, the test is not relevant for infectious pathogen shipments because the pathogens would be inactivated at temperatures much lower than those. The NEIDL packaging would fail the test, but there would be no risk to the public or the environment because the infectious pathogens would be inactivated.

Immersion—The package must be subjected to water pressures of 150 kPa (21.7 lbf/in²) gauge, which is equivalent to immersion in 15 m (50 ft) of water. 40 CFR 173.196 does not require a similar test for packaging of infectious substances. The primary or secondary container is required to withstand an internal pressure of 95 kPa (approximately 14 psi), which is about 60 percent of this criterion. The 2-mL primary containers are expected to survive the test according to their ability to withstand 20,000 g of acceleration (see Section G.1.3.1).

On the basis of the 10 CFR 71.73 criteria for severe hypothetical accident conditions, free drop, puncture, immersion, and thermal conditions are of minimal survival concern for NEIDL packages; the greatest concern is a crushing load. Therefore, this analysis will focus primarily on crushing loads for severe accident conditions.

G.2.2 Truck Shipments

Consistent with DOE NEPA guidance and the DOE transportation analysis guidance, this analysis used a sliding scale that “analyzes issues and impacts with the amount of detail that is commensurate with their

importance” (DOE 2004, 2002). Because the risks are relatively low and to maximize transparency, this analysis did not use the DOE computer codes (e.g., routing or risk analysis codes), but instead used the general methodology and input parameters provided by DOE for transportation analyses (DOE 2002) to perform simplified and more transparent calculations.

The frequency for ground accidents of a specific type is calculated by the following equation:

$$F = D \times R \times P \quad \text{Equation G-1}$$

where

F is the frequency of the event (/yr)

D is the travel distance (km/yr)

R is the accident, injury, or fatality rate (/km)

P is the conditional probability, or series of conditional probabilities, that lead to the outcome being considered

Transportation-related injury, fatality, and infectious pathogen release frequencies were calculated using Equation G-1. Accident, injury, and fatality rates associated with heavy trucks (i.e., greater than 10,000 lbs) are provided in the DOE transportation analysis guidance (DOE 2002) and are presented in Table G-1. Those transportation accident rates include accidents that do not necessarily result in injuries or fatalities, but might result in vehicle damage only.

Table G.2-1. National average accident rates

Road type	Accident rate (accidents/km)	Injury rate (injuries/km)	Fatality rate (fatalities/km)
Interstate highways	3.00×10^{-7}	2.25×10^{-7}	9.60×10^{-9}
Primary highways	2.78×10^{-7}	2.17×10^{-7}	1.78×10^{-8}
Other highways	4.56×10^{-7}	3.33×10^{-7}	1.71×10^{-8}
Combined total	3.21×10^{-7}	2.39×10^{-7}	1.42×10^{-8}

Source: DOE 2002, Tables 6-20, 6.38, and 6.39

The DOE transportation analysis guidance notes that those rates are based on shipment of all types of goods, but the rates for shipment of radioactive material, and presumably other hazardous materials, have lower accident rates. The pathogens addressed in this analysis are categorized as Class 6, Division 6.2 materials (i.e., biohazards) hazardous materials by DOT, Federal Motor Carrier Safety Administration (49 CFR 173.176). The accident rate for Class 6 materials is 2.29576×10^{-7} accidents per mile (Battelle 2001) or 1.43×10^{-7} accidents per km. The accident rate of 1.43×10^{-7} accidents per km was used for this analysis because it is the most relevant basis, but the injury and fatality rates of Table G.2-1 were used.

The conditional probabilities are for release are scenario dependent and are presented with the results.

G.2.3 Air Shipments

The guidance provided in *Accident Analysis for Aircraft Crash into Hazardous Facilities*, DOE STD 3014-2006 (DOE 2006) is used as the basis for this analysis of aircraft crash. The aircraft is assumed to be carrying an infectious pathogen to or from the Boston Logan International Airport, which is the airport expected to be used for all three sites being evaluated. The infectious pathogen is assumed to be transported via a certified commercial air carrier (i.e., a plane with 30 seats or more or a maximum payload of 3,401 kg [7,500 lbs] or more) in accordance with 14 CFR 121. Table G.2-2 provides the crash rate for commercial air carriers.

Table G.2-2. Aircraft crash rates

Aircraft operation	Crash rate
Commercial aviation—air carrier (takeoff)	1.9×10^{-7}
Commercial aviation—air carrier (landing)	2.8×10^{-7}

Source: Table B-1, page B-3, of DOE STD 3014-2006 (DOE 2006)

G.3 RESULTS

This section documents the frequency and consequence analyses for both truck and air shipments events that have the potential to result in an infectious pathogen release.

G.3.1 Truck Shipments

G.3.1.1 Frequency

As discussed in Section G.1.3, an average of 15 infectious pathogen shipments per year are assumed, 13 that are solely truck shipments and 2 that involve a combination of truck and air. To allow direct comparison of the sites, it is assumed that those same 15 shipments per year are associated with each of the three sites.

The frequency of a release in the vicinity of each site is calculated on the basis of a travel distance of 10 km (6 miles). The 10-km distance is greater than the distance recommended by the U.S. Nuclear Regulatory Commission to define the vicinity of a site for environmental justice purposes (Nuclear Regulatory Commission 2003). Therefore, the total distance for truck shipments is 150 km.

The injury and fatality rates for *other highways* was used for this analysis for all three sites because a portion of the travel at all three sites would be on other highways (i.e., non-interstate and non-primary highways), and it is the highest rate provided in Table G.2-1.

On the basis of the evaluation of the likely survivability of the NEIDL packaging (see Section G.2.1) the only type of truck accidents that have the potential to breach all containers and result in an infectious pathogen release are those that result in severe crushing forces. A review of the National Transportation Safety Board characteristics of truck accidents (NTSB 2002, Table B-7) identified only two categories of accidents that are judged to have the potential to result in severe crushing forces, namely, overturns (rollover) and collisions involving trains. The data for intrastate travel were selected because they include a greater fraction of travel on roadways other than interstate highways. The fraction of accidents that involved an overturn (rollover) was 2.9 percent and those involving collision with a train was 0.2 percent, for a combined total of 3.1 percent of all accidents.

The frequencies of accidents, injuries, and fatalities were calculated using equation G-1 and the values identified above. Those frequencies are provided in Table G.2-3.

Table G.2-3. Accident, injury, and fatality frequencies for truck shipments

Road type	Accidents	Injuries	Fatalities
<i>Other highway</i> rate (/km)	4.56×10^{-7}	3.33×10^{-7}	1.71×10^{-8}
Distance traveled (km/yr)	150	150	150
Conditional probability of overturn or train collision	0.031	0.031	0.031
Frequency (/yr)	2.1×10^{-6}	1.5×10^{-6}	8.0×10^{-8}

Only a small fraction of those overturns would result in an infectious pathogen release. There are no data to allow estimation of the conditional probability of a release, but the potential was qualitatively evaluated. In most cases, the truck is expected to merely roll onto its side, which does not challenge the pathogen packaging. In complete or multiple rollover events, the bed enclosure and the truck cab would both continue to protect the NEIDL package from crushing forces, even if they were severely damaged. Similarly, many collisions involving a train would not compromise the package because the truck would be slid along the tracks without any crushing forces being applied to the package. The fraction of the overturns and train collisions that result in severe crushing forces that might breach the NEIDL package is not known but is expected to be quite small. The humans involved in those events are far more vulnerable to impact loads than the NEIDL package, so the frequency of fatalities from overturns or train collisions is used as upper bound on the frequency of infectious pathogen releases. Therefore, the frequency of a

truck accident resulting in an infectious pathogen release is estimated to be less than 8×10^{-8} /yr, which is in the BEYOND REASONABLY FORESEEABLE frequency category ($< 10^{-6}$ /yr).

The accident, injury, and fatality frequencies for the entire distance (e.g., from CDC in Atlanta to NEIDL) of all truck shipments would have higher frequencies. Those frequency calculations were not performed for the following reasons:

- The majority of the routes would be identical for all sites and, therefore, such calculations would not provide insights into the risks to the population in the vicinity of the laboratory or the differences between sites.
- No specific scenarios were identified that could credibly lead to an aerosol release because of the multilayered packaging system. The analysis above uses the frequency of a fatality as the upper bound for the frequency of an aerosol release, but only a small fraction of the fatal crashes have the potential to result in a release. It would be speculative to estimate the actual conditional probability of an aerosol release because there are no tests or empirical data to support such an analysis.

G.3.1.2 Consequences

Because the frequency is in the BEYOND REASONABLY FORESEEABLE frequency category, detailed consequence calculations were not performed for truck shipment accidents. However, the consequences of a truck shipment accident are qualitatively considered to ensure that the consequences are not grossly larger than more frequent events.

Crushing forces capable of breaching the inner container will not result in public exposures because the foam interior of the Pelican case will confine any liquid or aerosol release. If the inner container is breached after being ejected from the Pelican case, a highly improbable event, then the potential exists for an aerosol release. The virus samples are expected to be frozen, which not result in a significant aerosol release. The consequence calculations for the maximum reasonably foreseeable (MRF) release earthquake (see Section F.8.3.4 of Appendix F) estimated that on average, a person 30 m from a ground-level release of the aerosol resulting from a 150-mL liquid suspension spill at any of the three sites would receive three units (the units were defined on a pathogen-specific bases in Section F.3 of Appendix F) for the pathogen resulting in the highest exposure. The exposure level for all other pathogens would be one to three orders of magnitude less. The transportation packages contain 2-mL samples and the exposure levels would scale approximately proportionally to the volume, so the 2-mL spill would result in exposures that are about 1.3 percent of the value for the MRF earthquake. Therefore, the average exposure 30 m from a

hypothetical aerosol release from a 2-mL spill is less than 0.4 (i.e., 3×0.013) unit for all pathogens. The average exposure levels would likely be greater at closer distances.

G.3.2 Air Shipments

G.3.2.1 Frequency

One inbound and one outbound pathogen air shipments are estimated per year (see Section G.1.3). The crash rate is 1.9×10^{-7} for takeoffs and 2.8×10^{-7} for landings, as shown in Table G.2-2. Therefore, the crash rate for inbound flights carrying a pathogen is $1.9 \times 10^{-7}/\text{yr}$ and for outbound flights carrying a pathogen is $2.8 \times 10^{-7}/\text{yr}$, for a total of $3.7 \times 10^{-7}/\text{yr}$ for all air shipment of a pathogen. Therefore, a pathogen-carrying aircraft crash is in the BEYOND REASONABLY FORESEEABLE frequency category ($< 10^{-6}/\text{yr}$).

An aircraft crash does not necessarily result in an infectious pathogen release. On the basis of the Army tests results discussed in Section G.1.4, the NEIDL packaging is expected to survive drops from both 500 ft and 1,000 ft, as well as the aircraft crash test without leakage from the primary container (see Section G.1.4). Therefore, a pathogen-carrying aircraft crash that results in an infectious pathogen release is certainly in the BEYOND REASONABLY FORESEEABLE frequency category ($< 10^{-6}/\text{yr}$).

G.3.2.2 Consequences

Because the frequency is in the BEYOND REASONABLY FORESEEABLE frequency category, consequence calculations were not performed for an air shipment accident; however, the consequences of an air shipment accident are qualitatively considered. The aerosol release and exposure from an aircraft crash are expected to be similar to those of a truck crash, so the discussion in Section G.3.1.2 is applicable, and exposure levels would average a fraction of a unit for all pathogens.

G.3.3 Summary

This analysis demonstrates that truck and air shipment accidents near each of the three sites do not pose a significant risk to the public within 10 km of any of the three sites for the following reasons:

- The accident and injury frequency for a truck crash within 10 km of any of the three sites is in the LOW frequency category ($< 10^{-4}$ to $\geq 10^{-6}/\text{yr}$). That would be an unperceivable increase in the number of crashes and injuries.
- Conservative calculations show that the frequency of an air or truck shipment crash that results in a loss of biocontainment within 10 km of any of the three sites evaluated is BEYOND REASONABLY FORESEEABLE frequency category ($< 10^{-6}/\text{yr}$).

- If a crash occurs that breaches the triple packaging and the Pelican case, the multiple layers of packaging are expected to confine all or nearly all the release.
- If the multiple layers of packaging do not confine the release, the exposure from a transportation accident is about 1.3 percent of the exposure calculated for the MRF release earthquake. Therefore, the MRF release earthquake frequency and consequence are bounded by those of a transportation accident.

6. Threat Assessment Methodology Overview

6.1 Introduction

The objective of this overview of the methodology for the Threat Assessment (TA) conducted for this RA is 1) to inform the reader of the need for the TA; 2) to provide the detailed, in-depth review of the process utilized in determining the threat, consequence and vulnerabilities of the security systems in place at NEIDL; and 3) to summarize the consequences of a malevolent act to NEIDL at the urban, suburban, and rural site.

6.1.1 Security Systems and Critical Assets

The TA was developed as a component of the RA in response to concerns raised by the public regarding the capability of the facility's security systems inclusive of personnel, policies, and procedures in place to prevent or withstand a malevolent action (e.g., disgruntled or unbalanced lab worker, terrorist action) against critical systems and assets at NEIDL that could result in the exposure of personnel or release of a pathogen into the community. It is important to note that for the context of the TA, the term *security system* is used to define an integrated approach to security that includes

- Security and police personnel and procedures (stationary and patrol);
- Electronic systems (such as access control, alarms, and cameras);
- Programs (including personnel hiring practices, two-person rules, select agent clearance);
- Facility design and construction; and
- Policy and procedures designed to protect NEIDL's critical assets (the facility, systems, personnel, and sensitive information).

One of the primary goals of a well designed security system, as well as one of the overarching philosophies in security and threat assessment practice, is the understanding that by protecting the high-value assets against a sophisticated adversary, the systems in place will also provide sufficient protection of all assets against lesser threats (i.e., adversaries).

As the TA was developed, the security risks and effective mitigation strategies for ensuring the secure operation of NEIDL at the urban, suburban, and rural sites were also validated by the following:

- Identifying and evaluating threats (i.e., adversaries) at each of the three comparable sites;
- Determining the likelihood of attack of those adversaries on NEIDL;
- Identifying the critical assets associated with NEIDL;

- Assessing the potential consequences associated with the impact or loss of critical assets (as defined by the previous Threat and Risk Assessment (TRA) conducted by Applied Risk Management, LLC (ARM) and validated by the Tetra Tech Team during this TA);
- Quantifying vulnerabilities of physical and operational security;
- Calculating the cumulative risks associated with the threats and consequences with respect to each comparable site being evaluated; and
- Providing effective mitigation measures to ensure secure operations against the identified threats.

In order to evaluate the security system in relation to the protection of the critical and non-critical assets, the TA provides an evaluation of *initiating events* associated with malevolent acts that could result in a pathogen release or loss. The TA developed and evaluated numerous malevolent act scenarios that had the possibility and capability of breaching engineering and security systems within the facility resulting in an exposure of laboratory workers or the public. Additionally, based on the results and outcomes of the scenarios developed and conducted against the security systems, the Tetra Tech team identified and recommended mitigation strategies to reduce the effects of deliberate efforts by terrorists to destroy, incapacitate, or exploit the facility's mission, pathogens, and technology (i.e., high-value, critical assets, the loss of which would have significant negative effects on the operation of the facility and possibly on the public).

6.1.2 Restricted Distribution of Security Information

Based on the information contained within the TA (including but not limited to security system's design and implementation, response capabilities, and system upgrades) the TA is required to be maintained as a "Controlled Document" under the provisions in the Public Health Security and Bioterrorism Preparedness and Response Act of 2002 (the Bioterrorism Act). The Bioterrorism Act was passed by Congress following the events of September 11 in order to enhance the security of the United States and improve, prevent, prepare for, and respond to bioterrorism public health emergencies.

6.2 Threat Assessment Methodology

The following is an overview of the methodology that was employed to quantify risks associated with malevolent acts against the critical assets at NEIDL. Additional information pertaining to risk evaluation in security applications can be found in references cited throughout this chapter. The TA accomplished this objective by answering the following questions:

- What needs to be protected (i.e., what are the high-value, critical assets)?

- What are their vulnerabilities (i.e., what are the gaps in the security system protecting those assets)?
- What are the threats (i.e., who are the potential adversaries with the capability to defeat the security system to destroy or illegally obtain those assets)?
- What can be done to minimize the risk of a malevolent act (i.e., how can the high-value critical assets be protected more effectively)?

The evaluation of risks associated with physical and operational security elements for NEIDL was based on the standard risk equation, the most basic form of which is represented as follows (Andrews 2002):

$$\text{Risk} = P \times C$$

where

P is probability, referring to the likelihood or chances of some adverse event;

C is consequence, referring to the effect of the adverse event.

In the security application, the generalized risk equation as defined in DHS's National Infrastructure Protection Plan (NIPP) is represented as follows (NIPP 2008):

$$\text{Risk} = f(T, V, C)$$

where

T is the *threat* which represents the likelihood of an adversary mounting a successful attack against a specific target;

V is the *vulnerability* of the security system's ability to protect an identified asset against a specific adversary (i.e., threat);

C is the *consequence* associated with the loss of a specific asset or component based on a specific threat (i.e., attack) scenario.

Therefore, the analysis associated with developing the TA primarily involved the definition and comparison of the T , V , and C variables in NEIDL's location at the urban site and its theoretical risks at the suburban and rural sites.

The following sections present an overview of the methods employed to define each of those primary variables to estimate the risks associated with NEIDL in its location at the urban site and its theoretical risks at the suburban and rural sites.

6.3 Review of Previous Threat and Risk Assessments

To accurately assess the risk to NEIDL associated with internal and external malevolent acts and to evaluate those same risks to similar facilities at the comparable sites, it was necessary to first conduct a thorough assessment of the effectiveness of NEIDL's security systems as constructed at the urban location. The effectiveness of the security system is typically determined by evaluating how effective system components are at deterring, detecting and assessing, and delaying and responding to malevolent acts. The assessment of those security systems was required to provide the baseline condition (i.e., to define the starting point). The process began by reviewing the previous TA conducted by ARM to determine the baseline condition of the facility.

The initial NEIDL threat risk assessment (TRA) was conducted as part of the conceptual design process and published in a limited-distribution report entitled *Risk and Vulnerability Assessment, Boston University, BU Medical Center, National Bio-Containment Laboratory* (NBL), dated August 5, 2004 (ARM 2004). In addition, a report update was issued on June 30, 2008, that included updated threat information (ARM 2008). The Tetra Tech TA team reviewed both of those documents and agreed with the identified targets (i.e., the high-value critical assets) and the consequences of their loss. However, because the initial assessment was performed before the building's final design and ultimate construction (i.e., the initial assessment evaluated security systems and operations at the conceptual phase), it lacked specific information related to the *as-built* condition of the facility. Additionally, the initial TRA did not analyze the risk associated with NEIDL at the suburban and rural sites. Therefore, an additional analysis (i.e., this TA) was required to accurately characterize the security of the built facility at the urban location, in addition to compare the threat and risks at the suburban and rural sites

6.4 Defining Threat

The threat variable in the risk equation, T , represents the relationship between a defined adversary with specific capabilities, motives and objectives, and a specified target (i.e., something the adversary identifies as having value to his specific motives and objectives). The threat (i.e., T) is therefore determined by combining specific adversary abilities with identified NEIDL critical assets to arrive at an estimate of the likelihood that a specific adversary would target a specific asset. The following steps were required to accomplish that task:

1. Analyzing crime statistics: This analysis was performed by use of the CAP Index, Inc., CRIMECAST© tool to identify specific crimes and, therefore, specific types of criminals within each of the three regions (urban, suburban and rural);

2. Determining the local threat environment: This step was accomplished by conducting site visits and interviews with federal, state, and local law enforcement agencies to define the history and current intelligence and capabilities related to adversary actions within the regions of the three comparable sites;
3. Collecting and evaluating threat intelligence: This step entailed research to identify threats against and attacks on similar facilities worldwide to develop the general and relevant threat information for each of the three comparable sites;
4. Determining the target *attractiveness* (i.e., the target's suitability to an adversary's primary goal) to each identified adversary.

Each of those components, described in the following subsections, was used to define the threat component of risk for NEIDL at each of the three locations.

6.4.1 CAP Index Analysis

The TA team used the services of CAP Index, Inc., to collect and categorize crime statistics by using the CRIMECAST® data analysis and assessment tool, which is continuously maintained by a team of criminologists, statisticians, and security and mapping professionals. This analytical technology enabled the TA team to generate predictive reports and graphics that provided precise information for each of the study locations and by crime and loss history via a scoring mechanism designed to objectively measure risk of criminal events.

Using regional crime data, the CRIMECAST® system provided a risk profile for each of the regions around the three comparable sites and an assessment of the crime in the surrounding areas. The regions were defined on the basis of the mailing addresses for NEIDL in downtown Boston (at 650 Albany Street, Boston, Massachusetts), the former BU Corporate Education Center (at 72 Tyng Road in Tyngsboro, Massachusetts), and the BU Sargent Center for Outdoor Education (at 36 Sargent Camp Road, Hancock, New Hampshire). In addition, global positioning system coordinates were determined (via Google Earth) for the geographical center of each site and validated against the mailing address before calculating the CAP indices.

The crimes against persons and crimes against property (CAP) profiles generated for each of the three comparable sites included a breakdown of offenses, along with a rating for the three regions. All CAP scores reported are based on a scale of 0–2,000, with 0 representing the lowest risk and 2,000 representing the highest. The rating scale is normalized to national and state averages (i.e., 100 is defined as the

average score). For example, using this scale, a score of 200 would indicate that the frequency of a crime in a region is at twice the normalized national or state average rate (depending on the data being compared in the tool) for that specific crime category. Similarly, a score of 600 would mean a risk level is 6 times higher than average. Conversely, a CAP score of 25 would indicate that the risk would be 0.25 times (i.e., one-quarter) the national or state average.

The CAP scores were calculated using two different radial distances from the geographical center of each actual and comparable location of NEIDL. The first analysis (i.e., the CRIMECAST® Standard Report) used a radius of 3 miles to calculate the index. The second analysis (i.e., the CRIMECAST® Expansion Report) applied the methodology to a radius of 6 miles. Producing and evaluating both reports allowed the TA team to determine the effect of the regional setting on the overall indices. For example, in a more rural setting, the CAP Index would be anticipated to increase in the expansion report analysis if neighboring communities with more dense populations are between 3 to 6 miles from the center of the observation area (i.e., the location of the comparable site).

Because of the sensitive nature of the crime statistical information collected and analyzed during this portion of the TA, that information is not included in this document. However, generally the CAP indices (i.e., the crime rates) decrease as the distance from downtown Boston increases.

6.4.2 Determining the Local Threat Environments

The local threat environment was defined by conducting interviews with federal (i.e., Federal Bureau of Investigation's Joint Terrorism Task Force representatives), state, and local law enforcement entities at each of the three comparable sites. In addition, representatives from the BU Police Department and the BU executive director of Public Safety were interviewed to obtain an overview of the crime history at the BUMC campus. Interviews were conducted during November 2008 and January 2009 by using a standardized set of data collection forms and threat definitions. Standardization assures consistency in the manner in which questions were presented to officials, and responses were recorded. The data collection forms were used to identify site-specific threat and crime information for each site. The information gathered during each interview was broken down into five categories:

1. History of threat, activity, or attacks in the region and area;
2. Identifiable threat intelligence;
3. Potential adversarial or threat groups present in the region;
4. Motivation, intent, and capabilities of identified threats;
5. Public safety response resources.

1 The results of the interviews and a compilation of the data collection forms are included in the TA.

2 3 **6.4.3 Determining Threat Information from National and International Intelligence**

4 The next phase of the threat definition involved developing a threat intelligence report to be used in
5 supporting and creating a threat definition and threat spectrum for evaluating the potential NEIDL
6 security risks at each of the three comparable sites from national and international terrorist organizations.

7 The focus of the research was on the potential threat levels determined to be applicable to the three sites
8 within the context of the threat faced, both past and present, by similar domestic and foreign facilities.

9 The task consisted of the identification and detail compilation of any and all threats, attacks, and other
10 adversarial actions against animal bio-research laboratories or similar facilities (whether government,
11 private, or academic), both domestically and internationally. The task included the identification as to
12 whether those types of facilities had been targeted in the past by terrorists, extremists, or other threat or
13 adversarial groups to determine the current NEIDL threat environment at each of the three comparable
14 sites. The intelligence review effort, therefore, focused on the following areas of research and analysis:

- 15 1. The general biosecurity environment worldwide;
- 16 2. Past events and current threats against 13 domestic BSL-3 and two domestic BSL-4 facilities
17 identified by NIH's NIAID;
- 18 3. The general threat environment at each of the NEIDL comparable sites.

19
20 Those tasks were accomplished by using thorough research methods, including both analyst- and
21 software-based techniques to research open-source materials. By using predefined screening criteria and
22 keyword searches, the process allowed the accumulation of a considerable amount of documentation
23 pertaining to topics of interest and aided in the efficient analysis to determine the relevance of the
24 material collected.

25
26 Because of the uncertain nature of potential threats, the analysis considered both official and unofficial
27 information sources to gain an understanding of the overall threat environment, the perspective of policy
28 makers, and the opinions of the general population, including dissenting groups within the communities
29 where BSLs existed or were being considered for future sites of similar facilities. Those sources included
30 transnational media, foreign state-run media, local media, government sites (including DHS, FBI, White
31 House, Government Accountability Office, Congressional Research Service, Interpol, United Nations,
32 World Health Organization, state, county, and local law enforcement agencies, state civilian government,
33 county civilian government, and local civilian government), university sites, nongovernment players,
34 blogs, chat-rooms, and online forums.

1 The analyses used the same threat categories that were used during interviews to identify and categorize
2 individuals and groups that could pose an identifiable threat to the facility specific to each of the three
3 locations being investigated.

5 **6.4.4 Target Attractiveness**

6 An assessment of a target's attractiveness was performed to determine how likely an adversary would be
7 to plan and carry out an attack on an asset. The target's attractiveness, therefore, becomes a function of
8 the adversary's assessment that the target is critical to their mission, it is easily accessible, it has some
9 identifiable vulnerability, and its destruction or loss would have the desired effect (e.g., panic among the
10 public, death of innocent victims, draw attention to the terrorist's cause). For those reasons, a target's
11 attractiveness is an integral part of the determination of the likelihood of an attack against a specific high-
12 value critical asset.

13
14 The TA team performed an analysis of the targets (i.e., the high-value, critical assets) that the identified
15 adversaries in each of the three regions would be most likely to attack. That analysis was used to identify
16 the areas within the NEIDL that must be considered as vital (i.e., high-consequence, critical assets) and
17 how they should be best protected against the identified adversaries. The outcome of the target analysis
18 was used to define the target portion of the threat variable in the risk equation.

19
20 Both the CARVER and MSHARPP methodologies were used to evaluate the attractiveness of specific
21 features and components of the NEIDL facility as potential targets from the perspective of the adversaries
22 identified in each of the three regions. Both of those methodologies were developed by the Department of
23 Defense for offensive target analysis based on military objectives. MSHARPP is a targeting analysis tool
24 geared more closely to assessing personnel vulnerabilities relative to terrorist scenarios, whereas the
25 CARVER method is used by Special Forces and commandos to target enemy infrastructure including
26 public works facilities such as bridges and power plants. Those methodologies were appropriate for use as
27 potential adversaries, both overt and covert, would employ similar methods to select and target identified
28 assets (e.g., facilities, personnel).

29
30 In addition to the CARVER and MSHARPP methods, target attractiveness was evaluated relative to other
31 critical assets in each of the three regions by use of the CAP Index's Proximity Analysis Tool. Each of
32 those methodologies and their individual evaluation criteria are described in the detail in the TA
33 document.

6.5 Defining Consequences

To quantify the variable *C* in the risk equation, consequences were defined in terms of the value of the loss of an asset (e.g., such as in the loss of NEIDL's mission or reputation, the intentional release of a pathogen). The value of the loss was assigned to the identified high-value assets for purposes of providing reasonably credible bounding threat scenarios for detailed analysis. The consequence of loss of an asset was defined by determining its criticality (i.e., the impact from the loss). NEIDL's mission statement was used to establish the list of assets for consideration in determining criticality (i.e., the high-value critical assets). Subsequently, a list of high-value critical assets was developed, compared, and integrated with the previous list compiled for the initial TA. The list was then used in the baseline risk calculation.

6.6 Determining Vulnerabilities
