Objective: This study evaluates the total antioxidant status (TAS) in plasma of stable chronic obstructive pulmonary disease (COPD) patients. Earlier studies of their relationship showed inconsistent findings.

Patients and Methods: We compared TAS between 90 COPD patients and 30 age- and sex-matched controls (mean age 67 ± 7.9 , 87 males and 33 females) according to airway obstruction severity, gender, smoking status (current/ former/ non-smoker), smoking-dose, the number of exacerbations in the previous year, nutritional status and hypercapnia.

Results: There were no differences in pack-years between COPD and controls, neither in COPD groups. The median time from the last exacerbation was 5 months (interquartile range 3–8.3). TAS was significant higher in COPD than controls (1.68 [1.55–1.80] versus 1.59 [1.54–1.68], respectively; $P = 0.03$). TAS was significantly higher in COPD men than women (1.7 [1.6–1.8] versus 1.57 [1.5–1.7], respectively; $P = 0.001$). In COPD groups, there were no significant differences between the severity of airway obstruction and TAS. We found significant positive correlation between pack-years and TAS in all participants ($Rho = 0.429$, $P = 0.004$) and COPD patients ($Rho = 0.359$, $P = 0.02$), but not in controls. TAS was a significant predictor of COPD ($\beta = 3.26$; $P = 0.04$; OR = 26.01; 95% CI: 1.20 to 570.8). We failed to find significant differences between TAS and smoking status, frequency of exacerbations in the previous year, nutritional status and hypercapnia.

Conclusion: TAS was a significant predictor of COPD. TAS was a significantly higher in stable COPD than controls, higher in COPD men than women, but there was no significant correlation between TAS and the airway obstruction severity. Our results suggest that it could be appropriate to include the time from the last exacerbation in the oxidant–antioxidant balance analysis of COPD patients.

Keywords: chronic obstructive pulmonary disease, antioxidants, airway obstruction severity, exacerbation, smoking

Introduction

The pathogenesis of chronic obstructive pulmonary disease (COPD) is in strong causal link with increased oxidative burden. The harmful oxidants and defensive intracellular and extracellular antioxidant systems are in gentle balance.¹ Antioxidants and antioxidant enzymes have an essential function against the oxidative burden in smokers and COPD lungs.² Oxidant–antioxidant imbalance has a significant role in different stages of COPD severity.³ It occurs when the resident antioxidants are insufficient or cannot increase enough to counteract an increased oxidative burden. The target of treating oxidative stress should be either to reduce oxidant formation or to increase antioxidants.⁴

Cigarette smoking is the most common identified risk factor for COPD.⁵ Despite that, only a minority of smokers develop COPD symptoms that are clinically significant.⁶ Approximately 13% of smokers have COPD and the risk for disease increased with the number of cigarettes consumed.⁷ Smoking cessation has the greatest impact on disease course and it is a key to prevent future COPD exacerbations.^{8,9} But even in former smokers that have signs of persistent chronic airflow limitation, there are signs of a low-grade systemic inflammation. It shows that, once COPD develops, smoking cessation may not stop the disease from progressing.¹⁰

Since it is difficult to measure each antioxidant in different biological samples, various methods have been promoted to determine the total antioxidant status (TAS). Some of them can define TAS in plasma of COPD patients.¹ Reports on the relationship between the oxidant–antioxidant imbalance and pulmonary function in COPD patients showed inconsistent results.¹¹ In stable COPD, there were reports of no significant differences of TAS,^{12,13} as well as a significant decrease of TAS compared to controls.^{11,14} In a study without the characteristics of disease activity, findings suggested a lower TAS in patients compared to healthy controls, confirming a presence of systematically oxidant–antioxidant imbalance in COPD patients.¹⁵ Some authors found a significant reduction in TAS only in exacerbation of COPD.^{16,17} Earlier reports that compared TAS and the airway obstruction severity in COPD patients, were found no significant differences.^{11,18,19}

In the present study, we have analyzed the predictive value of TAS for COPD and compared the plasma TAS values in stable COPD patients according to their clinical data and severity of the disease with healthy controls.

Patients and Methods

Study Subject

This was a single-center, cross-sectional observational study, taken in general hospital, between March and August 2018. The participants were above 18 years, both sexes, with a diagnosis of COPD and healthy volunteers. COPD patients were defined as stable based on having no exacerbation for the previous 2 months. The data about previous exacerbations were collected retrospectively. None of them use systemic corticosteroid medication during the study.

Exclusion criteria were: active malignant disease, febrile state, nonsteroidal anti-inflammatory and antioxidant

therapy (vitamins A, C and E). COPD patients with arterial hypertension, hyperlipidemia, ischemic heart disease and diabetes mellitus were included if they were under good therapy control.

The sample size was calculated to be 120, with an effect size of 0.35, level of significance 0.05 and power 0.9 (G*power software, version 3.1.9.2, by Franz Faul, University Kiel, Germany).

The study was approved by the ethics committee of General Hospital Našice (No. 01-497/3-2017) and Faculty of Medicine Osijek, University Josip Juraj Strossmayer Osijek, Croatia (No. 2158-61-07-17-209). All data were anonymized and the study was conducted in accordance with the amended Declaration of Helsinki. Informed consent was obtained from all individual participants included in the study. All participants signed an informed consent form before entering the study.

Study Design and Variables

According to international established Global Initiative for Chronic Obstructive Lung Disease (GOLD) criteria, COPD diagnosis was confirmed by post-bronchodilator forced expiratory volume in the one second (FEV₁) to forced vital capacity (FVC) ratio (FEV₁/FVC) of <0.70 in patients with appropriate symptoms. Spirometry findings of airflow limitation severity were based on FEV₁ and divided COPD in mild, moderate and severe/very severe group (GOLD classification).²⁰ According to number of exacerbations in the previous year, they were divided into non-exacerbators (0), infrequent exacerbators (1) and frequent exacerbators (≥ 2).²¹ A fourth group was healthy volunteers (FEV₁/FVC >70% and FEV₁ >80% of predicted value). The participants were demanded to refrain from caffeine, alcohol and increased physical activity at least 12 hours before entering the study.

Height and weight as the anthropometric measurements were determined, body mass index (BMI) calculated and expressed as weight (kg)/height (m²). Smoking status was recorded as current, former and non-smoker. We defined former smokers as those who had quit smoking at least one year prior to participating because the others are most likely to relapse.²² Pack-years were calculated using the formula: number of cigarettes per day x number of smoking years/20.¹¹ We defined light smoking as <20 and heavy smoking as ≥ 20 pack-years.²³ Spirometry (Spiroscout[®] Ganshorn, Germany) was carried out by specialized technician according to American Thoracic Society/European Respiratory Society standardization to all participants.²⁴

Biochemical Analysis

The capillary and venous blood was taken for biochemical analysis. An acid-base status was analyzed in COPD patients (Simens RAPIDLab 348EX, Germany) and complete blood count (Sysmex XN-1000 SA-01, Sysmex Europe GmbH), C-reactive protein (CRP) and TAS (analyzer Beckman Coulter DXC 700 AU, USA) in all. For TAS analysis, separated serum samples were frozen on -20°C , collected up to 14 days, collected ones were defrosted and analyzed in one day by colorimetric assay. The procedure was repeated until we reached the target number of participants. Blood samples for other parameters were analyzed instantly after taking.

The plasma antioxidant status was measured using a commercially available TAS kit (reagents Randox Laboratories Ltd, United Kingdom). The TAS assay is based on incubation of 2,2'-azino-di-3-ethylbenzthiazoline sulphonate (ABTS) with peroxidase (metmyoglobin) and hydrogen peroxide (H_2O_2) to produce the radical cation ABTS^+ . This has a relatively stable blue-green color, which is measured at 600 nm. Antioxidants in the added sample cause suppression of this colour production to a degree which is proportional to their concentration. The absorbance was read after exactly 3 minutes. Reference range is set at 1.30 – 1.77 and results are expressed as mmol/L.²⁵

Statistical Methods

Categorical data are represented by absolute and relative frequencies. Numerical data are described by the arithmetic mean and the standard deviation or the median and the limits of the interquartile range. Variations of categorical variables were tested by χ^2 test. The normality of the distribution of numeric variables was tested by the Shapiro–Wilk test. The differences between the normal distribution of numerical variables between the two independent groups were tested by the Student t test, and in the case of a deviation from the normal distribution by Mann–Whitney U -test. The differences between the normal distribution of numeric variables between groups considering the weight of COPD were tested for deviation from the normal distribution by Kruskal–Wallis test (post hoc Conover test). The correlation of numeric variables was evaluated by Spearman's coefficient of correlation ρ (rho). The estimate of the predictive value was tested by logistic regression analysis. All P values are two-sided. The level of significance is set to Alpha = 0.05. For statistical analysis,

statistical software MedCalc Statistical Software version 18.11.3 (MedCalc Software bvba, Ostend, Belgium; <http://www.medcalc.org>; 2019) and SPSS (IBM Corp. Released 2015. IBM SPSS Statistics for Windows, Version 23.0, Armonk, NY: IBM Corp.) were used.

Results

We included 120 participants, 90 COPD patients and 30 healthy volunteers – controls, mean age 67 ± 7.9 , 87 males and 33 females. Current COPD smokers had more heavy smokers and control group light ones, but according to pack-years there were no differences. As expected, lung function was significantly impaired in COPD patients versus controls. TAS was a significantly higher in COPD than controls (Table 1).

Among current COPD smokers, according to airflow obstruction severity, there was a significant rate of heavy smokers in severe/very severe group and light smokers in mild COPD group, but according to pack-years there were no differences. The severe/very severe COPD had a lower BMI and more infrequent and frequent exacerbators than other COPD groups. In COPD groups, there were no significant differences between the severity of airway obstruction and the TAS values (Table 2).

For all COPD patients, according to smoking status, pack-years, the frequency of exacerbations in the previous year and the findings of hypercapnia in blood samples, we failed to find significant differences in TAS values (Table 3).

For all participants, with Spearman's rank correlation coefficient ρ , there was no significant correlation between TAS and the parameters of lung functions. For all participants, control and COPD group, with Spearman's rank correlation coefficient ρ there was no significant correlation between BMI and pack-years, neither between BMI and TAS (data not displayed).

We found a significant positive correlation between pack-years and TAS in all participants and COPD patients, but not in controls (Figure 1A–C).

According to gender, in the controls, there were no significant differences between TAS values in men and women (1.62 [1.5–1.7] versus 1.56 [1.5–1.6], respectively; $P = 0.34$). In COPD patients, TAS was significantly higher in men than women 1.7 [1.6–1.8] versus 1.57 [1.5–1.7], respectively; $P = 0.001$, Mann–Whitney U -test).

Logistic regression analysis showed that TAS was a significant predictor of COPD ($\beta = 3.26$; $P = 0.04$; OR = 26.01, 95% CI: 1.20 to 570.8).

Discussion

The aim of this study was to test the predictive value of the antioxidative defense parameter – TAS for COPD and the value of TAS in plasma of COPD patients with stable disease state, according to airway obstruction severity, gender, smoking status, smoking-dose, the number of exacerbations in the previous year, nutritional status and hypercapnia. In our study, TAS was a significant predictor of COPD. TAS was a significantly higher in COPD than controls, higher in COPD men than women, but there was no significant correlation between TAS and the airway obstruction severity.

In an addition to the pulmonary impairment, COPD is associated with skeletal muscle wasting and muscle dysfunction. In a study with stable COPD patients, the biopsy of peripheral skeletal muscle in rest was performed and biochemical analysis of antioxidant parameters in muscle and oxidants in blood. The results of this study were the overall antioxidant capacity, included TAS, in muscle bioplate of COPD patients compared to healthy controls, but without any changes in oxidant parameters of blood. Probably the most influential way by which the antioxidant defense system can be triggered is exposed to oxidants. Although in study the analysis of oxidant parameters in muscle was not performed, they concluded that it is likely

that the observed increased antioxidant capacity is a compensatory adaptation to elevated oxidants in skeletal muscle of patients with COPD.²⁶

Our COPD participants were in a stable state of disease. In the previous study, the COPD patients with an acute exacerbation of disease had decreased antioxidant capacity in plasma at the beginning of treatment, for at least 48 hours, with a rise at the end of an exacerbation when they were considered to be clinically stable enough for discharge. However, the antioxidant capacity values had not returned to normal levels 5–10 days after admission.¹⁶ Previous studies that detected decreased TAS values defined stable COPD as those with 1 month^{14,19} or 2 months¹¹ of period after last exacerbation. They did not state neither took in account precise time from the last exacerbation like we did in our study. Our median time of five months from last exacerbation and higher values of TAS compared to controls could suggest a possible involvement of time needed for recovery of antioxidant defense system. The gentle oxidant–antioxidant balance and their dynamic relationship anyhow include deliberation of time in which the analyzed biological sample was taken. It could be appropriate to include the time from the last exacerbation in the oxidant–antioxidant balance analysis of COPD patients. It should be considered in future prospective studies and possible

Abbreviations: TAS, total antioxidant status; pack-years, number of cigarettes per day x number of smoking years/20; light smoking, <20 pack-years; heavy smoking, ≥20 pack-years; exacerbators, infrequent 1, frequent ≥2 in the previous year; P_k CO₂, capillary carbon dioxide partial pressure; hypercapnia, P_k CO₂ > 6.38 kPa (reference range 4.66–6.38 kPa).

interventions aimed to establish such balance. Since we did not determine the level of oxidants in serum of our participants, we could not know if the increased level of antioxidant is a compensatory adaptation to oxidative stress.

Our study confirmed earlier reports data that were no significant correlation between TAS and the airway obstruction severity.^{11,18,19}

In COPD patients, TAS was significantly higher in men. All women in our study were in post-menopausal period, thereby eliminated the effect of estrogen on oxidative stress which could occur in different age groups. Estrogen has helpful vasoactive and antioxidative characteristics and its decline in postmenopausal period is associated with increased oxidative stress.²⁷ Determine hormonal status was beyond the scope of this study, so we could not know whether this is the reason for the observed gender difference in TAS values.

In our COPD group, 10% were frequent exacerbators, and in a previous study, the reported rate was 13.6%.²¹ The frequency of exacerbations did not correlate with TAS values. Our severe to very severe COPD patients were underweight and moderate ones were obese. Underweight individuals without COPD disease showed decreased antioxidant status that was improved after re-nutrition.²⁸ In our study, there was no correlation between nutritional status and TAS in COPD patients and controls. Obesity is correlated with systemic inflammation and accompanied by high-oxidative stress.²⁹ It may stimulate TAS and the high values of antioxidant potential may be interpreted by

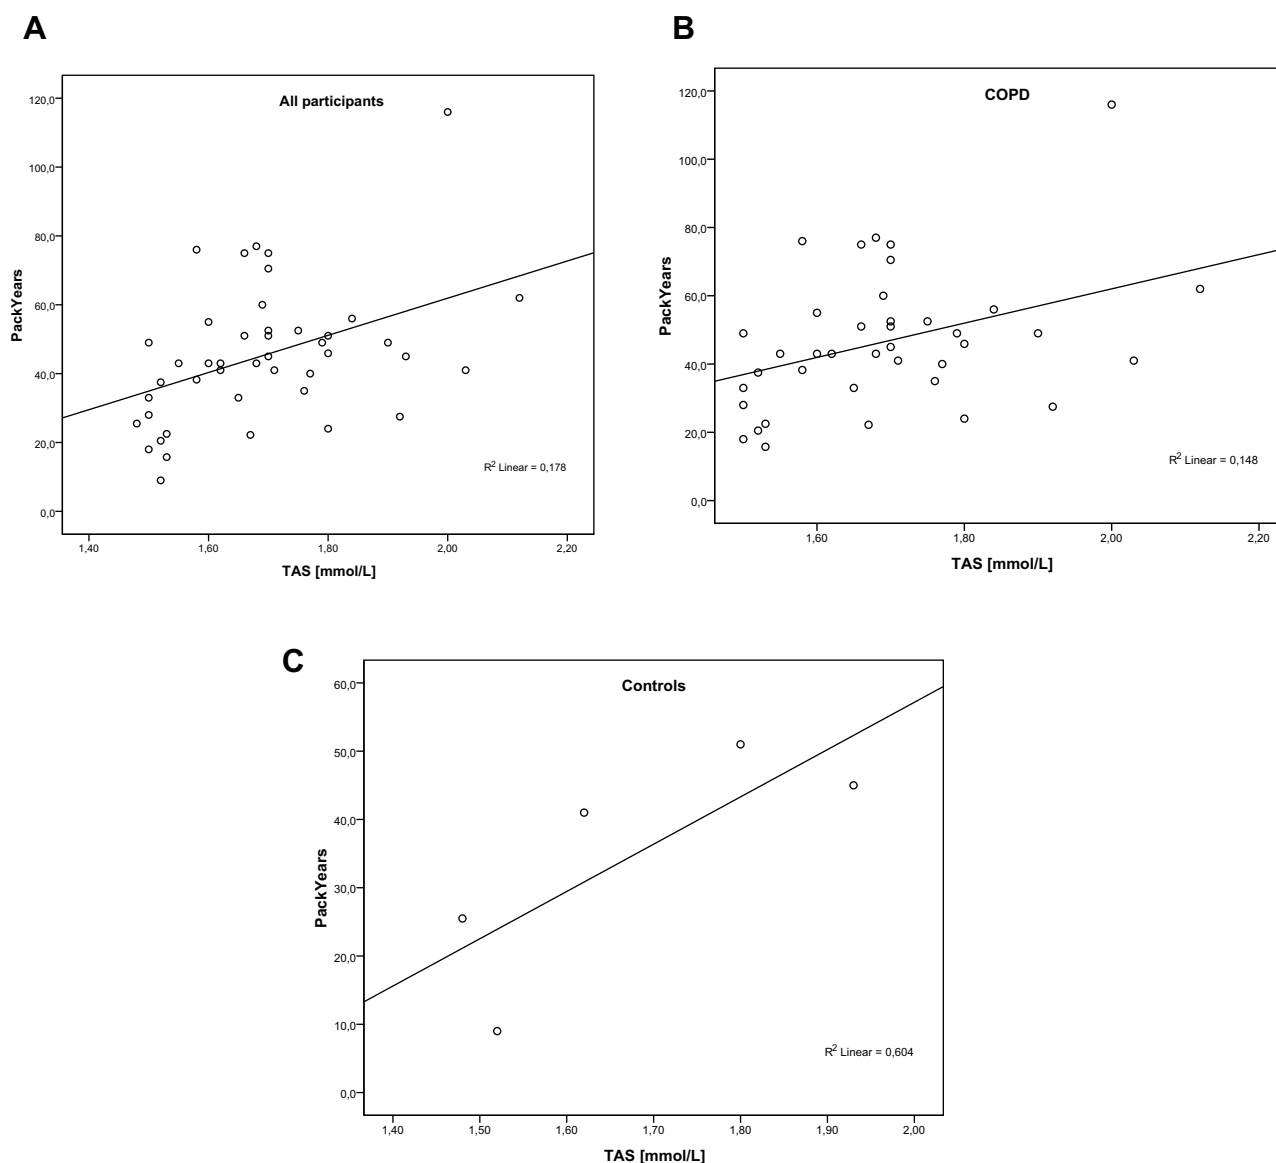

Figure 1 Correlation between pack-years and TAS With Spearman's rank correlation coefficient Rho we found a significant positive correlation between **(A)** pack-years and TAS in all participants ($Rho = 0.429$, $P = 0.004$) and **(B)** COPD patients ($Rho = 0.359$, $P = 0.02$), **(C)** but not in controls ($Rho = 0.800$, $P = 0.01$).

Abbreviations: Pack-years, number of cigarette per day \times number of smoking years/20; TAS, total antioxidant status.

compensatory response to aggravated oxidative stress in individuals with higher content of adipose tissue.³⁰ The earlier study that analyzed differences between obese and non-obese COPD smokers found higher value of antioxidative marker in the blood of obese ones.³¹ The recent study that analyzed muscle fat infiltration in COPD patients, according to nutritional status found that muscle fat infiltration is associated with increase inflammation/oxidative stress and reduction of TAS, independent of BMI. Their underweight subgroup had elevated risk of exacerbations.³² It would be useful to prospectively monitor frequent exacerbators and COPD patients, according to

nutritional status, the dynamics of TAS values over time and other clinical features of their disease phenotype.

In our study, we failed to find a correlation between TAS and hypercapnia, possibly because of the small sample size of that subgroup. Hypercapnia is frequently observed in COPD patients and, on a molecular level, participate in mitochondrial dysfunction. It represents as increased mitochondrial production of reactive oxygen species and causes oxidant-antioxidant imbalance.³³

We excluded the intake of dietary antioxidants; accordingly, the potential confusion impact of nutrition and lifestyle routine could not be part of explanations of our

conclusions. Earlier study with the male COPD patients who had smoked ≥ 20 pack-years exhibited an advantageous association between dietary antioxidant vitamin intake and FEV₁.³⁴ There is increasing interest in strategies based on nutritional or pharmacological stimulation of endogenous antioxidative defense genes. The Nuclear Erythroid-Related Factor 2 (Nrf2) is the leading antioxidative and cell-protective transcriptional nuclear factor regulated by those genes.^{35,36} Recently, the first study that analyzed expression of the Nrf2 gene in the samples of alveolar macrophages, nasal and bronchial epithelial and mononuclear cells of the periphery blood in current and former COPD smokers was performed. The expression of the Nrf2 genes was significantly higher only in bronchial epithelium of COPD smokers. There were no differences in TAS and inflammation markers in serum, plasma, bronchoalveolar lavage and exhaled breath condensate. The number of participants was not big enough to correlate between TAS and smoking-dose in the current smokers group. The conclusion was that the recognition of differences in expression of the Nrf2 gene between different biological systems could help that targeting of specific cells could have therapeutic potency of Nrf2 activators as it was already confirmed in animal and in vitro studies.³⁷ Such analysis far exceeds our technical capabilities, but it would certainly be useful to include genetic analysis in addition to the clinical manifestations of COPD in order to better understand the severity of disease, conduct therapeutic decisions, evaluate response to target interventions and provide prognostic information.

According to available data, except increased oxidants, inflammation and acute exacerbation, TAS in COPD patients could depend on gender, hormonal status in women, smoking status, smoking-dose, exacerbation number in the previous year, possibly the time from the last exacerbation, nutritional status, chronic hypercapnia, antioxidant supplementation, but also genotype and type of biological sample that was analyzed. The compensatory mechanisms of dynamic interaction between oxidant and antioxidant and the need for retention the balance, additional complicate the need for incorporating mentioned risk factors and their combination in definitive conclusions of finding interdependence.

Limitation and Strengths

The limitation of our study is the measurement of TAS in plasma, which might not reflect the local levels in the lungs. the other biological samples might be more

appropriate for estimate oxidant–antioxidant imbalance in COPD patients. We performed only one measurement of TAS at a random time point which might ignore any variation of them over time. The concentrations of antioxidants that were measured at a single point may not represent the usual concentration of the study participants.³⁸

TAS is the only biomarker that we performed because of technical and financial reasons. The combination of biomarkers increases the predictive value compared with single biomarker and clinical variables. On the other side, the literature data propose that a history of previous exacerbations is so firm correlate with future exacerbations that biomarkers may not contribute supplementary relevant information.³⁹

The technical disadvantage of our study was the inability to freeze blood samples at -80°C . That is why we were unable simultaneous defreezing all sample collection and their analysis in one act. We found higher values of TAS in the heavy COPD smoker group than in light one, but without significance; a significant positive correlation between pack-years and TAS in all participants and COPD patients, but not controls; and also TAS as predictor of COPD, but with a wide range of 95% confidence interval. A larger sample size would give bigger statistical power to detect significant associations and increase confidence in our findings.

Our conclusions are based upon results from a cross-sectional study and some of the aims could have been better addressed in a prospective study. Because the above limitations, the results could be potentially biased.

The strength of our study was a comparison of COPD patients with the well-matched control group. We exclude the intake of dietary antioxidants from the study and the potential impact of physical activity on antioxidant capacity. In COPD patients, during exercise, a significant increase in levels of blood markers of oxidative stress was observed that could be related to the disturbances of oxidant–antioxidant balance.¹²

Conclusions

The plasma TAS values in COPD patients depend on various factors. In our study, TAS was a significant predictor of COPD. TAS was a significantly higher in stable COPD than controls, higher in COPD men than women, but there was no significant correlation between TAS and the airway obstruction severity. We failed to find significant differences between TAS in stable COPD and

smoking status, frequency of exacerbations in the previous year, nutritional status and hypercapnia. The literature data on TAS value dynamics and our results suggest that it could be appropriate to include the time from the last exacerbation in the oxidant–antioxidant balance analysis of COPD patients. However, prospective studies are needed for further evaluation.

International Journal of Chronic Obstructive Pulmonary Disease

Dovepress

Publish your work in this journal

The International Journal of COPD is an international, peer-reviewed journal of therapeutics and pharmacology focusing on concise rapid reporting of clinical studies and reviews in COPD. Special focus is given to the pathophysiological processes underlying the disease, intervention programs, patient focused education, and self management

protocols. This journal is indexed on PubMed Central, MedLine and CAS. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Submit your manuscript here: <https://www.dovepress.com/international-journal-of-chronic-obstructive-pulmonary-disease-journal>
