Objective: The aim of this study was to investigate the fractional anisotropy (FA) and mean diffusivity (MD) using a diffusion tensor imaging technique and whole-brain voxel-based analysis in patients with comitant strabismus.

Patients and methods: A total of 19 (nine males and ten females) patients with comitant strabismus and 19 age-, sex-, and education-matched healthy controls (HCs) underwent magnetic resonance imaging examination. Imaging data were analyzed using two-sample *t*-tests to identify group differences in FA and MD values. Patients with comitant strabismus were distinguishable from HCs by receiver operating characteristic curves.

Results: Compared with HCs, patients with comitant strabismus exhibited significantly decreased FA values in the brain regions of the left superior temporal gyrus and increased values in the bilateral medial frontal gyrus, right globus pallidus/brainstem, and bilateral precuneus. Meanwhile, MD value was significantly reduced in the brain regions of the bilateral cerebellum posterior lobe and left middle frontal gyrus but increased in the brain regions of the right middle frontal gyrus and left anterior cingulate.

Conclusion: These results suggest significant brain abnormalities in comitant strabismus, which may underlie the pathologic mechanisms of fusion defects and ocular motility disorders in patients with comitant strabismus.

Keywords: comitant strabismus, diffusion tensor imaging, mean diffusivity, fractional anisotropy, resting state

Introduction

Strabismus is a very common eye disease characterized by abnormal eye movements. According to Fu et al,¹ the prevalence of strabismus was 108 out of 2,260 (5.0%) eligible students in the Central China. Strabismus can be roughly divided into comitant strabismus and incomitant strabismus. Strabismus is not only a cosmetic disease but also causes severe damages to visual acuity (VA), binocular vision, and stereopsis.² Surgery is currently the main treatment for strabismus.³

Strabismus demonstrates abnormal eye movements, which is accompanied by dysfunction of the cerebral cortex. A previous study showed that eye monosynaptic interhemisphere connections existed in strabismus cats.⁴ Other studies reported the abnormalities of visual cortex structure in infantile esotropic macaque monkeys.^{5,6} Another study demonstrated visual cortex suppression in patients with strabismus.⁷

Diffusion tensor imaging (DTI) is a widely used magnetic resonance imaging (MRI) modality that depicts water diffusion directionality as mean diffusivity (MD) and fractional anisotropy (FA).⁸ The MD value measures the total amount of diffusion within a

voxel and provides the overall magnitude of water diffusion, while the FA value is a scalar value between 0 and 1 calculated from the eigenvalues (λ_1 , λ_2 , and λ_3) of the diffusion tensor. It measures the overall directionality of water diffusion and reflects the complexity of cytoskeleton architecture, which restricts the intra- and extracellular water movement.⁹ The direction of water diffusion can indicate myelin sheath damage and tissue changes. Consequently, DTI has been applied to study various diseases, such as schizophrenia¹⁰ and stroke.¹¹ DTI has also been used to evaluate brain microstructural changes of patients with strabismus amblyopia. Duan et al¹² found that MD values were increased not only in optic radiation but also in certain brain regions of strabismus amblyopia patients with the DTI method. However, very few studies used the DTI strategy to investigate the microstructural changes in comitant strabismus. Here, to our knowledge, our study is the first to explore whole-brain microstructural changes in patients with comitant strabismus.

Patients and methods

Patients

A total of 19 patients with comitant strabismus (nine males and ten females; four esotropia; and 15 exotropia) were recruited from the First Affiliated Hospital of University of South China and the Department of Ophthalmology, The First Affiliated Hospital of Nanchang University. The diagnostic criteria for comitant strabismus were as follows: 1) strabismus starting from birth; 2) stereovision defects (no visual fusion); 3) equal binocular corrected VA; and 4) with alternated cover, the experimental and strabismus angle were equal. Patients were excluded if they met any one of the following conditions: 1) acquired strabismus, incomitant strabismus, and concealed oblique; 2) eye diseases (infection, inflammation, and ischemic diseases); 3) history of eye surgeries (extraocular or intraocular surgeries); 4) psychiatric disorders (obsessive-compulsive disorder, anxiety disorder, schizophrenia, depression, etc), diabetes, cardiovascular diseases, and cerebral infarction diseases; and 5) addictions (eg, drugs and alcohol).

Nineteen healthy controls (HCs; nine males and ten females) with similar age, sex, and education status were also recruited from healthy volunteers from citizens of Nanchang, Jiangxi, People's Republic of China. All HCs met the following requirements: 1) no abnormalities in the brain parenchyma on cranial MRI; 2) no ocular diseases with uncorrected or corrected VA >1.0; 3) no psychiatric diseases (obsessive-compulsive disorder, anxiety disorder, schizophrenia, depression, etc); and 4) able to undergo MRI

(eg, no cardiac pacemaker or implanted metal devices). All research methods followed the Declaration of Helsinki and were approved by the First Affiliated Hospital of Nanchang University Ethics Committee. All subjects participated voluntarily and were informed of the purposes, methods, and potential risks before signing an informed consent form.

Data acquisition

MRI scanning was performed using a 3T MR scanner (Trio, Siemens, Munich, Germany). Each subject underwent spin echo single-shot echo planar imaging with the following parameters: repetition time/echo time = 7,200/104 ms, number of excitations = 2, matrix = 128×128, field of view = 230×230 mm, slice number = 49, slice thickness = 2.5 mm, axial orientation, 64 nonlinear diffusion-weighting gradient directions with $b = 1,000$ s/mm², and additional image without diffusion weighting ($b = 0$ s/mm²).

Data processing

Diffuse tensor images were analyzed with voxel-based analysis of DTI¹³ and processed with Statistic Parametric Mapping 2 (SPM2; Wellcome Department of Cognitive Neurology, London, UK) and FMRIB Software Library (FSL) (Version 3.3; www.fmrib.ox.ac.uk/fsl) software. The analysis was performed according to a previous study.¹⁴

Statistical analysis

Analyses were performed using the SPSS 13.0 statistical software (SPSS Inc., Chicago, IL, USA) for Windows. Two-sample *t*-tests were used to compare differences of the FA and MD values between strabismus and HC groups in a voxel-based manner using the analysis of covariance, with age and sex as covariates to control the effect of age and sex. $P < 0.001$ was considered statistically significant.

Clinical data analysis

The cumulative clinical measurements including the duration of the onset of disease and best-corrected VA were recorded.

Results

Clinical data of subjects

There were no obvious differences in weight ($P = 0.958$) and age ($P = 0.986$) between the patients with comitant strabismus and the HCs. The mean duration of strabismus was 27.42 ± 9.04 years. No significant differences were found in the best-corrected VA-right ($P = 0.161$) and the best-corrected VA-left ($P = 0.750$) (clinical data are shown in Table 1).

Table 1 Demographic information and clinical measurements for Stra and HCs

	Stra	HCs	t	P-value
Male/female	9/10	9/10	N/A	>0.99
Age (years)	27.42±9.04	27.37±8.75	0.018	0.986
Weight (kg)	60.53±6.52	60.42±5.71	0.053	0.958
Handedness	19R	19R	N/A	>0.99
Exotropic and esotropic	4/15	N/A	N/A	N/A
Duration of strabismus (years)	27.42±9.04	N/A	N/A	N/A
Best-corrected VA-right	1.07±0.10	1.14±0.18	-1.430	0.161
Best-corrected VA-left	1.09±0.14	1.11±0.16	-0.321	0.750

Note: P-value <0.05, independent t-test P-value between Stra and HCs. Data are mean ± SD.

Abbreviations: HCs, healthy controls; N/A, not applicable; Stra, comitant strabismus; VA, visual acuity.

FA differences

Compared with the HC group, the FA values were significantly decreased in the brain regions of the left superior temporal gyrus ($P<0.001$) but increased in the areas of the bilateral medial frontal gyrus, right globus pallidus/brainstem, and bilateral precuneus in the comitant strabismus group ($P<0.001$; Figure 1 and Table 2). The mean values of altered FA values between the comitant strabismus and HC group are shown in Figure 3A and Table 3.

MD differences

Compared to the HC group, the MD values were significantly decreased in the brain regions of the bilateral cerebellum posterior lobe and left middle frontal gyrus ($P<0.01$) and increased in the brain regions of the right middle frontal gyrus

and left anterior cingulate in the comitant strabismus group ($P<0.01$; Figure 2 and Table 4).

The mean values of altered MD values between the comitant strabismus and HC groups are shown in Figure 3B and Table 5.

Receiver operating characteristic curve

We proposed that the differences of the FA and MD values between the strabismus and HC groups might be useful diagnostic markers. To test this possibility, mean values of the FA and MD of different brain regions were extracted and used to analyze receiver operating characteristic (ROC) curves. The areas under the ROC curve for FA values were as follows: bilateral medial frontal gyrus (0.964), right globus pallidus/brainstem (0.939), and bilateral precuneus (0.958)

Figure 1 Significantly altered FA values in patients with Stra compared with HCs.

Notes: The significantly altered regions were located in the left superior temporal gyrus, bilateral medial frontal gyrus, right globus pallidus/brainstem, and bilateral precuneus. Red and blue areas denote regions with higher and lower FA, respectively. Statistical thresholds were set at $P<0.01$ (two sample t-test, corrected for false discovery rate) with a minimum cluster size of 75 voxels.

Abbreviations: FA, fractional anisotropy; HCs, healthy controls; Stra, comitant strabismus.

Table 2 Brain regions with significant differences in the FA values between Stra group and HCs

Abbreviations: FA, fractional anisotropy; HCs, healthy controls; Stra, comitant strabismus.

(Figure 4A). The areas under the ROC curve for MD values were as follows: right middle frontal gyrus (0.931) and left anterior cingulate (0.978) (Figure 4B).

Discussion

Our study is the first to evaluate whole-brain microstructural changes of FA and MD values in patients with comitant strabismus using a DTI approach. The FA is markedly sensitive to microstructural changes of white matter (WM), while the MD may help to better understand how the diffusion tensor is changing. The reduction of the FA values indicates WM neuropathology. Increased tissue water will lead to an increase in the MD values, and the decreased MD value may indicate cell proliferation.¹⁵ We found FA values remarkably decreased in the brain regions of the left superior temporal gyrus but increased in the areas of the bilateral medial frontal gyrus, right globus pallidus/brainstem, and bilateral precuneus. Meanwhile, the MD values were significantly decreased in the brain regions of the bilateral cerebellum posterior lobe and left middle frontal gyrus and increased in the brain regions of the right middle frontal gyrus and left anterior cingulate.

The superior temporal gyrus located in the temporal lobe of the human brain is involved in the processing of language.¹⁶ A previous study has shown that the superior temporal area controls the representation of three-dimensional structures and shapes.¹⁷ It has been well known that patients with strabismus often manifest dysfunction of fusion and

stereopsis.¹⁸ Yan et al¹⁴ found that patients with comitant exotropia had smaller WM volumes in the right inferior temporal gyrus. In agreement with these findings, we found that the FA value was decreased in left superior temporal gyrus in comitant strabismus, which reflected abnormalities of WM fibers in these areas. These results suggest that comitant strabismus may cause dysfunction of the left superior temporal gyrus.

The medial frontal cortex is involved in the control, monitor, and selection of behaviors. The supplementary eye field located in the medial frontal cortex is involved in the execution of ocular movements.¹⁹ A previous study demonstrated that the frontal eye field (FEF) played an important role in controlling eye movements of monkeys.²⁰ Another research reported that the FEF was responsible for rapid or saccadic ocular movements.²¹ Moreover, the FEF was shown to be in charge of sustained attention.²² Yan et al¹⁴ found that patients with comitant exotropia had smaller WM volumes in right frontal lobe/sub-gyral. Additionally, Chan et al²³ observed increased gray matter volume in the FEF of adults strabismus. Consistent with these findings, we found that the MD values were significantly increased in the brain regions of the right middle frontal gyrus in patients with comitant strabismus, suggesting the dysfunction of WM fibers in these areas. Furthermore, we found that the mean area of the MD values of the right middle frontal gyrus was 0.931 in the ROC curve. Therefore, we speculated that comitant strabismus possibly caused abnormalities of WM fibers in right middle frontal

Table 4 Brain regions with significant differences in the MD values between Stra group and HCs

MD condition Brain areas	Stra group and health controls			MNI coordinates		
	BA	T values	Peak voxels	x	y	z
Stra < HCs						
Bilateral cerebellum posterior lobe	–	–3.756	1,434	–26	–52	–52
Left middle frontal gyrus	4, 9, and 46	–5.100	1,200	–48	14	36
Stra > HCs						
Right middle frontal gyrus	32 and 9	5.409	871	20	46	8
Left anterior cingulate	32 and 24	5.872	913	–10	32	10

Note: Multiple comparisons using GRF theory (voxel-wise $P < 0.01$ and cluster-wise $P < 0.05$ corrected).

Abbreviations: BAs, Brodmann areas; GRF, Gaussian random field; HCs, healthy controls; MD, mean diffusivity; MNI, Montreal Neurological Institute; Stra, comitant strabismus.

Table 5 Significant differences in the MD values between Stra group and HCs

MD	Stra	HCS	t	P-value
Bilateral cerebellum posterior lobe	0.00071±0.000071	0.00093±0.000094	-7.997	<0.001
Right middle frontal gyrus	0.0008±0.000025	0.00075±0.00002	6.558	<0.001
Left anterior cingulate	0.00081±0.000028	0.00076±0.000020	7.181	<0.001
Left middle frontal gyrus	0.00076±0.000071	0.00097±0.00010	-7.268	<0.001

Note: P-value <0.05, independent t-test P-value between Stra and HCs. Data are mean ± SD.

Abbreviations: HCs, healthy controls; MD, mean diffusivity; Stra, comitant strabismus.

gyrus, which may explain the impairment of regular eye movements in the patients with comitant strabismus.

Interestingly, we found that the FA values were markedly increased in the area of the bilateral medial frontal gyrus, and the MD values were decreased in the left middle frontal gyrus in patients with comitant strabismus. An increase in the FA values in the bilateral medial frontal gyrus may reflect the WM alterations in these areas. The decreased MD values in the left middle frontal gyrus may indicate cell proliferation defects in these areas. Moreover, the mean area of the FA of the bilateral medial frontal gyrus was 0.964. These changes may suggest a functional reorganization in the FEF in patients with comitant strabismus.

The cerebellum is involved in the control of movements²⁴ and the execution of cognition²⁵ and language.²⁶ Moreover, a previous study demonstrated that the cerebellum was involved in the execution of eye and hand movements.²⁷ Another study reported that activation of cerebellar vermis was related to visually guided saccades.²⁸ Joshi and Das²⁹ found that the

posterior interposed nucleus in the cerebellum participated in conjugating eye movements in strabismic monkeys. In our study, we observed that the MD values were significantly decreased in the brain regions of the bilateral cerebellum posterior lobe in patients with comitant strabismus, which may reflect abnormalities of microstructural changes in these areas. We speculated that comitant strabismus possibly lead to pathological microstructural changes in the bilateral cerebellum posterior lobe, which manifested in the impairment of regular eye movements in the patients with comitant strabismus.

The cingulate cortex, as a part of the limbic cortex, has many functions, such as pain,³⁰ depression,³¹ and anxiety disorder.³² Yan et al¹⁴ found that WM volumes were decreased in the right cingulate gyrus in patients with adult strabismus. In our study, we observed that the MD values were significantly increased in the brain regions of the left anterior cingulate in patients with comitant strabismus, which suggested abnormal microstructural changes in the left anterior cingulate. Furthermore, the mean area of the MD values

of the left anterior cingulate was 0.978 in the ROC curve. Therefore, we surmised that the comitant strabismus might lead to the dysfunction of the left anterior cingulate.

Conclusion

Our study showed that patients with comitant strabismus had microstructural changes of WM in many brain regions and provided important information to understand the underlying neural mechanisms of the fusion defects and ocular motility disorders in patients with comitant strabismus. However, there are some limitations to our study. First of all, the sample size is small, and we did not consider different clinical outcomes of the strabismus, such as exotropia and esotropia. Future research should distinguish between different types of strabismus to more accurately assess brain activities and functional changes.
