Introduction: The classic presentation of pigmentary dispersion syndrome (PDS) often consists of midperipheral iris transillumination defects, Krukenberg's spindle, and dense homogeneous trabecular pigmentation. Other subtle, sometimes overlooked features include pigment on the lens zonules, pigment on the anterior lens capsule and pigment along the equator of the posterior lens capsule.

Case: This unique presentation of PDS presented with bilateral, dense, oblique, and symmetrical pigment deposition along the posterior lens capsule that changed in shape, density, and extent over the span of 3 years.

Discussion: There have been few reports in the literature that describe a central accumulation of pigment along the posterior lens capsule associated with PDS. There are reported cases of pigment deposition along the central aspect of the posterior lens capsule, some changing over time, although none were bilateral and symmetrical. There are suggestions that perhaps this central pigment deposition is related to a break in the ligament of Weiger, allowing communication between the posterior chamber and posterior lens capsule. This is a case in which curvilinear, symmetrical, and changing pigment deposition on the posterior lens capsule is suggestive of perhaps another key features of PDS.

Keywords: pigment deposition, ligament of Weiger, space of Berger, zonules, pigmentary glaucoma

Introduction

Pigmentary dispersion syndrome (PDS) has many distinct clinical features that aide in its diagnosis and management. Ritch et al¹ estimated the prevalence of PDS to be 2.45% of Caucasian patients in a glaucoma screening. Roberts et al² estimated the prevalence of PDS to be 0.0015% of African Americans in a primary care setting. These estimates are likely disparate because of the difference in phenotypic expression between the two ethnicities, as noted by Roberts et al.² Although PDS is autosomal dominant in nature³ for both African American and Caucasian populations, it is thought to have incomplete penetrance in the African American population.⁴ Myopia has been noted as a significant corollary to PDS. Scheie and Cameron⁵ reported the incidence of myopia to be 65% in a group of 493 eyes with PDS, regardless of ethnicity. The classic clinical presentation of PDS includes midperipheral iris transillumination defects, Krukenberg's spindle, and dense homogeneous trabecular pigmentation.⁶ Other clinical

features that are often overlooked may include pigment on the lens zonules⁷ and pigment on the anterior and posterior lens capsule.⁸ It is estimated that patients with PDS have a 35%–50% chance of developing pigmentary glaucoma during their lifetime.⁹ Below is a case in which the patient presented with many of the known features of PDS, along with an uncommon presentation of symmetrical pigment on both posterior lens capsules with changes in morphology and density over time.

Case

A 45-year-old Caucasian male initially presented with reduced acuities in both eyes since childhood. His medical and family history was unremarkable, with best-corrected acuities 20/60 in each eye and correction $-8.00-2.00 \times 135$ OD and $-8.00-1.25 \times 020$ OS. External examination was normal, but slit lamp examination revealed midperipheral iris transillumination defects (Figure 1), pigment on the corneal endothelium and dense, and symmetrical pigment on the posterior lens capsules. Gonioscopy revealed angles open to ciliary body with grade 2+ pigment in all quadrants and no evidence of angle recession. Intraocular pressures (IOPs) were 17 and 18 mmHg in each eye. Dilated fundus examination with binocular indirect ophthalmoscopy and scleral depression revealed an intact retina, with no holes

or tears and no signs of pigmented cells in the vitreous. The optic nerves were small: $\sim 1 \text{ mm} \times 1 \text{ mm}$ as measured with Spectral Domain Optical Coherence Tomography (SD-OCT; © 2017; Carl Zeiss Meditec AG, Jena, Germany). We confirmed optic disc hypoplasia in both eyes as the likely cause of the patient's decreased vision. Over the course of 3 years, the IOP remained in the 15–19 mmHg range in both eyes. During this time, retinal nerve fiber layer thinning and corresponding visual field defects were evident. Given the presence of optic nerve hypoplasia in addition to PDS, it was difficult to assess the damage solely related to glaucomatous changes. For this reason, glaucoma therapy was initiated using Travatan Z ophthalmic solution once daily in both eyes. IOPs remained stable at 13 mmHg in each eye, and he continues to be monitored for any changes. Of particular interest was the unusual presentation of pigment deposition on the posterior lens capsules of each eye. The pattern of pigment was dense, oblique, and curvilinear and located along the posterior lens capsules (Figure 2). The pigment on the posterior capsule created shadows on the retina, which were best documented with Optos Daytona ultra-widefield imaging (© 2017; Optos plc, Dunfermline, UK), which provides ultra-widefield fundus imaging (Figure 3). Over time, it appeared that there was an increase in pigment deposition along the posterior lens capsule. Comparing photos 1 year apart, one can observe the apparent increase in the size of pigment deposition (Figure 4A and B). Interestingly, photos taken 2 years later showed a marked decrease in pigment deposition on the posterior lens capsules (Figure 5). There were no changes in the patient's medical history in that same time span, including a repeated denial of medication changes or incidents of trauma. A search of literature published in the last 15 years did not reveal any cases of bilateral, dense, and symmetrical pigment deposition on the posterior lens capsule with a change in morphology over time.

Informed consent

The patient described in this case has given written informed consent to have the case details and accompanying images published.

Discussion

A ring-shaped deposition of pigment on the equator of the posterior lens capsule along the zonular attachments can be found in patients with PDS.⁷ Proximal to the zonules is the ligament of Weiger, which is the ring-like attachment of the anterior limiting membrane of the vitreous to the posterior lens capsule. Another ring of pigment, known as Scheie's line,

Figure 2 Circumferential deposition of dense pigment along the posterior lens capsule of each eye.

Notes: The deposition in each eye (arrows) is virtually a mirror image of the other. The view with biomicroscopy of the posterior lens capsule matched the “shadow” seen with ultra-widefield images on each visit as seen in Figures 3–5.

Figure 3 Optos Daytona ultra-widefield imaging of each eye reveals shadows cast on the fundus from the pigment on the posterior lens capsule.

Note: These images also highlight the symmetry of pigment deposition (arrows) in the two eyes.

can deposit at the juncture of the ligament of Weiger.⁸ The ligament of Weiger encircles the space of Berger, which is located between the posterior lens capsule and the vitreous.¹⁰ This space is located centrally through the visual axis and is typically void of debris assuming that the ligament of Weiger remains intact.¹¹ In our patient, we observed an unusual and dramatic deposition of pigment on the central aspect of the posterior lens capsule, which was remarkably symmetrical when comparing one eye with the other. Theoretically, if the ligament of Weiger is intact, there should not be communication between the posterior chamber and the potential space of Berger.¹⁰ In our case, the pigment on the central aspect of the posterior lens capsule appeared to increase and then

to decrease in size over time (Figures 4A and B vs Figure 5). A possible explanation for this points to a break in the ligament of Weiger. If there was a break in the ligament of Weiger and the anterior hyaloid remained intact, it would allow aqueous to traverse from the posterior chamber to the space of Berger. The constant flow of aqueous through this space could bring loose iris pigment to deposit on the central aspect of the posterior lens capsule and then over time displace this same pigment to a different location. Given there was no pigment visualized in the vitreous and there were no retinal breaks noted on fundus examination, we believe the pigment cells in our patient originated from the iris, rather than the retina. Roberts et al¹¹ suggested that a disruption in

Figure 4 (A) Optos Daytona ultra-widefield images highlight an increase in pigment over time of the right eye from 2013 (left) to 2014 (right). (B) Optos Daytona ultra-widefield images highlight an increase in pigment over time of the left eye from 2013 (left) to 2014 (right).

Note: These are visualized by the shadows cast on the retina (arrows) from the pigment deposition along the posterior lens capsule.

Figure 5 Optos California images from 2016 reveal a decrease in pigment over time of the right eye (left) and left eye (right) compared to 2013 and 2014 (Figure 4A and B).

Notes: These are visualized by the shadows cast on the retina from the pigment deposition along the posterior lens capsule.

this natural barrier, such as with trauma, may allow pigment to enter the potential space of Berger. However, a bilateral break in the ligament of Weiger is rare without trauma and, therefore, remains to be explained. It should be noted that the commencement of travoprost drops after the first 3 years of observation could have had an effect on the change in

pigment. We do not feel that this change is significant, given that pigment deposition also decreased over time while on the same medication. Additionally, photos in Figure 4A and B were taken by the Optos Daytona and those in Figure 5 were taken by Optos California Daytona ultra-widefield imaging (© 2017; Optos plc). We do not believe that this would have

a significant impact on imaging the pigment on the posterior lens capsule.

There are few cases in the literature that describe findings of bilateral and symmetrical pigment deposition on the posterior lens capsule with changes in morphology over time. Al-Mezaine¹² reported a case of unilateral pigment deposition with a history of trauma in that same eye. Nagarajaiah and Shun-Shin,¹³ Lin et al,¹⁴ and Turgut et al¹⁵ describe cases of unilateral pigment deposition on the posterior lens capsule without a history of trauma. Nagarajaiah's case is similar to ours in that the pigment was noted to change over time. Roberts et al¹¹ reported a case of bilateral pigment deposition with the history of trauma in only one eye and a second case of unilateral pigment deposition without trauma. His first case is most similar to ours in that there was bilateral pigment deposition; however, his patient did not present with symmetry between the two eyes, nor was it noted to change over time.

As hypothesized earlier, a break in the ligament of Weiger is the only way in which pigment can reach the space of Berger. Since cases of spontaneous breaks in the ligament of Weiger are rare,¹⁶ we propose another mechanism for this break. Bernal et al¹⁷ were able to describe and document the precise insertion of the anterior and posterior zonules to the lens capsule. Traditionally, it was thought that both the anterior and posterior zonules began at the ciliary body and inserted directly to the lens. Bernal confirmed that the anterior zonules have a straight path from the ciliary body to the lens. However, the majority of the posterior zonules first inserted into the anterior hyaloid membrane proximal to the ciliary body and then to the lens capsule. Some of these fibers inserted into areas close to Weiger's ligament before adhering to the posterior lens capsule.¹⁷ If one could imagine the posterior bowing of the iris in a patient with PDS and its relationship to the anterior zonules, it could be perceived that such rubbing against the anterior zonules could also affect the posterior zonules, especially those which are directly adherent to the ligament of Weiger. After years of chronic contact, this would promote detachment of the ligament of Weiger, thereby allowing pigment to enter the space of Berger. Given that central posterior lens capsule pigmentation is not common in all patients with PDS, we propose that the amount of iris bowing may be related to this mechanical break in the ligament and perhaps a more concave iris would be more likely to cause a break in the ligament. The degree of iris concavity was not measured in our case but perhaps opens an area for future research.

The unusual presentation of the density, symmetry, and changing morphology of pigment has not been described previously in literature. This has clinical significance because

if the known and sometimes subtle findings of PDS such as Krukenberg's spindle, iris transillumination defects, and pigmented trabecular meshwork are initially overlooked by the examiner, observation of pigment on the posterior lens capsule may promote the examiner to check for these features more closely. Additionally, future studies relating the degree of iris bowing to a break in the ligament of Weiger may confirm such a relationship and thereby identify a new subset of patients with this feature of PDS.

Eye and Brain**Dovepress****Publish your work in this journal**

Eye and Brain is an international, peer-reviewed, open access journal focusing on clinical and experimental research in the field of neuro-ophthalmology. All aspects of patient care are addressed within the journal as well as basic research. Papers covering original research, basic science, clinical and epidemiological studies, reviews and evaluations,

guidelines, expert opinion and commentary, case reports and extended reports are welcome. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
