Abstract: To address the limitations of traditional drug delivery, TiO₂ nanotubes (TNTs) are recognized as a promising material for localized drug delivery systems. With regard to the excellent biocompatibility and physicochemical properties, TNTs prepared by a facile electrochemical anodizing process have been used to fabricate new drug-releasing implants for localized drug delivery. This review discusses the development of TNTs applied in localized drug delivery systems, focusing on several approaches to control drug release, including the regulation of the dimensions of TNTs, modification of internal chemical characteristics, adjusting pore openings by biopolymer coatings, and employing polymeric micelles as drug nanocarriers. Furthermore, rational strategies on external conditions-triggered stimuli-responsive drug release for localized drug delivery systems are highlighted. Finally, the review concludes with the recent advances on TNTs for controlled drug delivery and corresponding prospects in the future.

Keywords: TiO₂ nanotubes, electrochemical anodization, modification, stimulated drug delivery, drug-releasing implant

Introduction

To address the limitations of conventional drug therapies related to restricted drug solubility, short circulating time, lack of selectivity, side effects, and unfavorable pharmacodynamics, considerable studies have been carried out in past years toward the development of more efficient drug delivery systems.¹⁻⁴ Approximately 90% of drugs that are used currently on the market are hydrophobic and poorly water-insoluble, and this restricts their pharmacological efficiency and particularly challenges the systemic delivery route.^{5,6} Another inherent limitation of the therapies is that various drugs are inactivated or removed by the gastrointestinal system and other body organs including kidney and liver, and only <1% of administered drug molecules reach the site of interest, where higher dosages of drugs are required to achieve an optimized local concentration.^{7,8} Therefore, innovative drug delivery approaches are urgently needed to address the disadvantages of traditional drug delivery.

The inherent limitations of conventional therapies could be addressed on the basis of developing more efficient and rational drug delivery systems, in which two concepts involved in targeting drug delivery and localized drug delivery systems are verified to be the most perspective strategies. The utilization of nanotechnology to medicine is an emerging field with significant potential for localized drug delivery systems. Nanotechnology has boosted the development of various new nanomaterials and drug carriers for drug release applications, including polymer micelles, liposomes vesicle, multi-functional dendritic polymers, nanocapsules, nanospheres, TiO₂ nanotubes (TNTs),

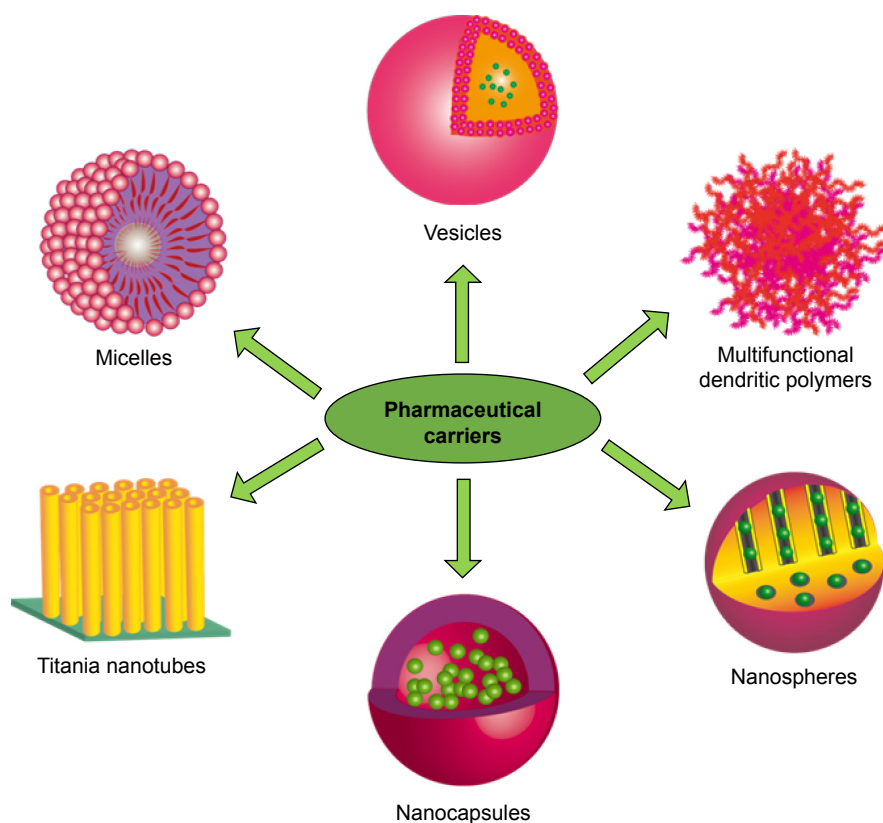

Figure 1 Some basic nanoscale materials and drug carriers for promising drug delivery applications.

and so on,^{7,9–12} as shown in Figure 1. For these nanoporous or nanotube carriers, a special niche in drug delivery technology has been guaranteed to correspond with them because of their simple preparation, controlled nanoporous or nanotube formation, mechanical rigidity, chemical resistivity, high loading capability, high surface area, and so on.^{13–21} TNT arrays formed on Ti surface by a facile electrochemical anodizing process are recognized as a desirable candidate to promote clinical therapeutic effect of medical implants.^{22–25}

This paper aimed at reviewing TNTs used as carriers for controlled drug release and compiling the most recent advances on TNT-based drug-releasing implants for localized and smart drug delivery applications. Various methods designed to control sustained drug release from TNT implants are discussed, which include controlling TNT morphologies and chemical modification. Additionally, some advanced strategies on externally triggered stimuli-responsive drug release are discussed, and these sources hold significant potential of producing alternative drug release pathways that could overcome the limitations of the traditional diffusion mechanism. Finally, this review concludes a general overview on the future trends, challenges, and the prospective outlook for the interesting and promising research field.

Development of TNTs by electrochemical anodization

With the development of TNTs constructed by electrochemical anodizing, more and more attention is paid to achieve higher nanotube growth rates, improve controllable dimensions and nanotubes ordering.^{19–31} In order to improve the technology of TNT fabrication, various electrochemical protocols were addressed to support it, which involve aqueous and organic electrolytes with different chemical compositions and electrochemical conditions. The electrochemical anodization process is carried out usually in electrolytes containing some fluoride ions to fabricate TNT layers. In electrolytes with acid, salt, or alkali solution, short tube lengths were formed (from 400 nm to 2 μ m) during anodization process, and these TNT arrays lacked organized structure and uniformity, which are described as the first generation of TNTs.^{32–35} Then TNTs of longer lengths (5–7 μ m) were fabricated in a pH-controlled electrolyte containing small amounts of fluoride ions, which are considered as the second generation of TNTs.^{36–39} The third generation of TNT arrays with further longer length (1,000 μ m) was fabricated in non-aqueous polar organic electrolytes in the presence of fluoride species by electrochemical anodization.^{40–43} Recently,

non-fluoride-based synthesis of TNTs has been reported, which are addressed as the fourth generation, showing significant improvement in the growth rate and the quality of fabricated TNTs.^{44–46}

For TNT arrays formed in fluoride-based electrolyte, an appropriate external voltage and low electrolyte acidity are needed for yielding TNT layers and growing long tubes. At a controlled anodization voltage of 80–120 V, electrochemical anodization of Ti results in vertically oriented and hexagonally closely packed TNT structures with high growth rate, optimal geometry, and stable mechanical characteristics.^{1,7} In addition, some other TiO₂ morphologies were reported, such as nanopore branched, bamboo-type nanotubes, inner tubes, spongy, nanolace, and multilayer nanotubes were fabricated by controlling the voltage during the process of nanotube preparation.^{47–50} Thereby the study of TNT fabrication is a dynamic and active research area, and the development of novel strategies and synthesis methods is expected to be extended in the future.

Strategies to control drug delivery from TNTs

Drug delivery from nanotubes is dependent on the diffusion process when TNTs are implanted into the host body with physiological milieu. This diffusion process can be defined by Fick's first law, which is influenced by various factors such as molecular size of the drugs, charge, dissolution rate and diffusion coefficient, dimensions of nanotubes, charge and surface chemistry, and interfacial interaction of drug molecules and TNT surface.^{51–55} Depending on these conditions, different drug release profiles were obtained and different strategies have been implemented into TNT-based systems in order to provide a controlled drug release for a broad range of clinical therapies. It is known that different drug release strategies need to be considered for different therapies, thus TNT-based drug-releasing systems must be designed with flexible drug release capabilities and optimized parameters in order to fulfill the requirements of different therapies. It is worthwhile stressing that zero-order type release is the most satisfactory release strategy for drug-releasing implants, which results in the drug being released at a uniform and constant rate independent of concentration and time.⁵⁶ Considering that, increasing studies are focused on exploring different strategies in TNT-based drug-releasing implants in order to design and advance their drug-releasing performances for specific drugs and therapies. A schematic diagram summarizing these strategies aimed at controlling the release of drugs from TNTs is presented in Figure 2.

In this schematic diagram, a single nanotube was subjected to various modifications for controlling drug release, including A) structural modifications of diameter and length of TNTs, B) surface modifications, C) adjusting pore openings of TNTs with polymer deposition, D) biodegradable polymer coatings, E) polymeric micelles as drug nanocarriers, and F) stimulated drug release strategies by external sources.

Dimensions of TNTs and surface functionalization

According to Fick's law, the diffusion rate of drug molecules from nanopores depends on their dimensions as these confined nanochannels can be controlled precisely at nanoscale.^{57,58} To investigate the influence of pore size on the drug release profiles, studies from several groups confirmed that the drug release is considerably related to the dimensions of TNTs.^{59–62} Aw et al studied the relationship between the length of the TNTs and anodization time, and their results demonstrated that length of TNTs is controlled by anodization time and that the drug release time was extended with an increase in the nanotube length based on drug loaded in TNT implants of different nanotube lengths (25–100 μm) and a fixed pore diameter of 110 nm.² The drug release from TNTs can be extended by shrinking their lengths and diameters, which results from the fact that drug molecules encapsulated deeper inside TNTs needed a longer time to diffuse out of nanotubes because of the capillary force. In addition, Hamlekhan et al studied that anodization condition (voltage and duration) influences the release profiles of TNT groups based on the dimensions of TNTs influenced by anodization conditions.⁵⁹ As demonstrated by various studies, length and diameter of TNTs are increased with the increasing anodization voltage. Moreover, the amount of drug loaded in TNTs increases as the anodization duration is increased based on comparing the profiles with the TNT dimensions specified in all TNT groups, as presented in Figure 3.⁵⁹

The next strategy for controlling drug release from TNTs was based on the surface functionalization of the nanotubes. The aim of this strategy is to dynamically change the interaction between drug molecules and inner walls of the nanotubes for altering the drug release kinetics. This approach was previously demonstrated on porous silica particles and was successfully translated into TNTs by using polymers and self-assembled monolayers with excellent stability and flexibility for surface modification.^{63–69} Organic silanes (ie, 3-aminopropyl triethoxysilane [APTES], penta-fluorophenyldimethylchlorosilan [PFPTES]) and phosphonic acids (ie, 2-carboxyethyl-phosphonic acid and 16-phosphono-hexadecanoic acid) were used to modify

Only single nanotube structure is shown to present an array of TNTs.

Abbreviations: APTES, 3-aminopropyl triethoxysilane; PLGA, poly (lactic-co-glycolic acid); TNT, TiO_2 nanotube; d, diameter; l, length; 2-phos, 2-carboxyethyl-phosphonic acid; 16-phos, 16-phosphono-hexadecanoic acid; PFPTES, penta-fluorophenyltrimethylchlorosilan; PNIPAAm, poly (N-isopropylacrylamide).

TNTs, which demonstrate that this approach could change drug loading and release characteristics of TNTs for hydrophilic and hydrophobic drugs, as shown in Figure 4.² It is worthwhile stressing that APTES holds the silane group hydrophilic that can impart different properties onto the surface of TNTs.^{70,71} Moreover, APTES protonates can give similar properties of drugs in phosphate-buffered saline (PBS) with neutral pH.

Based on the results presented above, it is demonstrated that drug loading and releasing features are significantly influenced by surface charge and chemical and interfacial properties. Specific surface modification strategy is useful for rational designing implants with splendid properties for optimized

application, whereas this strategy is still limited to achieve a sustained release of drugs from TNTs for a longer duration.

Plasma polymerized biopolymer coating modifications

In order to overcome the problem that a long and sustained drug release cannot be realized by surface modification of TNTs, a new strategy using plasma polymer coatings on the top surface of TNTs to reduce the opening of nanopores, which confirmed that drugs release from TNTs is possible to follow the zero-order release kinetics.^{72–76} Various drugs with different size and properties have been successfully performed on TNTs based on this concept, and these drugs

include anti-inflammatory drugs, anticancer drugs, functionalized metal oxide nanospheres, bovine serum albumin, and bone morphogenetic proteins (BMPs) drug micelles.^{73,77,78} It is worthwhile noticing that plasma deposition method holds a capability of modifying the top surface of TNT layers, and the modified TNTs are imparted to desirable properties including antibacterial activity, implant rejection, anti-biofouling, and better integration to reduce sensing capabilities.⁷² With the plasma deposition method being widely used in medical application, the disadvantages of this technology are also presented, such as the calibration requirement of plasma conditions, its high cost, and some unavailable technical knowledge.

Considering these limitations of the plasma deposition, a significantly simpler method with low cost was explored based on coating TNT opening.^{60,79} Poly (lactic-co-glycolic acid) (PLGA) and chitosan were selected for dip-coating, which result from two polymers with biocompatible and biodegradable possibilities and are known to have some beneficial properties including antibacterial and osseointegration and are also used for drug delivery systems. PLGA or chitosan was coated on drug-loaded TNTs by dip-coating for controlling drug release and improving antibacterial and bone integration of TNTs, as schematically shown in Figure 5.⁸⁰

Significant changes in drug release profiles were observed because of coating a polymer film on openings of the nanotubes as shown in Figure 6.⁸⁰ From the results, it was demonstrated that drug release profiles were significantly influenced by polymers' chemical composition and the thickness of polymer layer. Meanwhile, the burst release occurred at the first 6 hours is presented in release process regardless of a polymer film existed or not, which can be explained that the initial release is from drug loaded on TNTs' top surface, and the high concentration gradient through nanotubes allows drugs' rapid release at the beginning of release duration. In addition, it was also concluded that TNT arrays coated with a thin PLGA polymer layer shows an extended release duration with a higher level of burst release and that a thin chitosan layer coated on TNTs could provide a shorter release duration with a lower level of burst release.

Form these results, it was demonstrated that the drug release can extend to several months with zero-ordered kinetics by controlling the thickness of the biopolymer film coated on TNTs. This design of TNT implants is focused on its local drug delivery with several weeks releasing, which has been performed by a study based on post-surgical implant surgeries, and its result indicates that systemically delivered gentamicin has fewer side effects in promoting bone healing.⁸¹ The adhesion and prolifera-

tion of human osteoblastic cells on TNT implants were investigated to confirm polymer-coated TNTs, especially chitosan coating could enhance osteoblast integration to implants.² TNTs with dip-coating modification are believed to be achievable in a clinical environment because of their facile fabrication process and no specific technology requirements.

Advanced TNT drug systems with multi-drug and stimulated drug release

Multi-drug delivery with micelles as drug carriers from TNTs

Considering the treatment of some complex diseases that require more than one kind of drug, a new concept of using polymeric micelles for loading drugs was addressed, especially multi-drug nanocarriers were integrated into TNTs for designing implants with advanced multi-drug releasing. This advanced drug release strategy holds the capability of delivering several drugs for a pre-programmed time to permit a later release, as schematically presented in Figure 7A–D.⁵⁸ As the most desired candidates for this concept, hydrophobic and hydrophilic properties of drug carriers provide a desired

structure of polymer layers in TNTs without inter-mixing, and a unique successive release pattern from TNTs can be achieved based on this multiple-drug delivery system. In terms of drug release profiles based on TNTs loaded with two layers drug carries, Figure 7E shows the sequential releasing of regular micelles (d- α -tocopheryl polyethylene glycol 1000 succinate [TPGS]) encapsulating two hydrophobic drugs (indomethacin and itraconazole) loaded at the top, followed by the releasing of inverted micelles (PEGylated phospholipids [DGP]) encapsulating hydrophilic drugs (gentamicin) loaded at the bottom.⁵⁸

Compared with conventional drug carriers, polymeric micelles can enhance drug delivery system because of the prolonged therapeutic effects of drugs in targeted organs or tissues.⁸² Considering the candidates of polymers, poly(ethylene oxide) (PEO)-poly(propylene oxide) (PPO)-PEO consisted of hydrophilic polar head (PEO) and copolymers-lipophilic alkyl tail (PPO) was used as drug carriers due to its organic chains with different number of tri-block monomers.⁸³ TPGS, a vitamin E derivative, can significantly improve drug encapsulation efficiency and increase the bioavailability of anticancer drugs, thus was selected as a drug carrier.^{84,85} Moreover, the PEGylated phospholipids

(DGP 2000 and 5000) are also used in drug delivery system in broad commercial applications.⁸⁶

The multi-drug delivery system used in various local drug therapies presents sequential release of drug carriers by varying types of drug-loaded carriers and positions of carriers in TNTs. Release profiles of this multi-drug delivery system can be controlled by adjusting the length and pore diameters of TNTs, surface properties of micelles and their loading conditions. Furthermore, this multi-drug delivery system fully satisfies complex requirements for bone therapies required over long periods to prevent inflammation and improve implant integration.

Stimulated drug delivery from TNTs with external trigger

Extended drug release for long-term therapies are not satisfied in critical situations such as unexpected onset of inflammation, sudden viral attack, osteomyelitis, and so on, where high concentrations of drug are immediately required. To settle these emergency conditions, a concept of stimulated drug delivery system with external trigger based on TNTs is put forward to achieve therapeutic efficacy.⁷ Extensive investigations were explored to increase the treatment effect in the required time period, which sometimes needed high dosage with precise schedule or only for a short

period to treat urgent diseases.^{87,88} For satisfying the demand of delivering pre-determined amount of drugs required by pharmacokinetic parameters, several concepts are reported, including magnetic, ultrasound, and voltage.

Magnetic-sensitive drug delivery

A concept of drug encapsulated in nanomagnetic structures was proposed, which focused on designing triggered drug delivery systems because the nanomagnetic structures possess exciting possibilities for magnetic field triggered drug release. Regarding this concept, Shrestha et al reported on using TNTs filled with magnetic nanoparticles (MNPs) in order to achieve magnetic- and photocatalytic-guided release of drugs.⁸⁹ In this study, a model drug was attached to magnetic TNTs by using a silane coupling agent as a cross-linker, then ultraviolet (UV) irradiation was provided for inducing chain scission of this agent monolayer attached to TNTs, thus the release of the fluorescent molecule takes place at the anchoring siloxane groups as schematically outlined in Figure 8A. It was demonstrated by the phenomenon that the release of the fluorescent marker into the electrolyte was clearly visible after few seconds of UV irradiation imparted

to dye-functionalized TNTs, as presented in Figure 8B and C.⁸⁹ From these results, it is shown that the approach reported here can realize a temporally and spatially photoinduced drug release based on magnetic-sensitive drug delivery system.

In addition, a new concept was addressed, aiming to design drug-releasing implants being assisted by MNPs loaded inside TNTs.⁹⁰ In this study, iron oxide MNPs (DOPA- Fe_3O_4) with dopamine modification was used for improving the biocompatibility of the MNPs and their loading inside the TNTs. Considering drug carriers, three types of amphiphilic micelles including Pluronic F127, TPGS, and PEO-PPO-PEO were explored to study the concept of magnetic-sensitive drug delivery system. For the drug-release profiles, it is confirmed that cumulative release of the three drug carriers reaches ~100% within 1–1.5 hours under the application of the magnetic field.⁹⁰ Although this strategy also presents some limitations of uncontrolled release triggered by external magnetic fields from the environment, it is still particularly valuable for drug-releasing implants in orthopedics and bone surgery where on-demand release is required under emergency situation.

Magnetically guided titania nanotubes for site-selective photocatalysis and drug release. *Angew Chem Int Edit.* 2009;48:969–972. Copyright © 2009 WILEY-VCH Verlag GmbH & Co. KGaA, Weinheim.⁸⁹

Abbreviations: TNT, TiO_2 nanotube; UV, ultraviolet.

Ultrasound-sensitive drug delivery

In order to overcome the drawbacks of magnetic field-stimulated release, the drug-releasing system based on ultrasound-mediated drug and nanocarrier release from TNTs was explored. Aw et al reported the application of local ultrasonic external field for triggering drug release from TNTs.⁹¹ It is the first time that ultrasound-mediated drug micelles are selected for local drug delivery system, and Figure 9A shows this concept of using ultrasonic waves (USW) as a trigger combined with TNT implants. For controlling drug-micelles release from TNTs, several USW parameters were explored, including pulse length, amplitude, pulsation time, and power intensity. The USW power intensity controlled by various distance between probe and sample has a significant effect on the profile of drug release from TNTs as shown in Figure 9B. In this work, drug release profiles varies as the distance between the probe and sample is changed, for example, when the distance is set as 2.0, 1.5, 1.0, and 0.5 cm, it corresponds to the power of 25, 50, 75, and 100 W, as presented in Figure 9C. It is indicated that the distance between the probe

and sample is shorter, the USW power intensity is greater, and the force of the impact becomes stronger. These effects may result from the fact the wave energy could propagate directly without much hindrance in the medium.

With regard to the mechanism of drug-micelles release from TNTs by USW, it is likely involved that a combination of thermal and cavitation processes caused by mechanical vibration result from forces produced by the ultrasound waves in interaction with buffer and TNT implants. The application of this strategy can be involved in bone therapies and local delivery systems including stents or brain drug delivery. However, more ex vivo or in vivo studies based on various drugs loaded inside drug-released TNT implants are required to demonstrate the feasibility of this concept.

Voltage-sensitive drug delivery

Among various stimuli-responsive drug delivery system approaches, the voltage-sensitive release is another attractive strategy for its beneficial properties. Impartation of voltage could induce the chain scission based on TNTs grafted with

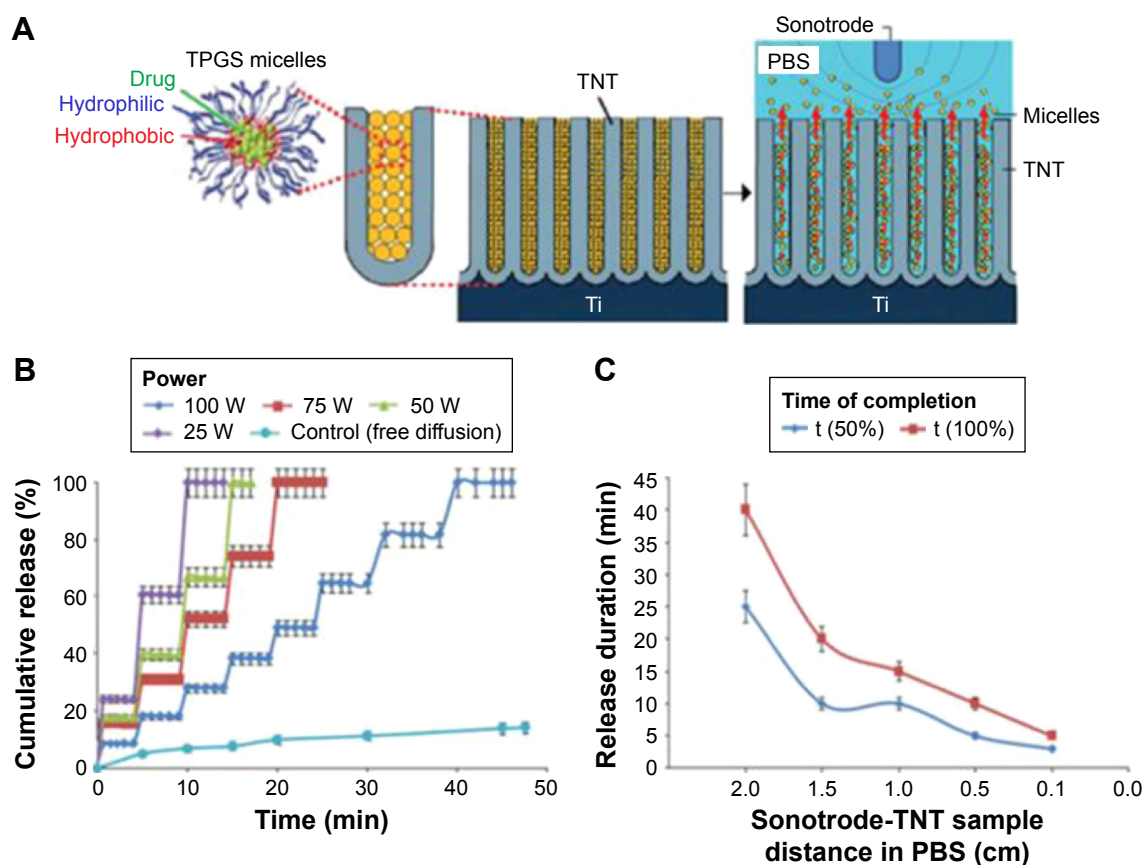

Figure 9 Ultrasound-stimulated drug release from TNTs.

octadecylphosphonic acid for wettability or attached to an enzyme of horseradish peroxidase, as reported by Song et al.⁹² In this study, a reaction of OH with terephthalic acid (TA) to form 2-hydroxyterephthalic acid (TAOH) results in a blue fluorescence at different voltages for identical duration as shown in Figure 10A.⁹² The results indicate that the strong blue fluorescence is visible when TNTs are held at 5 V, whereas virtually no fluorescence can be seen at 1.5 V or no voltage. For these reasons, it is possible that generated valence-band holes can react with their environment in a similar manner as photogenerated holes in TNTs at a potential of 5 V. Figure 10B schematically shows voltage-induced OH-radical formation and payload release, which demonstrates voltage-induced pseudo photocatalytic processes, and in particular the valence band ionization mechanism may result in the chain scission reactions from TNTs.

In addition, Sirivisoot et al reported an approach that was used to trigger drug release by an electrical field. In their study, drugs were encapsulated into multi-walled carbon nanotubes (MWCNTs) grown out of TNTs, where drugs release from TNTs under the control of electrical field.^{93,94} Their research achievement could be applied on treating bone repair and other more serious bone diseases. Furthermore, Sirivisoot et al carried out an experiment by doping polypyrrole with antibiotics (penicillin and streptomycin) and an

anti-inflammatory drug (dexamethasone); their loading by electrodeposition inside MWCNTs grown on TNTs was considered as the further advancement of voltage-sensitive drug delivery.^{95,96} Although the development of this strategy is in its primary stage, it has an enormous potential for advanced developments in drug-released TNT implants.

Ex vivo and in vivo studies of drug release characteristics

Most of the aforementioned studies on drug release therapies of TNTs were performed through in vitro experiments using PBS as eluting medium. This situation is significantly different from real clinical circumstances that possess the real bone tissues and real biological environment, thereby many challenges are presented for in vivo applications, especially for how to accurately monitor the distribution of drug molecules from TNTs to the bone tissue.⁷ For this challenge, implantable TNT-Ti wires were selected to be inserted into the bone for providing extended drug release as reported by Aw et al.⁹⁷ In this study, a TNT-Ti wire was inserted into a hole drilled through each bone core, fitting tightly into the bone core's center, as shown in Figure 11A, and trabecular bone core with TNT-Ti wire inside the bone chamber was connected to perfusion pump that provides culture media to keep bone cells alive as shown in Figure 11B.⁹⁷ Bioluminescence images were captured at different times for the 5-day experiment on drug-release studies as presented in Figure 11C–F.⁹⁷ From these results, it is demonstrated that the model drug's concentration in 3D bone matrix is increasing and changes in the concentration exist across all directions from TNT-Ti implants.⁹⁷ In brief, the TNT-Ti wire can be considered as a safe drug-releasing implant used in the local drug delivery system for bone therapies such as bone infection, bone inflammation, and even bone cancer.

A suitable in vivo performance must be provided before any biomaterial is used in a real clinical application, thus TNTs have to integrate within the bone tissue and survive the stresses experienced during surgical insertion inside the animal model. As described in the previous section, von Wilmsky et al used pigs for studying the in vivo performance of TNT-Ti implants.⁹⁸ In this study, investigations on peri-implant bone formation, bone-implant contact, and immunohistochemistry were performed for evaluating the effects of these implants, demonstrating that TNT coatings can enhance osteoblast functions, suppress shearing forces caused by implant insertion, and promote bone formation when compared to commercially available pure Ti implants. Another study reported by Park et al demonstrated that bone-implant contact results showed the

capability of improving osseointegration for protein-loaded TNT implants based on loading fibroblast growth factor and human fibronectin fragment (hFNIII9–10) fusion protein inside TNTs on Ti implants which were inserted in rabbit tibia, followed up for 3 months.⁹⁹ It is worthwhile stressing that these experiments were carried out over a period of 2–3 months, and more studies should be carried out to investigate longer healing periods of TNTs implants for clinical therapies.

Apparently, these studies help establishing future databases consisting of detailed information on the degree of toxicity on the nanoscale, which would help to clarify the division of toxic effects of nanoscale materials, including TNTs. Furthermore, extensive studies on the interaction between cells/tissues from different organs and parts of the body with TNTs are also required.¹⁰⁰

Conclusion and future perspectives

Recent advances of drug-releasing TNT implants are reviewed in this work, and it is indicated that the application of TNTs is a promising alternative to develop various localized drug delivery systems that possess the capability to overcome limitations of systemic drug therapies. TNTs present beneficial properties for drug delivery application, including controllable nanotube dimensions, tunable geometries and surface chemistry, high surface area, high and versatile drug-loading capacity for several drugs, ability to modulate drug release kinetics, and so forth.

In this review, it is confirmed that TNT implants have a significant potential in clinical therapeutics, and capabilities of this implant can be realized by tuning their drug-releasing characteristics and providing multi-drug release of different drugs in different fashions. These approaches aim to optimize drug dosage, release rate, and time needed for a broad range of specific therapies, which have been presented in detail in this review. For these purposes, several strategies including magnetic, electromagnetic, and ultrasonic were used as triggers to release drugs from TNTs, which present outstanding features offering great perspectives and opportunities for TNT applications. Although still at initial stage, these external stimulus strategies are considered as promising applications in drug-releasing implants for developing smart clinical therapies.

Regarding the excellent biocompatibility of TNTs, numerous studies based on cells, ex vivo or in vivo animal models have been performed to prove their excellent biocompatibility. It is indicated that long-term toxicity assay and tolerability studies are needed to be performed on animals to evaluate the safety of blank TNTs and drug-loaded TNTs before proceeding with human clinical trials, thereby more in vivo studies are urgently required before these localized drug delivery systems can be applied in clinical trials.

International Journal of Nanomedicine

Publish your work in this journal

The International Journal of Nanomedicine is an international, peer-reviewed journal focusing on the application of nanotechnology in diagnostics, therapeutics, and drug delivery systems throughout the biomedical field. This journal is indexed on PubMed Central, MedLine, CAS, SciSearch®, Current Contents®/Clinical Medicine,

Submit your manuscript here: <http://www.dovepress.com/international-journal-of-nanomedicine-journal>

Journal Citation Reports/Science Edition, EMBase, Scopus and the Elsevier Bibliographic databases. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
