Background: Osteoporosis (OP) is a major metabolic bone disease with significant health and socioeconomic impacts. The triglyceride-glucose (TyG) index and its derivatives, which reflect insulin resistance (IR), may play a role in bone metabolism. However, the relationship between TyG indices and OP is unclear. This study aimed to explore the association between TyG indices and OP in a low-income rural Chinese population.

Methods: This cross-sectional study was conducted in rural Tianjin, China, in 2020. Participants aged 60 years or older were included. Data were collected through interviews, including sociodemographic and clinical information, and physical examinations. Bone mineral density (BMD) of the femoral neck was measured using dual-energy X-ray absorptiometry (DXA). Multivariate regression models and restricted cubic spline (RCS) curves were used to assess the relationships between TyG indices and OP.

Results: A total of 437 individuals were included in the final analysis, with 38 diagnosed with osteoporosis (prevalence of 8.7%). After adjusting for all covariates, each 1-unit increase in triglyceride-glucose-body mass index (TyG-BMI) was associated with a 2% lower risk of osteoporosis, (OR: 0.98, 95% CI: 0.96–1.00, P=0.029), especially in women, individuals with hypertension, and non-diabetic populations. The OP risk of the fourth quartile (Q4) of the triglyceride-glucose-waist circumference (TyG-WC) index after correcting for all covariates is 5.58 times that of the first quartile (Q1) (OR: 5.58, 95% CI: 1.14–27.41, P=0.034). Linear regression showed a positive correlation between TyG-BMI and BMD, particularly in women, individuals under 70, and those with hypertension or non-hypertension, with the strongest correlation in the non-hypertensive group.

Conclusion: TyG-related indices are associated with OP, suggesting a potential role in the early prevention and management of osteoporosis in this population, ultimately improving public health outcomes.

Keywords: triglyceride glucose, triglyceride glucose-waist circumference, osteoporosis, bone mineral density, restricted cubic spline

Introduction

Osteoporosis (OP) is a metabolic bone disease characterized by low bone mass and the deterioration of bone tissue microarchitecture, leading to reduced bone strength and an increased risk of low-energy or fragility fractures.¹ The prevalence of OP is significantly higher in developing countries than in developed countries, with urban areas showing slightly higher rates than rural regions.² Approximately 10 million Americans over the age of 50 suffer from OP, with an estimated 1.5 million fragility fractures occurring annually.³ The prevalence of OP in Chinese adults aged 60 and older is 37.7%, increasing with age.⁴ A recent large-scale cross-sectional study⁵ conducted in China revealed that the prevalence of OP among individuals aged 40 years and older was 5.0% in men and 20.6% in women. In 2010, OP ranked as the third

leading risk factor for injuries in China,⁶ indirectly contributing to an increase in mortality rates. By 2025, the annual direct costs of OP are projected to reach approximately \$25.3 billion.⁷ The average hospitalization cost for osteoporotic fractures (OPF) in China is 27,561.27 yuan, with women being the most affected, posing a significant socioeconomic burden.⁸

OP commonly affects the spine, hip (including the femoral neck), lumbar spine, distal radius (wrist), and proximal humerus (upper arm), with the femoral neck being the most dangerous and potentially lethal fracture, described as is the most common type of hip fracture, often referred to as the “last fracture in life” in older adults.^{9,10} BMD is the primary method for diagnosing OP,¹¹ with lower BMD levels associated with higher OP risk. Elevated serum triglyceride (TG) levels are negatively correlated with Bone mineral density (BMD), while high glucose levels and advanced glycation end products (AGEs) increase the expression of sclerostin, a negative regulator of bone formation.¹² Insulin signaling plays a critical role in regulating bone marrow metabolism, suggesting a link between insulin resistance (IR) and bone health.^{13,14} The triglyceride-glucose (TyG) index, derived from fasting blood glucose (FBG) and TG, is considered a reliable marker for IR.^{15,16} Obesity plays a vital role in OP development,¹⁷ and the TyG-BMI and TyG-WC indices, which combine the TyG index with obesity measures such as body mass index (BMI) and WC, are good predictors of IR.^{18,19}

Association of TyG index with BMD is controversial. A cross-sectional study found that the TyG index was negatively correlated with femoral neck BMD in non-diabetic men and women, with the strongest correlation observed in women with a BMI < 23 kg/m².²⁰ Similarly, the TyG index was significantly associated with lower bone mass and increased risk of OP in the femur, hip, and lumbar spine.²¹ In the US, the TyG index was negatively correlated with BMD, although no significant interaction was observed between gender, age, or diabetes status.²² In non-diabetic US adults, a significant positive correlation was found between the TyG-BMI index and femoral BMD, with higher TyG-BMI levels associated with a lower risk of OP, especially in postmenopausal women over 40 and men over 60.²³ In middle-aged and elderly non-diabetic Chinese individuals, the TyG-BMI index was positively correlated with femoral neck BMD and negatively associated with fracture risk in both men and women.²⁴ Xuan X. et al²⁵ concluded that there is a non-linear association between the TyG-BMI index and femoral neck BMD in non-diabetic patients, with stronger correlations observed at higher TyG-BMI levels. The previous study observed positive correlations between the TyG-BMI and TyG-WC indices and BMD, with regression coefficients decreasing beyond certain thresholds,²⁶ differing from other studies but consistent with findings in HIV-infected individuals.²⁷ Some studies found no association between the TyG index and BMD or OP.^{28,29}

However, research on the TyG-BMI index has primarily focused on non-diabetic populations, while studies on the TyG-WC index are scarce, as well as most data are derived from public databases or hospitalized patients, with no studies reporting on rural populations. Previous studies have predominantly focused on either OP or BMD as single outcomes. To gain a more comprehensive understanding of the impact of the TyG index on bone health, we have chosen OP as the primary outcome and BMD as the secondary outcome, thereby corroborating our findings from different perspectives.

Therefore, we aim to evaluate the relationship between the TyG index, its derivative indices, and OP or BMD in the femoral neck of a low-income rural Chinese population through a cross-sectional study.

Methods

Study Population

This cross-sectional study selected participants from a low-income, low-education population in rural Tianjin, China in 2020. Individuals aged 60 and older (all females were postmenopausal) without malignancies, thyroid or parathyroid dysfunction, or other diseases affecting bone metabolism were invited to participate. After excluding individuals with incomplete BMD, TG, and FBG data, a total of 437 individuals were included in the final study. The study adhered to the principles of the Declaration of Helsinki and was approved by the Ethics Committee of Tianjin Medical University General Hospital (approval number: IRB2018-100-01). All participants provided written informed consent.

Data Collection

Sociodemographic and clinical information was collected through face-to-face interviews conducted by trained researchers. The data included name, gender, age, years of education, age at which the participant began working, smoking and drinking habits, and history of diabetes and hypertension. Laboratory data included TG, FBG, total cholesterol (TC),

high-density lipoprotein (HDL), and low-density lipoprotein (LDL). All participants underwent physical examinations, during which they wore light, loose-fitting clothing. Weight was measured using a standard scale, height was measured while participants stood straight, and WC was measured at the midpoint between the iliac crest and the lowest rib using a flexible measuring tape. All measurements were recorded by the same researcher to minimize systematic error.

BMD Assessment

BMD of the femoral neck was measured using dual-energy X-ray absorptiometry (DXA), and T-scores were recorded (ASY-00409, Hologic, MA, USA).³⁰ T-score is defined as patient measured BMD (in g/cm) value minus the reference BMD value (sex-matched, young adult reference population) divided by the reference standard deviation (SD). (sex-matched, young adult reference population).³¹ According to the World Health Organization's diagnostic criteria for individuals aged 50 and above, OP is defined as a T-score ≤ -2.5 .³²

Definitions and Groupings

Hypertension was defined as systolic blood pressure (SBP) ≥ 140 mmHg and/or diastolic blood pressure (DBP) ≥ 90 mmHg, or a self-reported history of antihypertensive medication use.³³ Diabetes was defined as HbA1c $\geq 6.5\%$ (≥ 48 mmol/mol), FPG ≥ 126 mg/dL (≥ 7.0 mmol/L), or a 2-hour postprandial glucose ≥ 200 mg/dL (≥ 11.1 mmol/L) during an oral glucose tolerance test (OGTT), or a self-reported history of diabetes or use of anti-diabetic medication.³⁴ BMI was calculated as weight in kilograms divided by height in meters squared (kg/m^2). Underweight was defined as BMI < 18.5 kg/m^2 , normal weight as $18.5 \leq \text{BMI} < 24$ kg/m^2 , overweight as $24 \leq \text{BMI} < 28$ kg/m^2 , and obesity as BMI ≥ 28 kg/m^2 .³⁵ The TyG index and its related indices were calculated using standardized formulas: $\text{TyG} = \ln[\text{TG (mg/dL)} \times \text{FPG (mg/dL)} / 2]$; $\text{TyG-BMI} = \text{TyG} \times \text{BMI}$; $\text{TyG-WC} = \text{TyG} \times \text{WC}$.³⁶ Participants were grouped into quartiles based on these indices.

Statistical Analysis

According to Kolmogorov-Smirnov test and Shapiro-Wilk test, the normality of continuous variables in the non-osteoporosis group and the osteoporosis group were tested respectively, and the normal distribution histogram was used to judge. Continuous variables were expressed as means and SD or medians (interquartile ranges) and compared using Student's *t*-test or the Mann-Whitney *U*-test. Categorical variables were presented as frequencies and percentages, with comparisons made using chi-square tests. Multivariate logistic regression was used to examine the relationship between TyG-related indices and OP. Subgroup analyses based on variables from the univariate analysis were performed to further explore the relationship between TyG-related indices and OP in different population subgroups. The relationship between indices and OP was expressed using adjusted odds ratios (OR) and 95% confidence intervals (CI). Linear regression models were used to verify the associations between TyG-related indices and BMD. For linear indices, multivariate linear regression was employed to confirm correlations, and subgroup analyses were performed based on age, gender, diabetes, and hypertension status. Standardized regression coefficients (β) and 95% CIs were used to express linear correlations. For non-linear indices, restricted cubic spline (RCS) curves were used to explore dose-response relationships between the indices and BMD. The number of knots was determined using the Bayesian Information Criterion (BIC). In the RCS graphs, bold lines represent point estimates of regression coefficients, and shaded areas represent 95% CIs. Statistical significance was set at $P < 0.05$. All statistical analyses were conducted using SPSS v.27.0.1 software (IBM Corp., Armonk, NY, USA). Flowcharts and forest plots were generated using GraphPad Software, Inc., San Diego, CA, USA (v.10.2.3), and R Foundation for Statistical Computing, Vienna, Austria (v.4.2) was used to create RCS curves.

Results

Baseline Demographic Characteristics

A total of 437 participants were included in this study (Figure 1), comprising 184 men (42.1%) and 253 women (43.5%), with an average age of 67.95 ± 6.55 years. The mean BMI of the study population was 25.02 ± 3.44 , the mean BMD was 0.43 ± 0.10 , and the mean T-score was -1.35 ± 0.85 . The TyG index, TyG-BMI index, and TyG-WC index were 8.68 ± 0.63 , 217.65 ± 37.07 , and 752.09 ± 103.72 , respectively (Table 1).

Figure 1 Flow chart of participants selection.

Notes: a total of 626 individuals underwent BMD examination, with 462 participants meeting the inclusion criteria. Participants who were under 60 years old, had a history of malignancy, thyroid or parathyroid dysfunction, or other conditions affecting bone metabolism were excluded. Of the 462 eligible participants, 25 were excluded due to insufficient fasting blood glucose and fasting triglyceride data. Finally, 437 participants were included in the analysis.

Univariate Analysis of Factors Influencing OP

Among the 437 participants, 38 were diagnosed with osteoporosis, representing a prevalence of 8.7%. Univariate analysis revealed significant associations between osteoporosis and variables such as gender, age, years of education, height, weight, BMI, and the TyG-BMI index ($P < 0.05$) ([Supplemental Table 1](#)).

Table 1 Demographic Characteristics Among All Participants

Characteristics	Men	Women	Total
Total, n (%)	184 (42.1)	253 (57.9)	437 (100)
Age, years	68.60 (7.10)	67.47 (6.09)	67.95 (6.55)
Age group, n (%)			
< 70 years old	114 (62.0)	170 (67.2)	284 (65.0)
≥ 70 years old	70 (38.0)	83 (32.8)	153 (35.0)

Multivariate Analysis of Factors Influencing OP

After multivariate adjustment, the TyG-BMI index remained significantly associated with osteoporosis in models 1, 2, and 3. After adjusting for all variables included in the univariate analysis, the risk of osteoporosis decreased by 2% for every 1-unit increase in BMI (OR: 0.98, 95% CI: 0.96–1.00, $P = 0.029$). The fourth quartile (Q4) of the TyG-WC index

was significantly associated with osteoporosis in models 2 and 3, with a 5.58-fold higher risk of osteoporosis compared to the first quartile (Q1) (OR: 5.58, 95% CI: 1.14–27.41, $P = 0.034$). No significant association was found between the TyG index, its quartiles, or the TyG-WC quartiles and osteoporosis (Table 2).

Subgroup Analysis of Factors Influencing OP

Subgroup analysis showed that after adjusting for factors with $P < 0.05$ in the univariate analysis, women, individuals with hypertension, and non-diabetic populations had a lower risk of developing osteoporosis. For each 1-unit increase in the TyG-BMI index, the risk of osteoporosis decreased by 2% ($P < 0.05$) (Figure 2). No significant associations between the TyG index or TyG-WC index and osteoporosis were found across gender, age, hypertension, diabetes, or BMI subgroups (Figures 3 and 4).

Univariate Analysis of Factors Influencing BMD

Linear regression analysis showed that gender, age, years of education, height, weight, BMI, smoking history, drinking history, and the TyG-BMI index were significantly associated with BMD ($P < 0.05$). Age and female gender (compared to male) were negatively correlated with BMD, while the other factors were positively correlated. However, no linear relationship was observed between the TyG index or TyG-WC index (and their quartiles) and BMD (Supplemental Table 2).

Table 2 Multivariate Analysis for the Prevalence of OP

Characteristics	Model 1 RR (95% CI), P value	Model 2 RR (95% CI), P value	Model 3 RR (95% CI), P value

Notes: (1) Model 1 is the variable with $P < 0.05$ among the single adjustment factors; Model 2 is a variable with $P < 0.5$ among the single factors; Model 3 is to adjust all variables in a single factor. (2) Bold fonts indicate $P < 0.05$, with significant differences in statistical results.

Figure 2 Subgroup analysis of TyG-BMI influencing OP.

Notes: The adjusted OR with 95% CI for various subgroups, including gender, age, hypertension, and diabetes status. The results showed a significant association between TyG-BMI and OP in women ($P = 0.036$), individuals with hypertension ($P = 0.042$), and non-diabetic individuals ($P = 0.042$). No significant association was observed in men or individuals aged <70 years.

Figure 3 Subgroup analysis of TyG influencing OP.

Notes: The adjusted OR with 95% CI for various subgroups, including gender, age, hypertension, and diabetes status. No significant associations were found in any of the subgroups.

Figure 4 Subgroup analysis of TyG-WC influencing OP.

Notes: The adjusted OR with 95% CI for various subgroups, including gender, age, hypertension, diabetes status and obesity situation. No significant associations were found in any of the subgroups.

Multivariate Analysis of TyG-BMI and BMD

After adjusting for factors with $P < 0.05$ in the univariate analysis, the associations between gender, age, TyG-BMI index, and the Q4 of TyG-BMI with BMD remained significant, with gender being the strongest factor (Table 3). Compared to men, the TyG-BMI index was negatively correlated with BMD in women (β : -0.347 , 95% CI: -0.372 , -0.322 , $P < 0.001$). For each 1-year increase in age, BMD decreased by 0.28 (β : -0.208 , 95% CI: -0.210 , -0.206 , $P < 0.001$). Each 1-unit increase in the TyG-BMI index was associated with a 0.15 increase in BMD (β : 0.150 , 95% CI: 0.1498 , 0.1502 , $P < 0.001$). Subgroup analysis showed that the associations remained significant in women, individuals under 70, and those with or without hypertension or diabetes, with the strongest association observed in the non-hypertensive group ($P < 0.05$) (Table 4).

Non-Linear Analysis of TyG Index and TyG-WC Index With BMD

No linear relationship was found between the TyG index, TyG-WC index, and BMD in univariate analysis (Figures 5A and 6A). Further exploration using RCS curves showed no significant non-linear associations between the indices and BMD, even after sequential adjustment for age, gender, education level, BMI (Figures 5B and 6B), smoking history, drinking history, hypertension, diabetes (Figures 5C and 6C), and laboratory indicators such as TC, HDL, and LDL (Figures 5D and 6D).

Table 3 Multivariate Analysis for the Prevalence of BMD

Characteristics	Reference	β (95% CI)	P value
Gender			
Women	Men	-0.347 (-0.372 , -0.322)	<0.001
Age, years		-0.208 (-0.210 , -0.206)	<0.001
Years of education, years		0.080 (0.078 , 0.082)	0.103
Smoking history			
Current smoking	Never smoking	-0.034 (0.063 , -0.005)	0.599
Ever smoking		-0.032 (-0.079 , 0.015)	0.596
Drinking history			
Current drinking	Never drinking	0.060 (0.029 , 0.091)	0.372

Figure 5 Relationship between the TyG index and the risks of BMD.

Notes: The nonlinear relationship between the TyG index and BMD. The inflection points are 8.63 for Panel A and 8.62 for Panels B, C, and D. **(A)** Relationship between the TyG index and the risk of OP in a univariate analysis. The overall P value is 0.360, and the nonlinearity P value is 0.863. **(B)** Relationship between the TyG index and the risk of BMD, adjusted for age, sex, education level, and body mass index. The overall P value is 0.014, and the nonlinearity P value is 0.147. **(C)** Relationship between the TyG index and the risk of OP, further adjusted for smoking history, drinking history, hypertension, and diabetes on the basis of Panel B. The overall P value is 0.019, and the nonlinearity P value is 0.110. **(D)** Relationship between the TyG index and the risk of BMD, further adjusted for TC, HDL, and LDL on the basis of Panel C. The overall P value is 0.056, and the nonlinearity P value is 0.279.

Discussion

The purpose of this study was to evaluate the relationship between TyG-related indices and bone health in a rural Chinese population, and to determine whether TyG-related indices can serve as independent predictors of OP risk as the primary outcome, with BMD as a supplementary secondary outcome. We found that the TyG-BMI index serves as a protective factor against OP, particularly in women, hypertensive individuals, and non-diabetic populations, where the risk of OP is lower. The TyG-BMI index and its Q4 were positively associated with BMD, especially in women, individuals under 70, those with or without hypertension, and non-diabetic populations, with the strongest correlation observed in non-hypertensive individuals. After multivariate adjustment, the Q4 of the TyG-WC index was associated with a higher risk of OP. No significant correlations were observed between the TyG index and either BMD or OP, even after stratifying by age, gender, BMI, hypertension, or diabetes. These findings suggest that the TyG-BMI index has a protective effect against OP, while the TyG-WC index is a risk factor, with varying degrees of association across different populations.

Osteoporotic fractures are the most severe complications of OP, with common sites including vertebral bodies, hips, distal forearms, and proximal humerus.³⁷ Severe cases can lead to vertebral compression fractures, which in turn cause height loss and kyphosis, leading to spinal deformities. The presence of OP leads to local mechanical risks and poses significant challenges for the prognosis of vertebral fractures and related surgeries.³⁸ Insulin signaling regulates

Figure 6 Relationship between the TyG-WC index and the risks of BMD.

Notes: the nonlinear relationship between the TyG-WC index and the risk of BMD. The inflection points are 743.96 for Panel A and 743.71 for Panels B, C, and D. **(A)** Relationship between the TyG-WC index and the risk of BMD in a univariate analysis. The overall P value is 0.176, and the nonlinearity P value is 0.677. **(B)** Relationship between the TyG-WC index and the risk of BMD, adjusted for age, sex, education level, and body mass index. The overall P value is 0.531, and the nonlinearity P value is 0.619. **(C)** Relationship between the TyG-WC index and the risk of BMD, further adjusted for smoking history, drinking history, hypertension, and diabetes on the basis of Panel B. The overall P value is 0.609, and the nonlinearity P value is 0.439. **(D)** Relationship between the TyG-WC index and the risk of BMD, further adjusted for TC, HDL, and LDL on the basis of Panel C. The overall P value is 0.915, and the nonlinearity P value is 0.679.

osteoblast bone formation and osteoclast bone resorption, and this connection may affect fracture risk and the development of OP by modulating bone turnover markers (such as osteocalcin and tartrate-resistant acid phosphatase), insulin-like growth factor 1 (IGF-1), and cytokines secreted by adipose tissue in obese patients (such as TNF- α and IL-6).¹⁴ The TyG-related indices, which combine obesity markers as a surrogate for insulin resistance, play an important role in bone health, but the underlying mechanisms have yet to be fully elucidated.

The correlation between the TyG index, a surrogate marker of IR, and BMD, as well as its role in predicting the risk of OP, remains controversial. Most cross-sectional studies suggest that the TyG index is negatively correlated with BMD and can act as a risk factor for predicting OP. Specifically, a study conducted in a non-diabetic, middle-aged, and elderly Korean population found that both men and women had a negative correlation between the TyG index and femoral neck BMD, with the strongest association observed in women with a BMI < 23 kg/m².²⁰ Similarly, a large prospective study in China found that the TyG index was significantly associated with lower bone mass and an increased risk of OP in the femur, lumbar spine, and hip.²¹ A large-scale prospective cohort study in China also indicated that the TyG index is an independent influencing factor for osteoporosis.³⁹ However, contrary to these findings, Tian N. et al²⁶ reported a significant positive correlation between the TyG index and total BMD, with regression coefficients increasing when the TyG index exceeded 9.106. A similar positive correlation was observed in studies of HIV-infected populations.²⁷ Other studies, however, found no

association between the TyG index, BMD, and OP. For example, Chen H. et al²⁸ reported no significant correlation between the TyG index and femoral neck BMD or low bone mass. Similarly, a study on postmenopausal women with type 2 diabetes in Guangzhou found no significant correlation between the TyG index and BMD in the lumbar spine, femoral neck, or hip, nor with OP.²⁹ Consistent with these findings, our study also did not observe a significant correlation between the TyG index and femoral neck BMD or OP. This could be due to our small sample size, which may not fully reveal the association, or because we only examined the femoral neck BMD and OP, which may not reflect overall bone metabolism. Moreover, the mechanisms underlying the relationship between IR and bone metabolism are not fully understood,^{12–14} warranting further investigation into the relationship between the TyG index, BMD, and OP.

Several studies suggest that the TyG-BMI index, which incorporates obesity metrics, is positively correlated with BMD and may act as a protective factor against OP. Research has shown that a high BMI is associated with higher BMD and a lower risk of fractures in postmenopausal women, and an increase in BMI is associated with higher femoral neck BMD in men up to 35 kg/m².^{40,41} Tian N. et al²⁶ found a significant positive correlation between the TyG-BMI index and total BMD, with regression coefficients decreasing when the TyG-BMI index exceeded 193.9265. In non-diabetic US adults, the TyG-BMI index was positively correlated with femoral neck BMD, with higher TyG-BMI levels associated with a lower risk of OP, particularly in postmenopausal women over 40 and men over 60.²³ Similarly, Wen Z. et al²⁴ reported a positive correlation between the TyG-BMI index and femoral neck BMD, and a negative association with fracture risk in middle-aged and elderly non-diabetic men and women. Xuan X. et al²⁵ also found a positive correlation between the TyG-BMI index and femoral neck BMD in non-diabetic elderly individuals, with consistency across subgroup analyses by age, blood pressure, and other factors, although no typical dose-dependent positive correlation was observed across its quartiles. Consistent with previous studies, we also found a positive correlation between the TyG-BMI index and BMD, and further identified its protective role against OP. Our study further demonstrated that this index had a significant correlation with BMD in women, individuals under 70, those with or without hypertension, and non-diabetic populations, with the strongest correlation observed in non-hypertensive individuals. Multiple studies have shown a significant positive correlation between IR and low bone mass as well as OP, particularly in postmenopausal women.^{21,42} IR affects BMD and contributes to OP by regulating estrogen levels. Hypertension may lead to calcium loss, activate inflammatory pathways, and enhance sympathetic nervous system activity, thereby affecting bone mineral density.⁴³ In this study, the complex effects of women and hypertensive people on bone metabolism amplified the protective role of TyG-BMI in OP. Meanwhile, the relatively smaller sample size of the non-hypertensive group intensified the observed correlation. Additionally, we found that the TyG-BMI index served as a protective factor against OP, especially in women, individuals with hypertension, and non-diabetic populations. This might be related to metabolic changes associated with hyperglycemia. Research has found that IR has a dual effect on BMD. In diabetic populations, IR inhibits osteocalcin production, reducing bone turnover, bone strength, and cortical thickness.¹⁴ Additionally, Sun W. W. et al⁴⁴ suggested that a high TyG-BMI index in individuals with type 2 diabetes might be related to impaired bone turnover, potentially reducing the positive association between the TyG-BMI index and BMD.

Research on the relationship between the TyG-WC index and BMD is limited. Studies have found that WC is more strongly correlated with the absolute amount of visceral fat or abdominal fat,⁴⁵ and increased visceral fat is significantly associated with the prevalence of OP. Moderate accumulation of visceral fat may benefit bone health, but excessive visceral fat could have adverse effects.⁴⁶ Tian N. et al²⁶ found a significant positive correlation between the TyG-WC index and total BMD, with regression coefficients decreasing when the TyG-WC index exceeded 667.5304. The TyG index, when combined with WC, provides a more accurate reflection of the impact of abdominal obesity. Abdominal obesity may influence bone metabolism through inflammatory responses and the secretion of cytokines by adipose tissue.⁴⁷ In our study, we found that the Q4 of the TyG-WC index is a risk factor for OP. However, the nonlinear relationship between TyG-WC and BMD was not significant in the secondary outcomes. This may be due to the relatively small sample size of our study, which may cause statistical noise and not fully capture the complex relationship between TyG-WC and BMD. Nevertheless, these findings provide insights that the impact of TyG-WC on bone metabolism may vary across different population groups.

This study has several limitations. First, as a cross-sectional study, we could not establish causal relationships between the TyG index, its derivative indices, BMD, and OP, nor account for factors influencing disease progression.

Further research is needed to confirm the predictive value of these indices for OP and BMD. Second, our sample size was relatively small, which limits the generalizability of our findings regarding the association between TyG-related indices and BMD or OP. This may introduce statistical noise in the nonlinear regression analysis using RCS, necessitating a larger sample size for more reliable conclusions. Third, we only measured femoral neck BMD, which may have reduced the prevalence of OP in our sample. Future studies should consider more comprehensive assessments, including hip and lumbar spine BMD, to enhance the generalizability of the findings. Fourth, there were limitations in our control of confounding factors that may not fully account for all variables affecting the outcomes. It is important to note that our study did not include a detailed assessment of participants' daily outdoor physical activities, dietary habits, dairy consumption, vitamin D, calcium supplementation, and blood cell counts, 25-OH vitamin D, calcium, ALB, and bone turnover indices. The absence of this information, which could have provided a more comprehensive understanding of the factors influencing bone health, may limit the broad applicability of our conclusions. Future research should further explore these and other potential confounders to enhance the reliability of the findings. Lastly, due to data limitations, we only evaluated BMD without assessing the relationship between TyG-related indices and bone quality (eg, microstructure, bone shape). Further studies should explore these aspects.

Conclusions

This study found that the TyG-BMI index is a protective factor against OP, particularly in women, individuals with hypertension, and non-diabetic populations. The TyG-BMI index is positively associated with BMD, especially in women, individuals under 70, those with or without hypertension, and non-diabetic populations, with the strongest correlation observed in non-hypertensive individuals, which proves the reliability of the result from the side. In contrast, the Q4 of TyG-WC index is a risk factor for OP. Although BMD results do not confirm this point well, it also indicates that the predictive value of OP by TyG-WC index is a complex non-linear relationship, which is related to the selected population. These findings enhance our understanding of the relationship between TyG-related indices and bone health and provide clues for future studies on the relationship between these indices and OP. Monitoring TyG-related indices in hypertensive, non-diabetic women over 70 may help prevent the risk of OP and improve public health outcomes by enabling earlier treatment.

Data Sharing Statement

The datasets generated during and/or analyzed during the current study are available from the corresponding author on reasonable request.

Ethics Approval and Consent to Participate

The study adhered to the principles of the Declaration of Helsinki and was approved by the Ethics Committee of Tianjin Medical University General Hospital (approval number: IRB2018-100-01). All participants provided written informed consent.

Acknowledgments

We thank all participants of the Tianjin Brain Study, and local medical care professionals for their valuable contributions.

Author Contributions

All authors made a significant contribution to the work reported, whether that is in the conception, study design, execution, acquisition of data, analysis and interpretation, or in all these areas; took part in drafting, revising or critically reviewing the article; gave final approval of the version to be published; have agreed on the journal to which the article has been submitted; and agree to be accountable for all aspects of the work.
