Background: Acquired reactive perforating collagenosis is a rare skin disease characterized by the discharge of collagen fibers through the epidermis. There is no standard treatment for this disease currently. Here, we report a case of ARPC that has been successfully treated and cured.

Case Description: A 32-year-old man developed severe itching papules on his torso and limbs for 3 months. Skin lesions were keratotic papules scattered on the limbs and trunk, with a diameter of 3 to 12 mm. Some lesions had umbilical recesses and the shape of a crater with positive isomorphic reactions. The patient scratched his severe itching lesions which merged into large ones. This patient had histories of hypertension and dilated cardiomyopathy with mild congestive heart failure. The clinical presentation and histopathology of skin lesions met Faver's diagnostic criteria for ARPC.

Treatment: Oral Doxycycline 100mg/d, NB-UVB phototherapy 3 times a week with initial dose 400mJ/cm², gradually increased to 1200mJ/cm²(total cumulative dose 16700J/cm²).

Outcomes: After a week of treatment, the patient's itching symptoms were significantly reduced and stopped presenting any new skin lesions. Most of the lesions healed in 6 weeks of treatment.

Lessons: Doxycycline combined with NB-UVB may be an effective treatment for ARPC.

Keywords: acquired reactive perforating collagenosis, doxycycline, NB-UVB, hypertension

Introduction

Acquired reactive perforating collagenosis (ARPC) is a rare skin disease characterized by the excretion of collagen through the epidermis, first reported by Mehregan in 1967. There are two types of RPC, hereditary RPC and acquired RPC (acquired RPC, ARPC). The former is relatively rare, seen in infancy or early childhood. The acquired RPC is common in adults. The pathogenesis of ARPC is not yet clear. No standardized treatment is available at present. Here we report a case of ARPC that had been successfully cured.

Consent

This patient signed informed consent for the publication of this case report and the associated images. And this study was approved by the ethics committee of Affiliated Hospital of Nantong University.

Case Presentation

A 32-year-old man came to our outpatient clinic with severe itching papules in his torso and limbs for three months. Initially, itchy keratotic papules appeared on his lower extremities, then on his upper limbs and trunk. The keratotic papules were scattered on the limbs and trunk, with a diameter of 3 to 12 mm. Some skin lesions had a concave umbilical shape and a crater shape (Figure 1). Koebner Phenomenon is positive in this case. The patient scratched both upper arms, waist, and lower limbs due to severe itchiness. Some of the scratched lesions merged into large ones (Figure 2). This patient had a 5-year history of uncontrolled hypertension and a 2-year history of dilated cardiomyopathy with mild congestive heart failure. Lab results showed decreased creatinine clearance (CKD stage 3b), but normal creatinine, urea nitrogen, blood glucose and glycated hemoglobin. Histopathological manifestations were localized epidermal defects with cup-shaped depressions. The defects contained a large number of keratinized plugs (Figure 3A, HE×40). Locally visible

Figure 1 Clinical images of ARPC. Scattered keratotic papules on the trunk, part of the lesions may have umbilical recesses, and the shape is crater-shaped (White arrow).

collagen fibers that vertically penetrated the epidermis were characteristic, with infiltration of inflammatory cells around them (Figure 3B, HE×100), Masson staining showed collagen fibers stained in the superficial dermis and blue in the epidermis (Figure 3C, Masson stain×400). The clinical presentation and histopathology of skin lesions meet Faver's diagnostic criteria for ARPC. Treatment: oral Doxycycline 100mg/d, NB-UVB phototherapy 3 times a week, 400mJ/cm² increasing gradually to 1200mJ/cm² (total cumulative dose 16700J/cm²). After 1 week of treatment, the patient's itching symptoms were significantly reduced, and stopped presenting new skin lesions. Most of the lesions subsided after 6 weeks of treatment (Figure 4).

Discussion

The etiology and pathogenesis of ARPC are still unclear. Childhood onset is related to autosomal dominant or recessive inheritance. Adult patients are often accompanied by one or more systemic diseases.¹ Among systemic diseases accompanied by ARPC, hypertension is the most common, followed by diabetes, and kidney failure.² At present, some studies have found that there is overexpression of transforming growth factor (TGF)-β3 in many ARPC patients³ suggesting that this factor may be related to the incidence of ARPC. Advanced glycosylation end product receptor (RAGE) is a multi-ligand transmembrane receptor that plays an important role in the inflammatory response. The overexpression of RAGE in skin lesion specimens of ARPC patients may be involved in the pathogenesis of ARPC.⁴ Micro-trauma caused by itching and scratching has been considered to be an important cause of ARPC and plays an important role in the development of the disease.⁵ After itching control, the improvement of clinical symptoms supports this view. There is no standardized treatment currently. Various ARPC treatments mainly include topical application of glucocorticoids, antihistamines, retinoic acid drugs, vitamin D analogs, allopurinol, and phototherapy. Glucocorticoids and antihistamines are the most commonly prescribed drugs.⁶ Therapeutic agents that have been used to treat and reduce lesions without major side effects include isotretinoin, corticosteroids, allopurinol, antibiotics such as doxycycline, and phototherapy. Treatments of ARPC should be prioritized according to patients' needs and availability. The patient is obese, hyperlipidemia, hypertension, and hyperuricemia. In addition, his skin lesions are large and skin infections are likely to occur. All things considered, doxycycline is considered

Figure 2 Clinical images of ARPC. (A) Koebner Phenomenon due to scratching can be seen at the elbow, and the lesions are fused into a piece (Yellow arrow). Typical rash for crater-shaped (White arrow); (B) crater-shaped rash of waist; (C) Koebner Phenomenon of lower limb.

beneficial and more suitable for him. Combination treatment, rather than monotherapy, has been shown to result in more favorable outcomes.⁷ So we chose doxycycline combined with NB-UVB phototherapy for acquired reactive perforating collagenosis. Our treatment plan for this patient was oral Doxycycline 100mg/d, combined with narrow-band UVB 3 times a week, the initial dose was 400mJ/cm², then increased to 1200mJ/cm² gradually (Total cumulative dose 16700J/cm²). After a week of treatment, the patient's itching symptoms were significantly improved, and no new skin lesions appeared. Most of the lesions subsided after 6 weeks of treatment. It has been reported Doxycycline was an effective treatment,⁸ but the exact mechanism of action is unclear. Doxycycline has immunomodulatory and anti-inflammatory effects, of which the inhibitory effect on stroma proteins has been emphasized as a major non-antibacterial effect. Therefore, Doxycycline may play a role by

inhibiting matrix metalloproteinases, regulating inflammatory cytokines, and inhibiting the chemotaxis and activation of leukocytes.⁹ NB-UVB is also a commonly used treatment method and has achieved good results in some patients.¹⁰ Neutrophils are the main cells in the pathogenesis of ARPC,¹¹ which may promote the development of disease by releasing matrix metalloproteinases and other serine proteases to destroy the structure of the basement membrane.¹² NB-UVB may play a therapeutic role by inhibiting neutrophil infiltration and regulating immune function.¹³

Conclusions

In summary, we report a case of ARPC that showed great response to Doxycycline in combination with NB-UVB. Our treatment is supported by the literature, indicating that Doxycycline combined with NB-NVB may be an effective method for the treatment of ARPC. Due

to the rareness of this disease, further Study Is needed to validate the treatment protocol and maximize therapeutic benefit in ARPC.
