**Purpose:** To compare clinicopathologic factors including tumor-node-metastasis (TNM) stage between young and elderly patients with non-small cell lung cancer (NSCLC).

**Methods:** This retrospective study compared the following characteristics between 52 young patients with NSCLC (<50 years of age) and 67 elderly patients with NSCLC (>60 years): duration of symptoms before medical consultation, smoking index, family history of cancer, Ki-67 index, and pTNM stage. A binary logistic regression analysis was used to identify factors predictive of greater stage NSCLC (stage III/IV compared to stage I/II) within each age group.

**Results:** The incidence of adenocarcinoma was higher in the young than in the elderly ( $P=0.006$ ). Smoking index ( $P=0.002$ ) and Ki-67 index ( $P<0.001$ ) were lower in the young than in the elderly. In young patients with NSCLC, delayed treatment (greater duration from symptoms to medical consultation,  $P=0.050$ ) and active tumor proliferation (higher Ki-67 index,  $P=0.003$ ) were predictive of more advanced cancer stage (III/IV), with only symptom duration being predictive of stage III/IV NSCLC among elderly patients. Among young patients, cough ( $P=0.021$ ) and chest congestion ( $P=0.040$ ) were the most significant warning symptoms of advanced-stage NSCLC.

**Conclusion:** High tumor proliferation and delayed treatment are predictive of advanced NSCLC on presentation among young individuals. Early diagnosis by imaging, such as with the use of low dose computed tomography (LDCT), for young individuals with coughing and chest congestion over 1 month might be effective to improve prognosis and outcomes.

**Keywords:** NSCLC, young adult patients, symptom assessment, Ki67

## Introduction

Lung cancer is the most common and lethal type of cancer worldwide, with a morbidity rate of 11.6% and a mortality rate of 18.4%.<sup>1</sup> Most new lung cancer cases and deaths occur in patients 60–70 years of age.<sup>2</sup> However, the incidence rate of lung cancer among younger individuals is not insignificant at 5%–10%<sup>3</sup> and, therefore, should not be ignored. However, current research on non-small cell lung cancer (NSCLC) among younger individuals is insufficient. In part, the definition of “young” itself is controversial and confusing, with cutoff ages of 40 years,<sup>4,5</sup> 45 years,<sup>6,7</sup> and 50 years<sup>8,9</sup> having been used to define “young.” Therefore, a unified age standard to guide research is lacking.

Moreover, tumorigenesis itself is a complicated process with numerous influential factors. The National Comprehensive Cancer Network (NCCN) has suggested

Tel +86-10-83922236  
Email zhangyi@xwhosp.org

that individuals with certain characteristics such as a smoking history, family history of lung cancer, and radiologic factors should be periodically examined for lung cancer prevention.<sup>10</sup> Of note, some of these risk factors such as smoking and radiation may give rise to lung cancer due to years of exposure. As such, the contribution of these factors to NSCLC in young and elderly individuals needs to be evaluated beyond simply their “presence” or “absence.” An objective standard for comparing clinicopathologic factors between young and elderly patients with NSCLC would be desirable in this regard.

Human factors influence disease progression and therefore need to be considered. Specifically, it is well recognized that some patients overlook early diseases symptoms and, thus, miss the opportunity for early diagnosis. Moreover, it is possible that a cancer with onset at a young age might reflect genetic susceptibility. These human risk factors can influence the tumor proliferation rate, playing an important role in oncogenesis and prognosis.<sup>11,12</sup> Therefore, the aim of this study was to compare clinicopathologic factors including tumor-node-metastasis (TNM) stage between young and elderly patients with NSCLC.

## Patients and Methods

### Patient Selection

In this single-center retrospective study, patients eligible for our study group were those receiving surgical treatment for NSCLC in our department, between November 2013 (when electronic medical records were implemented at our hospital) and March 2019. To balance the sample size and subgroup difference, patients <50 years of age were classified as young patients, with the elderly comparison group comprising patients >60 years of age, in whom the incidence of NSCLC is the highest (as mentioned above). To eliminate the effects of confounding symptoms, we excluded patients with chronic respiratory and cardiovascular diseases such as chronic obstructive pulmonary disease (COPD), tuberculosis, coronary heart disease, or heart failure. Patients with incomplete records were also excluded.

Information of the following variables was extracted from patients' records in our hospital's electronic information system: sex; age at the time of diagnosis; duration of symptoms until medical consultation; smoking index (cigarettes smoked per day × years of tobacco use); family

history of cancer; histologic type of tumor; and the Ki-67 index, described below. The pTNM stage was evaluated according to the 8th edition of the lung cancer staging classification system.<sup>13</sup>

### Statement of Ethics

This study complied with the Declaration of Helsinki, conformed with the relevant regulations and was approved by ethics committee of Xuanwu Hospital, Capital Medical University. All patients provided informed consent for the surgical treatment and for the use of their medical information for research.

### Ki-67 Index Assessment

Surgically resected tissue was made into slices and observed under 400-fold high-power field. Positive-nuclear cells were counted out of 100 cells in 10 randomly selected fields. Ki-67 index = (number of positive cells/1000) × 100%.

### Statistical Analysis

The Pearson's chi-squared test and Fisher's exact test were used to analyze patients' gender, symptoms, family history, histological type and TNM stage. The quantitative data were examined under independent-samples *t*-test (normal distribution) or Nonparametric test (abnormal distribution) in corresponding age subgroups. The binary logistic regression was used to evaluate meaningful clinicopathologic characteristics between stage I/II and stage III/IV patients. All statistical analyses were conducted in the SPSS 20.0 for Windows (SPSS Inc., Chicago, IL, USA). *P*<0.05 was considered statistically significant.

## Results

Within our study period, from November 2013 through March 2019, 1936 patients received surgical treatment for NSCLC. Of them, 119 met our exclusion criteria and were enrolled in our study: 52 in the young group and 67 in the elderly group. Patients' clinicopathologic characteristics are summarized in [Table 1](#).

### A Comparison of Clinical and Pathological Characteristics in Young and Elderly Patients

The young group included 52 patients, 26 males, with a mean age of 44.5±5.48 years and a mean initial symptom duration of 3.23±6.95 months. Of them, 13 were smokers (with a smoking index ranging

**Table 1** Clinical and Pathological Characters in Young Patients Comparing with the Elderly

Variables		Young Patients (n=52)	Elderly Patients (n=67)	P value
Gender (Male/Female, F%)		26/26, 50.00%	41/26, 38.81%	0.222
Age/y (Min-Max, Mean±SD)		25–50, 44.5±5.48	60–78, 68.0±5.14	
Symptoms (n,%)	Cough	22, 42.31%	32, 47.76%	-
	Hemosputum	6, 11.54%	12, 17.91%

	Chest	8, 15.38%	9, 13.43%	
	Congestion			
	Fever	3, 5.77%	5, 7.46%	
	Weight Loss	5, 9.62%	5, 7.46%	
	Others	3, 5.77%	2, 2.99%	
Asymptomatic		20, 38.46%	26, 38.80%	
Symptom Duration/Mo (Mean ±SD)		3.23±6.95	1.72±2.87	0.145
Smoking Index (Min-Max, Median, %)		0–800, 0, 25.00%	0–2400, 0, 49.25%	0.002
Family History(n,%)		13, 25.00%	8, 11.94%	0.064
Histological Type	AIS(n,%)	8, 15.38%	3, 4.48%	0.006
	ADC(n,%)	39, 75.00%	44, 65.67%	
	SCC(n,%)	4, 7.69%	20, 29.85%	
	ASC(n,%)	1, 1.92%	0, 0.00%	
pTNM Stage	0/I/II	8/20/4, 33	3/31/11, 45	0.673
	III/IV	14/5, 19	20/2, 22	
Ki-67 Index (Mean±SD)		18.5%±19.0%	35.3%±26.9%	<0.001

between 2 and 800), 13 had a positive family history of malignant tumors, and 19 had a diagnosis of pTNM stage III or IV disease. The mean Ki-67 index was 18.5±19.0%. Symptoms leading to a medical consultation included: coughing (n=26); hemosputum (n=6); chest pain (n=9); chest congestion (n=8); fever (n=3); weight loss (n=5); heart palpitations (n=1); night sweat (n=1); and one patient reported dizziness and headache, with this patient ultimately being diagnosed with brain metastases. The pathological classification of tumors among patients in this group was as follows: adenocarcinomas in situ (AIS), n=8; adenocarcinomas (ADC), n=39; squamous carcinoma (SCC), n=4; and adenosquamous carcinoma (ASC), n=1.

The following characteristics were significantly different between the young and elderly groups: age ( $P<0.001$ ), smoking index ( $P=0.002$ ), histological tumor type ( $P=0.006$ ), and Ki-67 index ( $P<0.001$ ), summarized in Table 1.

## Binary Logistic Regression Analysis of the Relation Between Risk Factors and pTNM Stage

Within the young group, compared to patients with stage I/II, those with stage III/IV had longer initial symptom duration before consultation, higher rate of smoking, and higher Ki-67 index and were predominantly male. The same factors were identified between patients with stage I/II and stage III/IV in the elderly group. On logistic regression analysis, symptom duration ( $P=0.05$ ) and Ki-67 index ( $P=0.003$ ) were retained as predictive variables of stage III/IV cancer for the young group, indicating that delayed treatment and active tumor proliferation (higher Ki-67 index) are factors associated with advanced cancer stage. In the elderly group, only symptom duration was identified as a predictive factor ( $P=0.05$ ). Results are shown in Tables 2 and 3.

## Symptom Differences Between Stages in Age Subgroups

Presenting symptoms were also compared between patients with stage I/II and stage III/IV NSCLC within each age group (Table 4). Overall, the most common presenting symptoms among patients in our study group were cough, hemosputum, chest pain, chest congestion, fever, and weight loss. Of these, cough and chest congestion were more frequent among patients in stage III/IV than those in stage I/II (cough, 63.2% versus 30.3%,  $P=0.021$ ; chest congestion, 31.5% versus 6.1%,  $P=0.040$ ) in the young group, which is hemosputum (31.8% versus 11.1%,  $P=0.038$ ) in elderly group.

## Discussion

Cancer is often considered to be a “senile disease” because of its strong correlation with older age. With regard to lung cancer, this incidence rate of NSCLC among individuals <50 years of age is estimated at 5.6%.<sup>14</sup> The 2014 Japan Lung Cancer Registry Study<sup>15</sup> reported a sharp increase in the incidence of lung cancer among patients <50 years of age. It is not uncommon for pulmonary lesions in young patients to be identified on LDCT, with patients seeking further medical consultation after identification. Although the predictive clinical characteristics of NSCLC in young individuals are still uncertain, specific pathological characteristics, smoking status, family history, and TNM stage are known factors that influence prognosis. Differences in risk factors between young and elderly patients might

**Table 2** Single Factor Analysis of the Relation Between Risk Factors and Staging

	Variables	0/I/II	III/IV	P value
Young	Gender (Male/Female, F%)	15/18, 54.55%	11/8, 42.11%	0.388
	Age/y (Mean±SD)	45.39±5.08	42.84±5.89	0.106
	Symptom Duration/Mo (Mean±SD)	1.34±2.67	6.52±10.29	0.044
	Smoking Index (Min-Max, Median, %)	0–800, 0, 21.2%	0–600, 0, 31.6%	0.388
	Family History(n,%)	9, 27.3%	4, 21.1%	0.746
	Ki-67 Index (Mean±SD)	11.2%±15.1%	31.1%±18.8%	<0.001
Elderly	Gender (Male/Female)	26/19, 42.22%	15/7, 31.82%	0.412
	Age/y (Mean±SD)	68.0±5.18	68.0±5.16	0.973
	Symptom Duration/Mo (Mean±SD)	1.22±2.15	2.75±3.82	0.091
	Smoking Index (Min-Max, Median, %)	0–2400, 0, 42.22%	0–2400, 500, 63.64%	0.276
	Family History(n,%)	6, 13.30%	2, 9.10%	1.000
	Ki-67 Index (Mean±SD)	31.8%±22.7%	42.5%±24.0%	0.125

explain differences in the distribution of the types of NSCLC between young and elderly patients.

Among young patients, the incidence of ADC was higher than any other type of NSCLC (AIS, SCC, and ASC) and was specifically higher than the rate of ADC in the elderly group (Table 1, 75.00% versus 65.67%, respectively,  $P=0.006$ ). Previous studies have reported the high proportion of ADC among young patients with lung cancer, with the prevalence being higher in females than in males.<sup>5,9,16,17</sup> We believe that this SCC-ADC shift may be a result of the accumulation of risk factors, one of which is tobacco use.

Smoking was more frequent among elderly than among young patients (Table 1,  $P=0.002$ ). As a longer history of smoking would increase the accumulation of toxins over time, the risk of these toxins inducing gene mutations leading to lung cancer would also increase. Smoking has been associated with a higher specific risk for SCC (91%), compared to ADC (82%).<sup>18</sup> We noted, from our findings, that the difference in the smoking index between patients with early- and late-stage NSCLC was not significantly different for both the young ( $P=0.388$ ) and elderly ( $P=0.276$ ) groups (Table 2). Therefore, smoking may have triggered the disease.

**Table 3** Binary Logistic Regression Analysis of the Relation Between Risk Factors and Advanced Stage

	Variables	B	S.E.	Wald	P value	OR (95% CI)

	P value	0.437	0.038	1	0.461	1	1	0.091

Note: \*Fisher's Exact Test.

Various environmental factors other than smoking have been associated with lung cancer. Among these factors, second-hand smoking increases the risk for lung cancer among non-smokers by 1.31 (95% confidence interval (CI) of the odds ratio, 1.17–1.45).<sup>19</sup> Air pollution caused by PM<sub>2.5</sub> or indoor radon<sup>20–22</sup> and depression generated (identified in 40% of patients with advanced NSCLC)<sup>23</sup> have also been associated with lung cancer. Considering the impact of these factors on the incidence of lung cancer, we propose that smoking status might be an “optional” condition to recommend advanced imaging such as thin-slice computed tomography, rather than a “compulsory” condition. Further research is warranted to clarify this issue.

Family history was not a specific risk factor to NSCLC in the young group, with the presence of a family history of cancer not being different between the young and elderly groups (Table 1,  $P=0.064$ ). We do note that a large sample study, including 5048 patients with lung cancer, reported a significant and marked increase in the risk for lung cancer for each additional lung cancer first-degree relative (relative risk, 2.57; 95% CI, 2.39–2.76).<sup>24</sup> Further research on this specific factor is warranted to improve screening algorithms for individuals at high risk for lung cancer.

The tumor proliferation characteristics also need to be considered. Tumorigenesis, as previously mentioned, is influenced by multiple factors and interactions. The high proliferation rate activated by these factors can explain why some patients, even without typical risk factors for lung cancer, are diagnosed with advanced NSCLC when first walking into a clinic. The Ki-67 index has been used in clinical practice to evaluate proliferative activity in many cancers, including lung cancer.<sup>25–27</sup> The lower Ki-67 index for young than for elderly individuals in our study ( $P<0.001$ ) would explain the higher proportion of early-stage diagnosis in the young group than in the elderly group and may be predictive of a better disease prognosis as previously reported.<sup>9,28</sup> The difference in the Ki-67 index between patients with early-stage NSCLC than those with late-stage NSCLC within the young group (Table 2,  $P<0.001$ ) may indicate that unique risk factors, other than smoking or family history, affect tumorigenesis among young patients.

Lastly, human factors must be considered. We note that the identification of non-symptomatic pulmonary nodules or masses has increased as a function of the increased use of LDCT (or other imaging technique) for screening of individuals deemed at high risk for lung cancer. Consequently, this has raised the diagnosis rate of lung cancer. Yet, delay in onset of symptoms and medical consultation for lung cancer remains

a problem among young individuals who are more likely to ignore early symptoms such as cough or chest congestion.<sup>29,30</sup> A delay in diagnosis results in more advanced stages of cancer at the time of presentation and a poor prognosis (Table 4,  $P=0.044$ ). In our research, we identified cough and chest congestion for >1 month as symptoms predictive of lung cancer among young patients. Therefore, young individuals presenting with these symptoms excluded the possibility of chronic diseases like COPD, coronary heart disease and asthma should be investigated for lung cancer.

Our research has several advantages over previous studies on this issue. Exposure to smoking, rather than simply a positive or negative history of smoking, should be considered in a screening algorithm. The Ki-67 index should also be included, based on the finding that the tumor proliferation rate itself plays an important role in the progression of NSCLC among young patients and, ultimately, prognosis. Early diagnosis is necessary to improve disease outcomes and survival among young patients with typical symptoms.

The limitations of our study also need to be considered. Foremost, the study has a retrospective design, which may have caused bias in the selection of the study group. This was a single-center study, and therefore, the study sample may not be comparable to that used in epidemiological studies from other regions, which limits comparison of findings. We did not evaluate the outcomes of the surgical treatment and did not perform a prognostic analysis due to the high rate of missing follow-up data.

## Conclusion

This is one of the largest studies in China to analyze the relationship between clinical-pathological characteristics and TNM stage in young NSCLC patients after the 8th edition of the lung cancer staging classification system was published. It demonstrates that the high tumor proliferation and delayed treatment are predictive of advanced NSCLC on presentation among young individuals. Early diagnosis by imaging, such as with the use of LDCT, for young individuals with cough and chest congestion over 1 month might be effective for early diagnosis to improve prognosis and outcomes.

**Risk Management and Healthcare Policy**

Dovepress

**Publish your work in this journal**

Risk Management and Healthcare Policy is an international, peer-reviewed, open access journal focusing on all aspects of public health, policy, and preventative measures to promote good health and improve morbidity and mortality in the population. The journal welcomes submitted papers covering original research, basic science, clinical & epidemiological studies, reviews and evaluations,

guidelines, expert opinion and commentary, case reports and extended reports. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
