Background: Cinnamic acid (CA) is a phytochemical originally derived from *Cinnamomum cassia*, a plant with numerous pharmacological properties. The intercalation of CA with a nanocarrier, zinc layered hydroxide, produces cinnamate-zinc layered hydroxide (ZCA), which has been previously characterized. Intercalation is expected to improve the solubility and cell specificity of CA. The nanocarrier will also protect CA from degradation and sustain its release. The aim of this study was to assess the effect of intercalation on the anti-inflammatory capacity of CA.

Methods: In this study, the anti-inflammatory activity of ZCA was investigated and compared with that of nonintercalated CA. Evaluations were based on the capacity of ZCA and CA to modulate the release of nitric oxide, prostaglandin E₂, interleukin (IL)-6, tumor necrosis factor alpha (TNF- α), IL-1 β , and IL-10 in lipopolysaccharide-induced RAW 264.7 cells. Additionally, the expression of proinflammatory enzymes, ie, cyclooxygenase-2, inducible nitric oxide synthase, and nuclear factor kappa B (NF- κ B), were examined.

Results: Although both ZCA and CA downregulated nitric oxide, prostaglandin E₂, tumor necrosis factor alpha, IL-1 β , and IL-6, ZCA clearly displayed better activity. Similarly, expression of cyclooxygenase-2 and inducible nitric oxide synthase were inhibited in samples treated with ZCA and CA. The two compounds effectively inactivated the transcription factor NF- κ B, but the anti-inflammatory cytokine, IL-10, was significantly upregulated by ZCA only.

Conclusion: The present findings suggest that ZCA possesses better anti-inflammatory potential than CA, while zinc layered hydroxide had little or no effect, and these results were comparable with the positive control.

Keywords: cinnamic acid, zinc layered hydroxide, inflammation, RAW 264.7 cells

Introduction

Inflammation is a beneficial host response to foreign attack or tissue injury that eventually leads to restoration of normal tissue structure and function.^{1,2} Acute inflammation is a controlled beneficial process, especially in response to infectious agents, but chronic inflammation is an obnoxious persistent phenomenon that may result in inflammatory disease.^{3,4} Detection of invaders through a wide range of foreign molecular patterns, which induce initiation of the protective innate immunity and inflammatory process, encompasses the first line of the body's defense system. The major components of innate immunity are phagocytes (macrophages, neutrophils, and dendritic cells), complement system protein, and natural killer cells.^{5,6} Although the first immune cells

to reach an area of attack are the neutrophils, macrophages mastermind the activation of the inflammatory reaction.^{7,8}

Macrophages and other activated inflammatory cells secrete high amounts of prostaglandin PGE₂ (PGE₂), nitric oxide (NO), and cytokines, such as interleukin (IL)-6, tumor necrosis factor alpha (TNF- α), and IL-1 β . Undoubtedly, host defense is complemented by these mediators, and their uncontrolled production can be a factor in the pathogenesis of many diseases, such as rheumatoid arthritis, atherosclerosis, sepsis, and pulmonary fibrosis.^{9–11} They may also induce cell and tissue damage.^{12,13} Since the production of these soluble factors is associated with macrophages, they are considered to play a critical role during inflammation by managing various immunopathological phenomena.^{14,15} Likewise, the presence of these mediators in the macrophages of inflammatory tissues with increased expression of their mRNAs, following exposure to an inflammatory stimulus, has been proven. Thus, inhibiting the production of these mediators remains a critical target in combating inflammatory diseases.^{16,17}

Cinnamomum cassia, an evergreen plant of the *Lauraceae* family, has long been associated with the treatment of inflammatory disease, dyspepsia, blood circulation disturbances, and gastritis. Its extracts contain phenolics such as cinnamic alcohol, cinnamic aldehyde, coumarin, and cinnamic acid (CA).^{18,19} CA has recently demonstrated significant anti-inflammatory potential in both in vitro and in vivo experiments.²⁰ Apart from its antioxidant properties, CA has been found to reduce cell proliferation by 50% in melanoma, glioblastoma, and lung and prostate carcinoma cells.^{21,22} The compound also displayed antidiabetic activity in insulin-resistant FL83B cells.²³

Basically, the factors that determine the effect of a drug molecule are its natural therapeutic activity and its efficient delivery at the site of action.^{24,25} However, most conventional drugs or therapeutic agents suffer from nonspecificity of action, degradation of the drug before reaching the target site (low bioavailability or failure to traverse the blood–brain barrier), and poor solubility in the delivery medium. Drug intercalation with nanoparticles improves their efficacy by sustaining release and targeting the cell surface rising ligands connected with membrane disruption and endosomal uptake. They also permit drug release in the cell cytoplasm and shield the drug from enzymatic degradation.^{26–28} Use of inorganic nanoparticles in nanodrug development has gained considerable acceptance in recent times, due to their versatile features such as good biocompatibility, wide availability, rich surface functionality, and prospective capability of drug delivery.^{29–32}

Intercalation of an active compound into inorganic nanoparticles such as zinc layered hydroxide (ZLH) has been successful due to the anionic exchange capacity of the nano-carrier. Apart from CA, many compounds of pharmacological importance have been successfully loaded into ZLH. These include gallic acid,^{33,34} nucleoside monophosphate, DNA,^{35,36} linoleic acid,³⁷ and sunscreen materials such as 4-amino benzoic acid.^{38,39} This study was designed to determine the effect of intercalation on the anti-inflammatory potential of CA by evaluating the production and expression of various inflammatory mediators, ie, NO, PGE₂, TNF- α , IL-6, IL-1 β , IL-10, cyclooxygenase-2 (COX-2), inducible NO synthase (iNOS), and nuclear factor kappa B (NF- κ B), in lipopolysaccharide (LPS) stimulated RAW 264.7 macrophages.

Materials and methods

Materials

The RAW 264.7 cell line was sourced from the American Type Culture Collection (ATCC, Manassas, VA, USA), cultured and maintained in Dulbecco's modified Eagle's medium, and supplemented with 10% fetal bovine serum and 1% antibiotics. LPS and dexamethasone were sourced from Nacalai Tesque Inc (Tokyo, Japan). CA was supplied by Acros (Geel, Belgium), while ZLH and cinnamate-ZLH (ZCA) were synthesized and characterized in the Institute of Advanced Technology, Universiti Putra Malaysia.³⁹ PGE₂ and an enzyme-linked immunosorbent assay kit were purchased from R&D Systems (Minneapolis, MN, USA). All Western blotting apparatus and reagents were from Bio-Rad (St Louis, MO, USA). The primary antibodies iNOS, COX-2, NF- κ B, and appropriate secondary antibodies (goat anti-rabbit and goat anti-mouse) were purchased from Santa Cruz Biotechnology (Dallas, TX, USA). Enhanced chemiluminescence substrates were manufactured by Nacalai Tesque Inc, while the polyvinylidene fluoride membrane was from Bio-Rad.

Synthesis of nanocomposite and characterization

ZLH and ZCA were synthesized and characterized in the Institute of Advanced Technology, Universiti Putra Malaysia. ZLH was synthesized by a conventional coprecipitation method using aqueous solutions of zinc nitrate hexahydrate.⁴⁰ ZnO was used as the parent material in the synthesis of ZCA through a newly developed direct method.³⁹ Hydrolysis of ZnO formed a layer of Zn(OH)₂, while the reaction of Zn ion species, hydroxyls, water, and cinnamate anions in the solution generated ZCA. Basal spacing of the nanocomposite

obtained from power X-ray diffraction was 23.9 Å following intercalation of cinnamate between the interlayer spaces of ZLH. Fourier transform infrared analysis showed that the nanocomposite possesses the absorption characteristics of both ZLH and pure CA. However, elemental analysis showed that 40.4% w/w of CA was contained in the nanohybrid, and the intercalated compound exhibited excellent ultraviolet A and B capacity. ZnO exhibited a slow absorption rate, reaching an optimal uptake at 8 cm³/g, but after intercalating CA into ZLH layers, the adsorption uptake reached 37 cm³/g. In addition, various types of medium were used to show slow and saturated release at low concentrations as evidence of retention of cinnamate in the ZLH interlayers. The resultant ZCA was found to be an effective and safe sunscreen agent.³⁹

Cell viability assay

Cell viability was determined by the ability of mitochondrial reductase to convert 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) to formazan dye. Overnight culture of RAW 264.7 cells in 96-well plates was done at a density of 1.5×10⁴ cells/100 µL in each well. This was followed by treating the cells with ZCA, CA, and ZLH for 24 hours, after which 10 µL of MTT at a concentration of 5 mg/mL was added to each well and kept in a 5% CO₂ incubator for 4 hours at 37°C. The MTT solution was then removed and 100 µL of dimethyl sulfoxide was added to each well to lyse the cells. A Lambda 35 microplate reader (Perkin-Elmer, Boston, MA, USA) was used to measure absorbance at 570 nm.

Determination of NO production

RAW 264.7 cells were seeded in 24-well culture plates at a density of 2×10⁵ cells/well in 1 mL of culture medium followed by overnight incubation. Confluent cells were treated with varying concentrations of ZCA, CA, and ZLH (2.5, 5 and 10 µg/mL) for one hour. The cells were then challenged with a 1 µg/mL concentration of LPS and incubated for a further 24 hours. Accumulated nitrite in the culture medium was measured as a representative of NO production using Griess reagent (0.1% N-1-[naphthyl] ethylenediamine dihydrochloride and 1% sulphanilamide and 5% H₃PO₄). Next, 100 µL of cell supernatant and an equal amount of Griess reagent were plated in each well of a 96-well plate. They were incubated for 10 minutes followed by absorbance reading at 550 nm.

Determination of cytokine production

The inhibitory effect of ZCA on the production of IL-6, IL-1β, TNF-α, and IL-10 were determined by enzyme-linked

immunosorbent assay using medium collected from the treated cells. RAW 264.7 cells were seeded into a six-well plate at a density of 2×10⁵ cells/well and incubated overnight. The cells were then treated with ZCA, CA, and ZLH (2.5, 5 and 10 µg/mL) for one hour. This was followed with addition of 1 µg/mL LPS for 24 hours to induce inflammation. Culture supernatants were assayed according to the protocol of the enzyme-linked immunosorbent assay kit (R&D Systems) to measure the amount of IL-6, IL-1β, TNF-α, and IL-10 produced in each sample. The experiment was carried out in triplicate.

Determination of PGE₂ level

RAW 264.7 cells plated at a density of 2×10⁵ in six-well plates were incubated overnight. Confluent cells were then treated with ZCA, CA, or ZLH at concentrations of 2.5, 5, and 10 µg/mL for one hour, followed by induction of inflammation with LPS for another 24 hours. The concentration of PGE₂ was determined using a PGE₂ immunoassay kit (R&D Systems) according to the manufacturer's guidelines.

Western blot analysis

Confluent RAW 264.7 cells were treated with ZCA, CA, or ZLH (2.5, 5, and 10 µg/mL) for one hour and then challenged with LPS 1 µg/mL for 24 hours. Thereafter, the cells were scraped and centrifuged at 1,200 rpm for 10 minutes at 4°C. The supernatant was discarded, and phosphate-buffered saline was added followed by centrifugation at 1,200 rpm for 10 minutes at 4°C. Ice-cold cell lysis buffer were added to the cells for 30 minutes with intermittent shaking. Finally, the cells were centrifuged at 14,000 rpm for 30 minutes at 4°C. Protein concentrations in the samples were estimated using a bicinchoninic acid protein assay kit with bovine serum albumin as the standard. Total proteins (20 µg) were separated by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) using 10% polyacrylamide gel and transferred to a polyvinylidene fluoride membrane. Blocking was done with 5% skimmed milk in PBST (1% v/v Tween-20 in phosphate-buffered saline, pH 7.2) for one hour. The membranes were thereafter incubated with anti-mouse iNOS, anti-mouse NF-κB, and anti-mouse COX-2 (Santa Cruz Biotechnology) in a 1:1,000 concentration at 4°C overnight. The membranes were then washed six times in PBST at regular intervals for one hour. This was followed by incubation with horseradish peroxidase-conjugated goat anti-rabbit and goat anti-mouse, immunoglobulin G secondary antibodies (Santa Cruz Biotechnology) at a concentration of 1:2,000 for one hour. Membranes were finally washed six times in PBST for 10 minutes each. Chemiluminescence

substrate (Thermo Scientific, Rockford, IL, USA) was used to reveal the blots detected with Chemidoc™ XRS (Bio-Rad). Intensity of the blots was finally analyzed using Bio-Rad Lab image software.

Statistical analysis

The statistical significance of differences between the various experimental values and control values was determined using the Student's *t*-test. The data are expressed as the mean \pm standard deviation, and the results were selected from at least three independent experiments performed in triplicate. *P*-values of 0.05 or less were considered to be statistically significant.

Results

Effect of ZCA, CA, and ZLH on cell viability

The cytotoxicity potential of compounds, ie, CA intercalated with ZLH (ZCA) which is the nanocomposite of interest, CA and the nanocarrier system, ZLH, were tested in RAW 264.7 cells. As shown in Figure 1, incubation of cells with ZCA showed a 40% reduction in cell viability at 40 μ g/mL, but cell viability was above 80% when ZCA 20 μ g/mL was incubated with confluent cells. While coinubation of cells with ZLH 40 μ g/mL yielded 53% cell viability, other concentrations showed more than 80% cell viability. However, CA did not display any toxicity even at 40 μ g/mL. Nevertheless, the three concentrations (2.5, 5.0, and 10.0 μ g/mL) were chosen for subsequent assays and analysis.

Effects of ZCA on LPS-induced NO production

The inhibitory effect of ZCA on the production of NO was investigated using LPS-activated RAW 264.7 macrophages.

Inhibition of NO by ZCA occurred in a dose-dependent manner (47.66%, 52.52%, and 65.12% at 2.5, 5, and 10 μ g/mL, respectively, as shown in Figure 2). The activity displayed by CA was lower than that of ZCA when the compound was incubated with LPS-stimulated RAW 264.7 macrophages. CA achieved 36.31%, 39.198%, and 53.27% inhibition of NO production at 2.5, 5, and 10 μ g/mL, respectively. ZLH did not show any significant inhibitory activity. However, dexamethasone, which served as the positive control, was found to inhibit the production of NO by 86.24%.

Effect of ZCA on PGE₂ biosynthesis

The downregulatory activity of ZCA on production of the proinflammatory marker PGE₂ was investigated using LPS-activated RAW 264.7 cells. Enzyme-linked immunosorbent assay results showed a significant increase in levels of PGE₂ in the culture supernatants of RAW 264.7 cells stimulated with LPS (7,611.62 pg/mL) compared with nonstimulated cells (197.65 pg/mL). Addition of ZCA to the mixture significantly inhibited the production of PGE₂ at different concentrations, as shown in Figure 3. The activity of ZCA in samples treated with 10.0 μ g/mL was the highest, ie, 89.98% (762.34 pg/mL) inhibition ($P < 0.01$), while inhibition was 53.14% (3,566.70 pg/mL) at 5 μ g/mL and 48.35% (3,931.35 pg/mL) at 2.5 μ g/mL. CA showed comparatively lower effects, ie, 10.65% (6,800.70 pg/mL), 20.16% (6,077.59 pg/mL), and 57.73% (3,069.84 pg/mL) inhibition at 2.5, 5.0, and 10.0 μ g/mL, respectively. ZLH exhibited the lowest inhibitory activity, ie, 0.78% (7,551.19 pg/mL), 3.50% (7,345.56 pg/mL), and 2.27% (7,438.53 pg/mL). The inhibitory effect of the positive control drug, dexamethasone, was 49.94% (3,760.05 pg/mL).

Notes: The data are presented as the mean \pm standard deviation of three independent experiments. ** $P < 0.01$ versus untreated lipopolysaccharide-stimulated group.

Abbreviations: CA, cinnamic acid; ZCA, cinnamate-zinc layered hydroxide; ZLH, zinc layered hydroxide.

Figure 2 Inhibitory effects of ZCA on LPS-induced NO production in RAW 264.7 macrophages.

Notes: Production of NO was assayed in the culture medium of macrophages pretreated with ZCA, CA, and ZLH (2.5, 5, and 10 µg/mL, respectively) and later stimulated with LPS (1 µg/mL) for 24 hours. Each value indicates the mean \pm standard deviation of three independent experiments. * $P < 0.05$, ** $P < 0.01$ versus untreated LPS-stimulated group.

Abbreviations: CA, cinnamic acid; LPS, lipopolysaccharide; NO, nitric oxide; ZCA, cinnamate-zinc layered hydroxide; ZLH, zinc layered hydroxide; DEX, dexamethasone.

Effect of ZCA on LPS-induced production of proinflammatory cytokines

The concentrations of IL-6, TNF- α , and IL-1 β (suggestive of proinflammatory cytokine activity) and IL-10 (suggestive of anti-inflammatory activity) in the treated RAW 264.7 cells are shown in Figure 4A–D, respectively. The results indicate that concurrent ZCA or CA treatment with LPS-stimulated cells significantly inhibited levels of IL-6, TNF- α , and IL-1 β . Although production of IL-6 was reduced by both ZCA and CA in a similar manner, the inhibitory activity of ZCA in the synthesis of TNF- α was comparatively higher. While

Figure 3 Inhibitory effect of ZCA on LPS-induced production of PGE₂ in RAW 264.7 macrophages.

Notes: Production of PGE₂ was assayed according to an enzyme-linked immunosorbent assay protocol, using the culture medium of confluent cells pretreated with ZCA, CA, and ZLH (2.5, 5, and 10 µg/mL, respectively) and later stimulated with LPS (1 µg/mL) for 24 hours. Each value indicates the mean \pm standard deviation of three independent experiments. * $P < 0.05$ and ** $P < 0.01$ versus untreated LPS-stimulated group.

Abbreviations: CA, cinnamic acid; DEX, dexamethasone; LPS, lipopolysaccharide; PGE₂, prostaglandin E₂; ZCA, cinnamate-zinc layered hydroxide; ZLH, zinc layered hydroxide.

CA exhibited 15.60%, 15.83%, and 19.96% inhibition at 2.5, 5 and 10 µg/mL, respectively, ZCA inhibited TNF- α production by more than 40% in all treatments. The highest augmentation of IL-1 β inhibition was observed in samples treated with ZCA at a concentration of 10 µg/mL. Although inhibitory activity of ZLH was not significant when compared with nanocomposite, ZCA and free drug CA.

In the case of anti-inflammatory cytokine activity, ZCA treatment potentiated a significant rise in levels of IL-10 in RAW 264.7 macrophages. In comparison with LPS-stimulated groups, ZCA treated samples were highly significant ($P < 0.01$), with 17.17% upregulation at 10 µg/mL, while its activity at 2.5 and 5 µg/mL was less significant ($P < 0.05$), with upregulation of 8.31% and 8.43%, respectively. Although CA upregulated the IL-10 cytokine at all three concentrations applied, the effect of CA was not significant when compared with samples stimulated with LPS alone. In contrast, treatment with ZLH did not improve production of IL-10.

Effects of ZCA on LPS-induced COX-2, iNOS and NF- κ B expression

The effect of ZCA on the protein expression of iNOS, COX-2, and NF- κ B was investigated using LPS-induced RAW 264.7 macrophages. From the Western blotting data shown in Figure 5, nonstimulated RAW 264.7 cells lacked iNOS activity. When the cells were induced with LPS, some level of iNOS expression was observed. On the other hand, expression of iNOS protein was significantly reduced by ZCA and CA when incubated with LPS-stimulated RAW 264.7 cells.

Additionally, while COX-2 was hardly detected in non-stimulated cells, high expression of the enzyme was observed on Western blotting analysis in samples treated with ZLH at 5.0 and 10.0 µg/mL (Figure 5). Both ZCA and CA exhibited low expression of COX-2 in contrast with the expression observed in samples treated with LPS alone. RAW 264.7 cells incubated with LPS alone showed a high intensity of NF- κ B, while samples pretreated with ZCA and CA before LPS stimulation showed downregulated expression of NF- κ B. Although CA inhibited NF- κ B to a better extent than the intercalated compound, the activities of the two compounds were highly significant ($P < 0.01$), as shown in the analysis. Again, high expression of NF- κ B was observed in samples treated with the nanocarrier, ZLH. Nevertheless, dexamethasone inhibited NF- κ B in a manner comparable with that of CA.

Discussion

The role of macrophages in many inflammatory processes highlights their importance in both innate and adaptive

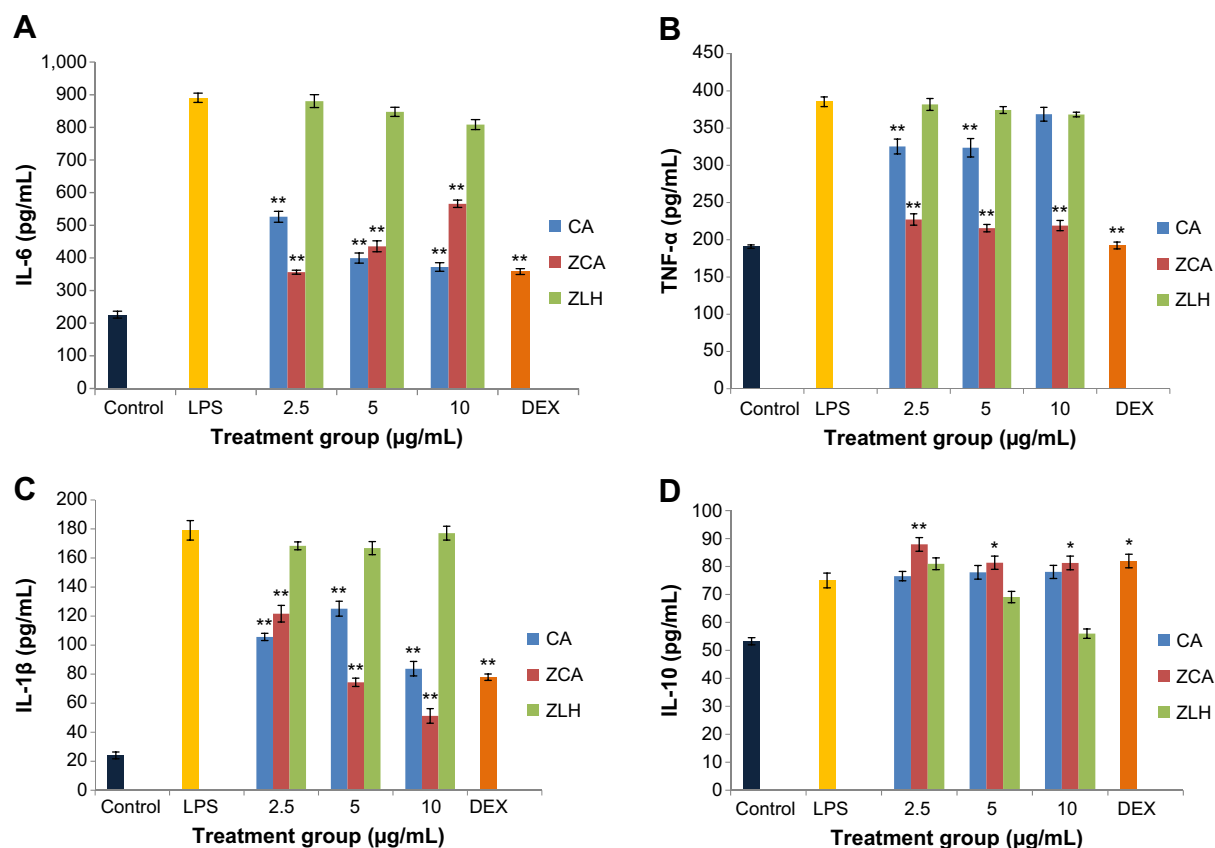

Figure 4 (A–D) Effect of ZCA on IL-6, TNF- α , IL-1 β , and IL-10 production in LPS stimulated RAW 264.7 macrophages.

Notes: Production of cytokines was assayed according to an enzyme-linked immunosorbent assay protocol using the culture supernatant of macrophages pretreated with ZCA, CA, and ZLH (2.5, 5, and 10 $\mu\text{g/mL}$) and later stimulated with LPS (1 $\mu\text{g/mL}$) for 24 hours. Each value indicates the mean \pm standard deviation of three independent experiments. * $P < 0.05$, ** $P < 0.01$ versus untreated LPS-stimulated group.

Abbreviations: CA, cinnamic acid; DEX, dexamethasone; IL, interleukin; LPS, lipopolysaccharide; TNF- α , tumor necrosis factor alpha; ZCA, cinnamate-zinc layered hydroxide; ZLH, zinc layered hydroxide.

immunity.^{41,42} Macrophages are associated with many disease conditions, such as inflammation, infection, atherosclerosis, lupus, cancer, and diabetes.⁴³ In this study, the RAW 264.7 macrophage was selected to evaluate the potential of CA-ZLH intercalation to improve the anti-inflammatory properties of CA. Some recent studies have reported the anti-inflammatory activity of CA.⁴⁴ However, its effect on the production of NO, PGE₂, and cytokines in LPS-stimulated RAW 264.7 cells is yet to be reported. Apart from a report on the potential of ZCA as a sunscreen agent with an ultraviolet protection effect,³⁹ there is no report on the anti-inflammatory activity of the nanocomposite (ZCA) in LPS-induced inflammation.

The LPS endotoxin triggers an extensive injury to the macrophage. Apart from a reduced capacity to produce antigen, synthesis of important mediators, such as reactive oxygen species, free radicals, cytokines, and bioactive lipids, are altered.^{45–47} In recent times, treatment of inflammatory disorders has been largely based on inhibiting the action or synthesis of important mediators that prompt the host's response to attack. Many therapeutic agents, such

as nonsteroidal anti-inflammatory drugs, steroids, and histamine, were developed based on this strategy. Data acquired from the assays undertaken in this research confirm that LPS endotoxin activates significant production of NO, PGE₂, and inflammatory cytokines (IL-6, TNF- α , IL-1 β), in RAW 264.7 cells.

However, the data reported in the previous sections show the enhanced anti-inflammatory potential of the ZCA nanocomposite when compared with CA. Synthesis of ZCA involved loading of only 40.4% of CA between the ZLH interlayers, but ZCA reduced the production of inflammatory markers in a manner comparable with that of the positive control. Samples treated with ZCA at all concentrations showed low levels of NO, providing clear evidence that the intercalation enhanced the anti-inflammatory activity of CA. The inhibitory effect of ZCA on production of NO may be associated with downregulation of iNOS expression by the same compound (Figure 5). NO production is strongly linked with the continuous synthesis of iNOS, which breaks down arginine to NO and citrulline. Increased NO production is

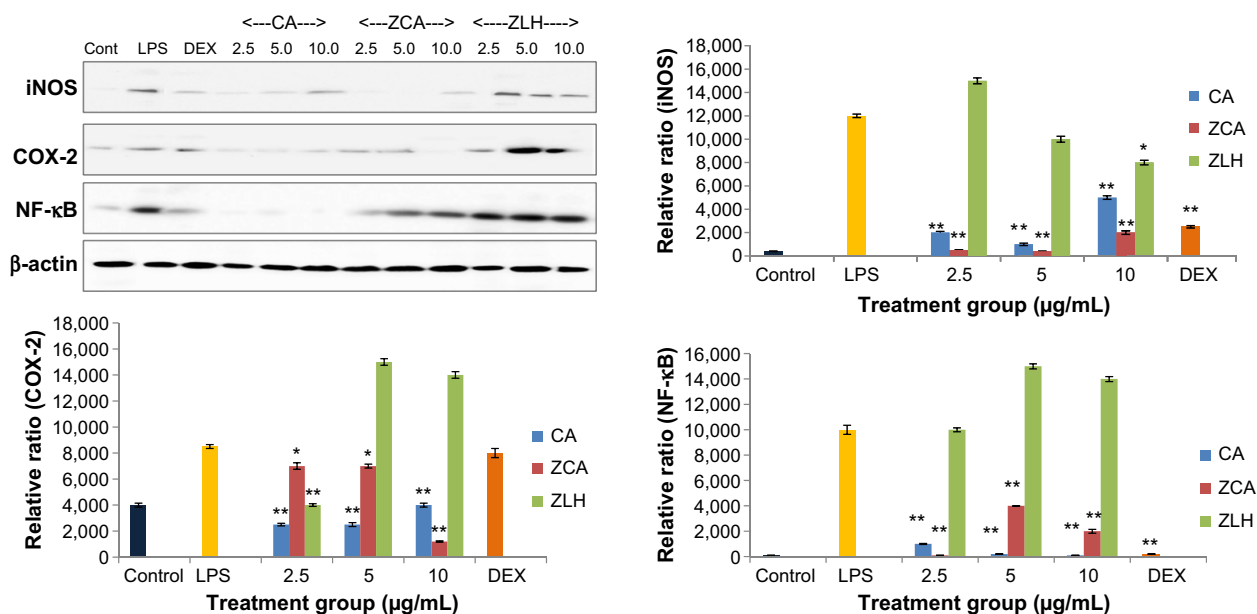

Figure 5 Inhibitory effect of ZCA on LPS-induced iNOS, COX-2, and NF-κB expression in LPS stimulated RAW 264.7 macrophages.

Notes: RAW 264.7 macrophage cells were pretreated with ZCA, CA, and ZLH (2.5, 5, and 10 μg/mL) for one hour. The cells were then challenged with LPS 1 μg/mL for 24 hours. Levels of NF-κB expression were detected with immunoblotting using NF-κB antibodies while β-actin served as the internal control. * $P < 0.05$, ** $P < 0.01$ versus untreated LPS-stimulated group.

Abbreviations: CA, cinnamic acid; Cont, control; COX-2, cyclooxygenase-2; DEX, dexamethasone; iNOS, inducible nitric oxide synthase; LPS, lipopolysaccharide; NF-κB, nuclear factor kappa B; ZCA, cinnamate-zinc layered hydroxide; ZLH, zinc layered hydroxide.

observed in various diseases, and NO synthase inhibitors have successfully reversed many classic signs and symptoms of inflammation.^{48,49} Mulligan et al, using experimental rats with immune complex-induced lung injury, found that inhibitors of NO synthesis have protective properties in this model.⁵⁰ In contrast, L-arginine, which is a precursor of NO, complicates tissue injury. Similarly, the effect of inflammatory bowel disease was reduced in experimental animals with induced colitis by administration of two different NO synthase inhibitors, ie, N-nitro-L-arginine methyl ester and aminoguanidine.^{48,49} Therefore, any compound that is capable of inhibiting iNOS, like ZCA, may be a potential anti-inflammatory agent.

Further, the effect of ZCA in inhibiting production of PGE₂ was not only significant at the lowest concentration but comparatively better than CA and even dexamethasone (Figure 3). COX-2 is a key mediator in the inflammatory process, and is responsible for production of PGE₂ from arachidonic acid. Downregulation of COX-2 is therefore a condition for the inhibition of PGE₂, which is expressed in all processes that lead to major signs of inflammation, ie, swelling, redness, and pain.^{51,52} Hence, in Figure 3 and Figure 5 there is a strong relationship between the activity of ZCA, where the expression of COX-2 was significantly inhibited by the nanocomposite. Administration of N-398, a COX-2 inhibitor, after treatment with carrageenan lowered the production of PGE₂ and the same pattern was observed

in COX-2 knockout mice. Deficiency of COX-2 was also observed to reduce PGE₂ by 75%.^{53,54} The COX-2/PGE₂ pathway is the major target for designing pain-relieving drugs for osteoarthritis, but most nonsteroidal anti-inflammatory drugs inhibit the activity of COX-1/COX-2, which may result in unwanted side effects. Limited side effects are some of the advantages of drugs such as celecoxib that exclusively target COX-2.^{55–57} ZCA is a potential anti-inflammatory agent that can selectively block the synthesis of the inducible enzyme, COX-2.

The inhibitory effect of ZCA on the secretion of TNF-α in Figure 4B and a similar downregulation of IL-1β in Figure 4C (5.0 μg/mL and 10.0 μg/mL) were better than with CA. The carrier system did not have any inhibitory effects on these cytokines, which dispels any possibility of ZLH contributing to the anti-inflammatory activity of ZCA. Proinflammatory cytokines like TNF-α, IL-1β, and IL-6 are small molecules that modulate inflammation and immunity. Bacterial LPS activates macrophages to secrete TNF-α, and the released TNF-α or LPS then triggers production of IL-6 and IL-1β.^{58,59} TNF-α induces many physiological changes, including inflammation, septic shock, and cytotoxicity.⁶⁰ However, anti-TNF therapy triggers a rapid improvement in many serological parameters and histological characteristics of the synovium.^{61–63} Blockade of TNF-α activity has also been linked with improved survival in animal models of sepsis and shock.^{64–66}

The inhibition of TNF- α and other cytokines may be connected with low expression of NF- κ B in samples treated with ZCA and CA, as shown in Figure 5. NF- κ B is a key transcription factor that coordinates the expression of proinflammatory cytokines and enzymes.^{7,67} Treatment with anti-TNF- α antibody after LPS activation inhibited TNF- α and NF- κ B in an in vivo animal model; moreover, the kinetics of the NF- κ B activation and TNF- α secretion triggered by LPS in this model were similar.^{68,69} This shows that any treatment that affects the expression of NF- κ B is likely to influence the production of proinflammatory cytokines. Agents that block proximal cytokines such as TNF- α and IL-1 β also restrict activation of NF- κ B, thereby inhibiting the inflammatory cascade.^{70,71}

It has been established that IL-10 influences the inflammatory process by suppressing inflammatory mediators, including proinflammatory cytokines, adhesion molecules, and antigen-presenting molecules in neutrophils, monocytes/macrophages, and T-cells.^{72,73} IL-10 blocks the expression of proinflammatory cytokines such as IL-6, TNF- α , and IL-1 β in activated macrophages. In specific terms, it upregulates other endogenous anticytokines and inhibits proinflammatory cytokine receptors.^{59,74} Therefore, it can counter-regulate the release and roles of proinflammatory cytokines at multiple levels. Given that inflammatory proteins are transcriptionally regulated by NF- κ B, it has been proposed that IL-10 may express a major part of its anti-inflammatory activity by inhibiting the transcription factor.^{75–77} As a result, upregulation of IL-10 may be associated with inhibition of NF- κ B by ZCA and CA.

NF- κ B is known for its unique role in coordinating the immune and inflammatory responses.⁷⁸ They are identifiable with the homodimer or heterodimer structure of the Rel proteins. In resting cells, NF- κ B forms an inactive complex with inhibitory κ B (I κ B) proteins like I κ B α , I κ B β , and I κ B ϵ .⁷⁹ Upon recognition of LPS by toll-like receptor-4 and MD2, its accessory protein attached to immune cells and activates the I κ B kinase (I κ K) complex, which phosphorylates cytoplasmic I κ Bs.^{80,81} Subsequently, ubiquitin-mediated degradation of I κ Bs occurs, and NF- κ B is liberated and moves into the nucleus. The binding of NF- κ B to the κ B sequences regulates the transcription of immune and inflammatory genes such as COX-2, iNOS, and inflammatory cytokines (IL-6, IL-1 β , TNF- α , IL-10).⁸² Since the expression levels of these proinflammatory mediators are regulated by NF- κ B, our findings suggest that their production is transcriptionally inhibited by ZCA by blocking of the NF- κ B signaling pathway.

Finally, findings from ELISA and western blot analysis revealed that ZLH exhibited a slight upregulation of inflammatory enzymes and NF- κ B activation in LPS stimulated RAW cells. Although, ZLH has been found to have a low toxicity profile, studies have shown that some nanomaterials have the potential to stimulate inflammatory reactions. Notably, ZnO, which can serve as precursor for ZLH, has been reported to cause marginal production of IL-6 and IL-8 in HK-2 and HEK 293 cells. Release of ions by ZnO materials has been proposed as the likely mechanism of cytotoxicity.^{39,83} Studies have also shown that nanoparticles generate reactive oxygen species through interaction with the plasma membrane, but the cell has a self-repair mechanism to maintain its integrity, and overexpression of inflammatory mediators may not be associated with production of reactive oxygen species.⁸⁴ The increased level of inflammatory mediators beyond the negative control thresholds may be due to a synergistic action between LPS and ZLH. Nonetheless, ZLH on its own was not toxic at the doses applied.

Conclusion

The present study is an example of fundamental research towards developing ZCA as a strong anti-inflammatory nanomedicine. Our results suggest that ZCA has better inhibitory activity for LPS-stimulated proinflammatory mediators than that of the free drug, CA. Therefore, ZCA possess therapeutic potential for the regulation and modulation of macrophage activation, and may serve as effective alternative treatment for a number of inflammation-mediated diseases.
