Republic of China

**Abstract:** Regional anesthesia has been widely used in clinical practice. Over the past 30 years, various guidance techniques have been developed for regional anesthesia ranging from paresthesia progressing to neurostimulation and currently ultrasound guidance. Especially, the use of point-of-care ultrasound greatly enhances the success rate of regional anesthesia. However, the poor imaging quality of ultrasound in patients with obesity, fat infiltration, etc., limits the use of ultrasound. The combined use of ultrasound with neurostimulator, electromyography, pressure monitoring, etc. is advocated in order to facilitate regional anesthesia in this cohort of patients. The accumulated evidence has shown that the ultrasound combined with other techniques (UCOT) can help to solve the difficulties of puncture location caused by obesity, anatomical variation, and other factors when using ultrasound guidance alone. In recent years, with the development of medical image fusion and medical image artificial intelligence identification technology, guidance techniques for regional anesthesia have advanced considerably. To understand the advantages and disadvantages of the various guidance techniques for regional anesthesia developed in recent years and to guide their rational clinical application, this paper reviews these techniques, describing the progression from the early use of paresthesia to the latest UCOT, as well as the latest research on UCOT, and the prospects for the development of new guidance techniques for regional anesthesia.

**Keywords:** guidance, neurostimulation, ultrasound, regional anesthesia, artificial intelligence

## Introduction

Compared with the conventional nerve block method using anatomical localization and paresthesia, localization using neurostimulation is more accurate, objective, and safer.<sup>1</sup> However, neurostimulator guidance operates blindly and there is a high failure rate in patients with anatomical variations. Ultrasound can provide more intuitive and accurate nerve location, clarify the relative positions of blood vessels, nerves, and muscles around the puncture site, provide real-time images when blocking the target nerve, and monitor the diffusion of local anesthetics in real-time to achieve accurate anesthesia.<sup>2</sup> In recent years, with the application of computer techniques in medical imaging, it has been possible to combine ultrasound and artificial intelligence (AI) with medical image fusion, which can be applied to guide the nerve block, allowing the development of sophisticated guidance techniques for nerve block (denoted as the ultrasound combined with other techniques (UCOT)). These techniques have produced excellent preliminary results

in the clinic. However, the success rate, operation time and patient comfort of all regional block anesthesia depend on the operator, and the results achieved by operators with different seniority and proficiency are not the same, which is the main limitation addressed by the relevant studies.<sup>3,4</sup> This paper reviews the advantages, disadvantages, and clinical applications of both the conventional and latest guidance techniques for regional anesthesia (Figure 1).

## Regional Anesthesia Guided by the Paresthesia or Neurostimulation

### Advantages of Nerve Block Guidance by Neurostimulation Compared with Paresthesia

The use of neurostimulation increases the nerve block success rate and reduces the blocking time compared

with conventional paresthesia guidance. Sia et al<sup>5,6</sup> compared the difference between paresthesia guidance and neurostimulation guidance in brachial plexus block. The results showed that the neurostimulation group was superior to the paresthesia group in the success rate (91% vs 76%, respectively) and onset time of the block. Additionally, in a three-point axillary brachial plexus block, nerve block guided by neurostimulation can shorten the block onset time and the waiting time for surgeons, which is helpful for emergency surgery and patient satisfaction as well as reducing the discomfort of a tourniquet.

This is related to the high accuracy of localization and more effective musculocutaneous nerve block<sup>7,8</sup> (Table 1).

## Association of Nerve Paresthesia Induced by Landmark-Guided Puncture with the Motor Response Induced by Neurostimulation

Urney et al<sup>9</sup> reported that, of 30 patients who received nerve paresthesia induced by the conventional landmark-guided puncture with an interscalene brachial plexus block and subsequent neurostimulation, only 30% had a motor response

under 1 mA while all patients experienced a successful block. It indicates that the lack of motor response cannot exclude the possibility of nerve-needle touch. Choyce et al<sup>10</sup> in a similar study, found that 30% of patients had the separation of paresthesia and motor response in axillary brachial plexus blocks. Hence, the nerve electrical stimulation does not necessarily produce the motor response when patients have the nerve paresthesia during the landmark-guided nerve block procedure. On the contrary, in the process of neurostimulation-guided nerve block, patients may not experience the nerve paresthesia in the presence of motor response produced by nerve stimulation.

## Neither Nerve Paresthesia nor Neurostimulation Guidance Technique Can Avoid the Intraneural Injection

Selander et al<sup>11</sup> believed that paresthesia occurrence during nerve block may lead to the increased risk of nerve injury after nerve block. Previous studies have shown that intraneural injection occurs frequently in conventional paresthesia-guided block. The closer the puncture needle is to the nerve, the stronger the paresthesia. Because of differences in sensory thresholds and anatomical variations, it is often difficult to determine the exact positioning of the needle and thus, intraneural injection may occur. Proponents of neurostimulation-guided nerve block believe that the use of this technique can reduce the risk of nerve injury. They consider that if neurostimulator is used, the blocking needle can trigger a corresponding muscle contraction before touching the nerve, and then the further advancement of needle can be avoided.<sup>12</sup> However, Choyce et al<sup>10</sup> have questioned this view. They considered that although the 0.5 mA to be a reasonable threshold for the use of neurostimulation, it was unknown whether the intraneural injection happened below this threshold. Mulroy and Mitchell<sup>13</sup> also reported that four patients experienced inadvertent paresthesia during neurostimulation guidance, indicating that the use of neurostimulation cannot always avoid the contact between puncture needle tip and nerve. Robards et al<sup>14</sup> found that in 24 patients undergoing ultrasound-guided sciatic nerve block for knee surgery, 20 (83.3%) had a motor response only when the puncture needle was inserted into the nerve, while the remaining four (16.7%) had no motor response when the puncture needle was inserted into the nerve with the stimulation current adjusted to 1.5 mA. The intraneural injections occurred in patients who experienced motor responses under a stimulation current of 0.2–0.4 mA. All 24 patients were fully anesthetized without

**Table 2** All of Nerve Block Guidance Methods Do Not Avoid the Occurrence of Intraneural Injection

postoperative neurological dysfunction. These results indicate that neurostimulation guidance cannot prevent intraneural injection.

Sala Blanch et al<sup>15</sup> found that the cross-sectional area of the sciatic nerve in the popliteal fossa changed after intraneural injection using ultrasound and computed tomography (CT) scanning but no nerve dysfunction was found in clinical and electrophysiological studies. This indicates that intraneural injection occurring during neurostimulation-guided sciatic nerve block may not lead to clinical nerve injury. Although the above reports of Robards et al<sup>14</sup> and Sala Blanch et al<sup>15</sup> showed that intraneural injection did not lead to postoperative neurological dysfunction, the risk of neurological dysfunction in some high-risk patients (such as diabetic patients) cannot be ruled out. Kirchmair et al<sup>16</sup> demonstrated that the amplitude of the compound muscle action potential was significantly decreased after nerve injury by acupuncture or intraneural injection, which was found to be due to nerve conduction block caused by myelin sheath rupture or axon loss (Table 2).

## Ultrasonic Guidance for Regional Anesthesia

### The Ultrasound Guidance Technique Cannot Avoid the Intraneural Injection

Neurostimulation alone cannot reduce the incidence of nerve injury. Theoretically, ultrasonic guidance for peripheral nerve block can display the relative positions of the nerve and needle tip more intuitively as well as being able to observe dynamic

changes in the local anatomical structure after drug injection, which can contribute to the avoidance of nerve injury.<sup>17</sup> However, some studies have found that ultrasound-guided nerve block cannot avoid intraneural injection entirely<sup>18</sup> and thus cannot reduce the incidence of postoperative nerve injury effectively.<sup>19,20</sup> The reasons are as follows: first, the resolution of portable ultrasound machine is not yet able to distinguish the perineurium, so the perineurium injury cannot be avoided. Second, nerves on ultrasonic images may not display adequately in some patients, resulting in fuzzy and poor-quality images. Third, the scanning skills of different operators can also affect the ultrasound image quality.

In addition, the intraneural injection during ultrasound-guided nerve block may not necessarily lead to nerve injury. Chin et al<sup>21</sup> have shown that ultrasonic observation of nerve expansion after intraneural injection does not represent permanent functional damage to the nerve. In conclusion, ultrasound-guided and neurostimulation-guided nerve block cannot completely avoid intraneural injection, and intraneural injection may not necessarily lead to nerve injury (Table 2).

## Advantages of Ultrasound Guidance Compared with Neurostimulation Guidance

Previous studies have compared the advantages and disadvantages of neurostimulation guidance and ultrasound guidance in brachial plexus block and found that the onset time of sensory and motor block using ultrasound guidance was shorter than that of neurostimulation guidance.<sup>22</sup> The reason may be that we can clearly see the location of the target nerve, the local anesthetic injection site, and the diffusion around the nerve in the ultrasonic image. Another advantage of ultrasound-guided brachial plexus block is a reduction in the amount of local anesthetic used. In addition, studies have found that when patients have musculoskeletal system abnormalities, the use of a neurostimulator may fail due to anatomical variation. Compared with neurostimulation, ultrasound guidance can significantly increase the success rate of nerve block in patients with malformations. Ultrasound and neurostimulator positioning technology can complement each other.<sup>23</sup> The latest study shows that in brachial plexus blocks in obese patients, nerve blocks using ultrasound guidance had shorter onset times, longer duration, better anesthetic effects, lower incidence of complications, and should be safer in the clinic than the use of a neurostimulator or the conventional landmark-guided

method.<sup>24</sup> However, some studies from the end of the last century to the beginning of this century held the opposite view, and Franco et al<sup>25</sup> and Vester-Andersen et al<sup>26</sup> showed that the success rate of using neurostimulation was more than 95% compared with ultrasound-guided (Table 1).

## Advantages and Limitations of Regional Blocks Under Ultrasound and Neurostimulation Guidance

The combined application of ultrasound and neurostimulation to block specific nerves makes the procedure effective and safe. The advantages are as follows: first, the combination of ultrasound and neurostimulation can result in a better blocking effect and success rate in patients with anatomical variations. Second, the combination of ultrasound and neurostimulation can help to identify the nerve when the nerve is unclear under ultrasound imaging alone. Third, the combined guidance can avoid the trauma caused by multiple punctures under neurostimulation guidance alone.

Although ultrasound combined with neurostimulation-guided nerve block has many advantages, it cannot entirely avoid postoperative nerve injury. Barrington et al<sup>27</sup> analyzed the data of more than 8000 patients with peripheral nerve block. They found that the use of ultrasound guidance, neurostimulation guidance, or a combination of the two had no significant effect on the incidence of nerve injury, and there was no significant difference between the incidence of long-term nerve injury observed in that survey and similar reports from the previous decade. It is difficult to avoid nerve injury using ultrasound alone. Timely and effective detection misplacement of puncture needle into nerve remains an ongoing clinical problem. Some studies have attempted to judge the relative positions of the needle tip and the nerve by comparing changes in the electric resistance of puncture needle. Tsui et al<sup>28</sup> found that the electric resistances of the insulated puncture needle in and out of the nerve were significantly different whether the nerve was punctured under ultrasonic guidance or directly exposed. The electric resistance of the puncture needle outside the nerve was less than that of the puncture needle inside the nerve, and the difference was statistically significant. This conclusion suggests that the position of the needle tip can be determined by monitoring the needle body resistance with the neurostimulator, and the combination with ultrasound guidance could avoid the

injection of drugs into the nerve. Additionally, awareness of resistance changes during injection and keeping the patient awake during the nerve block procedure are also considered to be effective means of avoiding avoid nerve injury<sup>29–31</sup> (Table 2).

## UCOT for Regional Anesthesia

Ultrasound resolution is poor for some deep structures. In addition, when ultrasonic guidance is used for in-plane or out-of-plane punctures, it is often unable to correctly determine the accurate position of the puncture needle tip. Therefore, ultrasound should be combined with other emerging technologies to further improve the accuracy and reduce the incidence of complications (Table 1).

## UCOT (Magnetic Navigation)

Although ultrasonic guidance nerve block has many advantages, it also has some disadvantages, including difficulty in displaying the out-of-plane and deep puncture needle tip. Due to the lack of clarity of the needle tip position, the distance between the needle tip and the nerve cannot be judged. The needle tip position can be judged only by the diffusion range of local anesthetics, which limits the realization of accurate anesthesia. This disadvantage of ultrasound prompted us to study the combination of tip navigation technology and ultrasound in guiding nerve block. In 2009, Ultrasonix launched an ultrasonic puncture navigation system based on magnetic positioning, which enables puncture at any angle and monitors the position of the needle tip in real-time. This can help to save the puncture time and reduce the puncture risk. Then, Philips launched the three-dimensional ultrasonic navigation system G4 xMATRIX iU22 that realized the puncture navigation at any angle in the three-dimensional region and avoided the interference by surrounding organs or blood vessels (Declaration: All authors of this article do not have any conflict of interest with the device manufacturers listed above).<sup>32</sup> Magnetic positioning is a real-time positioning technique using a nonvisual state based on the ability of magnetic fields to penetrate unshielded objects. It is composed of an electromagnetic field transmitter with a specific coverage and one or more small receivers and microprocessors that can be attached to the probe. The microprocessor is used to control the transmitter's emission of the electric field into space, and the receiver is fixed on the probe and puncture needle. In nerve block puncture, the receiver can sense the coordinate information and orientation information of the probe and puncture needle in three-dimensional space. These two

groups of freedom parameters are then stored in the computer. Through post-processing, the position information of the puncture needle can be matched with the position information of the ultrasonic image.<sup>33</sup> In short, UCOT (magnetic navigation) for guiding nerve block solves the problem of real-time tracking of the needle tip and has broad developmental prospects for future regional block anesthesia.

## UCOT (Pressure Guidance)

Many of the target spaces of regional anesthesia have negative pressure (such as the epidural and thoracic paravertebral spaces). When regional anesthesia puncture is performed by ultrasound combined with pressure monitoring, it is possible to judge when the needle tip reaches the target space by the change of pressure and the position of the needle tip on the ultrasonic image. This technology can increase the puncture success rate. In addition, monitoring pressure changes during puncture can avoid intraneural injection. There has been some research on pressure-guided nerve block.<sup>34–36</sup> Recent studies from our group have attempted to evaluate the value of ultrasound and pressure mediated guidance for thoracic paravertebral block (TPVB) in patients treated by video-assisted thoracic surgery (VATS).<sup>37</sup> TPVB has traditionally been used for postoperative pain management, relying on factors such as the use of air or loss of resistance with 0.9% saline to accurately determine anatomical localization. However, a sudden drop in resistance is more subjective for paravertebral space (PVS) navigation.<sup>38</sup> When the needle tip is in erector spinae muscle, the inspiratory/expiratory pressure reading are higher. The pressure decreased suddenly when the needle tip penetrated the superior costotransverse ligament and into the PVS. These studies suggest that the position of the puncture needle can be indirectly determined by changes in pressure, which further expands the visual measurement range and provides new possibilities for research into ultrasonic guidance nerve block. In the future, more prospective randomized controlled trials targeting UCOT (pressure guidance) are needed to validate the advantages of this novel regional block technique.

## UCOT (Video Visualization Guidance)

Ultrasound is widely used because of its unique advantages. However, ultrasonic images are not real tissue images, so image quality often becomes an important factor limiting its development. There is a constant need for the improvement of ultrasonic image quality. When ultrasonic imaging of the puncture site is blurred due to obesity or trauma, reliable

image confirmation methods are needed. When the puncture needle or the needle tip cannot be adequately displayed in the ultrasonic image either for out-of-plane or in-plane puncture, reliable image confirmation methods are also needed. This inspired us to develop an UCOT (video visualization guidance) in which ultrasonic guided nerve block is performed under direct video visualization.<sup>39,40</sup>

Video-guided visualization techniques have been widely used in surgical deep tissue manipulation or refined treatment, such as gynecological and general surgery using video-assisted laparoscopy for deep abdominopelvic surgery; thoracic surgery using video-assisted thoracoscopic surgery for pulmonary surgery; urology using ureteroscope to grasp high stones such as renal pelvis and calyces in a small field of view; and spinal surgery using a bore scope for the treatment of intervertebral discs and spinal nerves. In the future, anesthesiologists and pain physicians can also use video-guided visualization techniques for regional anesthesia techniques and treatments such as paravertebral block or fascial compartment block. At present, the aperture endoscope in spinal surgery has been very slender. Whether a thinner aperture endoscope can be inserted into the nerve block needle or radiofrequency puncture needle for regional block or treatment, so that the real-time image and adjacent structures during block can be clearly projected on the television. Combined with the use of ultrasound, the UCOT (video visualization guidance) can be realized to perform the ultrasound-guided nerve block or pain treatment under direct video vision.<sup>41,42</sup>

## UCOT (Electromyography (EMG) Guidance)

Improving the accuracy of puncture needle localization can effectively reduce the risk of complications such as accidental injury to intra-abdominal structures, femoral nerve palsy, or local anesthetic toxicity during abdominal plane block.<sup>43</sup> EMG is a mode of understanding the electrical activity present within a muscle.<sup>44</sup> This can be done using surface electrodes, or more precisely, using needle electrodes (called needle EMG) from within the muscle. By using needle EMG, we can obtain the anatomical position and discharge pattern of single muscle fiber and the whole motor unit. The measured potential between the needle and the reference can be shown graphically or transmitted through a speaker with LED display.<sup>45</sup>

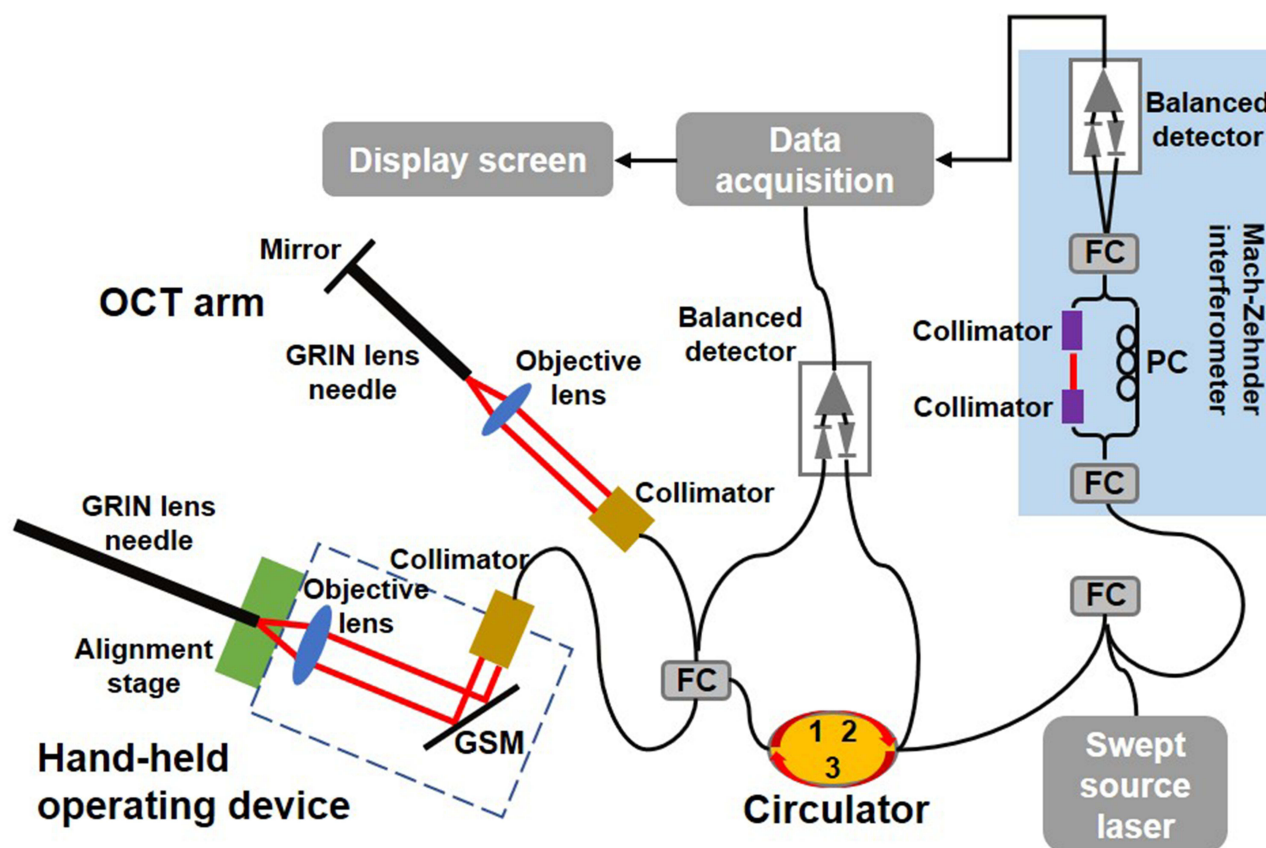

Mullins et al's study<sup>46</sup> is the first to report the use of needle EMG technique combined with ultrasound localization for quadratus lumborum block for postoperative analgesia in

open appendectomy. The needle tip provides useful feedback to the operator as it penetrates the tissue and complements the corresponding ultrasound image so that the exact position of the needle tip can be determined more accurately. Needle EMG techniques have also been used to assist piriformis injection in the treatment of piriformis syndrome.<sup>47</sup> While the flow of fascial layers during piriformis injection therapy is associated with artifacts on EMG, the resulting associated signals and information can be useful when used in conjunction with ultrasound for these therapies.

Hodes et al<sup>48</sup> pioneered studies using electromyography and nerve conduction to assess motor function by the strength of the response to compound muscle action potentials (CMAPs). The study by Qian et al intends to evaluate the efficacy of obturator nerve block by the change of CMAP amplitude of adductor longus muscle.<sup>49</sup> Because the anterior branch of the obturator nerve innervates the adductor longus muscle, the amplitude of the adductor longus CMAP provides information about the degree to which the motor fibers of the obturator nerve are blocked.<sup>50</sup> This effectively combines the advantages of EMG and ultrasound, making the position of the puncture needle more accurate and the operation of nerve block safer. In the future, further studies are needed to validate the use of UCOT & EMG in regional anesthetic techniques and pain treatment.

## UCOT (Optical Coherence Tomography (OCT) Guidance)

Epidural anesthesia is one of the most widely used anesthetic techniques. Due to the lack of real-time navigation and feedback of puncture needles, anesthesiologists often face challenges in the operation of complex patients such as obesity and spinal deformity. In order to solve these problems, ultrasound-guided and fluoroscopic needle insertion is a good method, which can make the operation more accurate. However, these techniques do not provide sufficient contrast and resolution to effectively distinguish the tissue layers through which the needle passes or to specifically identify the epidural space. To accurately identify the epidural space, Tang et al<sup>51</sup> invented a small handheld optical coherence tomography (OCT) forward imaging puncture needle device for real-time guidance of epidural anesthesia and demonstrated its feasibility through animal experiments (in vivo and ex vivo) (Figure 2).

**Figure 2** Diagram of hand-held OCT needle imaging system.

**Abbreviations:** FC, fiber coupler; PC, polarization controller; GSM, galvanometer scanning mirror; OCT, optical coherence tomography; GRIN, gradient-index.

OCT is an ultrasound-based optical simulation technique that provides micron-level imaging resolution, an order of magnitude greater than ultrasound.<sup>52</sup> Raphael et al<sup>53</sup> showed the feasibility of OCT imaging techniques for puncturing structures such as arteries, nerves, and dura mater in ex vivo animal studies. Using the principle of microoptics, OCT technology can be transformed into a small device for needle imaging to assist in minimally invasive procedures.<sup>54,55</sup> During the experiment, the needle tip of the device was slowly inserted into different layers in the tissue. OCT images corresponding to different anatomical structures were acquired separately during the entire process from the skin to the epidural space. It is not difficult to conclude from the images that there are characteristic differences between different anatomical structures, especially between the ligamentum flavum and the dura membrane or fat. In vivo OCT images clearly show the feasibility of distinguishing anatomical structures and tissue types in real time, therefore, identifying the needle tip position in real time during epidural anesthesia will make the operation more accurate and have lower risks.<sup>51</sup> OCT needle imaging

technology will reduce the incidence of complications, reduce the induction of pain, and the risk of surgical failure by visualizing the needle tip and clarifying the tissue structure where the needle tip is located compared with standard procedures. In addition, this technique can be used in combination with ultrasound/X-ray to achieve precise anesthesia and reduce patient suffering.

## UCOT (AI Guidance)

Due to a lack of experience, it is often difficult for trainee doctors to identify the structure when using ultrasound, especially in obese patients, elderly patients with poor imaging quality, and trauma patients with tissue edema. In these cases, ultrasonic guidance becomes difficult and an AI recognition system is needed for guidance.

AI technology includes features such as neural networks with expert system and pattern recognition.<sup>56</sup> Neural networks have the advantages of strong learning ability, multi-input, and multi-output. The technology is also easy to implement in terms of hardware and can be effectively combined with medical imaging. Deep learning is an automatic feature extractor,

which imitates the signal processing process of the human nerve. In the presence of sufficient training data (neural images and expert annotation), it can automatically learn the image features of particular situations through deep learning without the need to design the features artificially. Ultrasound combined with AI has been proved to be more accurate. When the noninvasive liver fibrosis rating system was established using this technique, the accuracy of the trained model reached 88.3% after evaluation. When the technique was used to classify early-stage benign and malignant thyroid nodules, the accuracy, sensitivity, and specificity of the technique were 82.3%, 84.5%, and 79.1%, respectively.<sup>57</sup> In nerve block anesthesia, nerve performances may differ due to the actual scanning position, image parameters, and patient specificity. Compared with conventional feature extraction methods, the deep learning neural network is more stable and accurate.<sup>31</sup> This provides us with a new direction of exploration. The AI system can be used to help identify neural structures resulting in improved understanding and interpretation of complex images by junior doctors. The use of UCOT & AI will have a broader prospect in the future development of regional anesthesia.

## UCOT (Image Fusion Guidance)

Medical image fusion is the spatial registration and superposition of medical images from the same or different imaging methods. The outstanding advantages of CT are high-density resolution, clear sectional anatomical relationships, and good display of lesion details; disadvantages include the use of radiation and large size requiring adequate space. Magnetic resonance imaging (MRI) has the advantage of multiplanar imaging, which compensates for the disadvantages of CT. MRI can display lesions clearly without the interference of bone artifacts and can display the structures of the skull base and spinal canal well.<sup>58</sup> However, it has the disadvantages of high cost, complex imaging, inconvenience for emergency examination, and inconvenience for fracture observation. Ultrasound has the advantages of convenience, a lack of radiation, and bedside operation. Ultrasound combined with CT and MRI for image fusion can display fine structures that cannot be recognized in ultrasonic images to realize the interventional operation of these fine structures under bedside ultrasonic guidance.<sup>59,60</sup>

The UCOT (image fusion) has been applied in the field of regional anesthesia. Strid et al<sup>61</sup> conducted the first randomized controlled trial of ultrasound/MRI fusion for lumbosacral plexus block and confirmed that ultrasound/MRI fusion technology was effective and safe. However, compared with

ultrasonic guidance, it requires a longer preparation process. Munirama et al<sup>62</sup> proposed a novel image fusion technique composed of ultrasound B mode and elastography to enhance the function of elastography. Through the different imaging modalities, intraneural injection can be observed in an early stage according to the different cross-sectional area and brightness of the nerve, allowing the puncture needle to be withdrawn to avoid possible postoperative nerve injury. This can be used as an important means of real-time monitoring of intraneural injection and can effectively reduce the incidence of intraneural injection. In recent years, many reports have advocated the use of selective nerve root block under CT guidance, which is taking advantage of CT imaging for lumbar applications. However, CT guidance has the disadvantages of high cost and the use of radiation. Study by Li et al<sup>63</sup> showed that the number of X-ray fluoroscopy used in fusion imaging was lower than that in ultrasonic guidance alone, which reduced the patients' exposure to radiation. However, the total puncture time in fusion imaging was not statistically different from that using ultrasound alone, which may have been related to the operator's extensive experience in ultrasonic operation. In addition, Nix<sup>64</sup> and Lim<sup>65</sup> demonstrates the feasibility of 3D reconstruction techniques in the clinic and the significant promise of the UCOT (image fusion).

## Conclusions and Prospects

In regional anesthesia, none of the currently used guidance methods including ultrasound, neurostimulator, or ultrasound combined with neurostimulator can effectively avoid intraneural injection. Although the ultrasound guidance technique is gaining popularity in the clinic, many questions remain to be addressed regarding the use of ultrasound for deep target block as well as in obese or elderly patients. The UCOT is helpful to solve the difficulty of puncture localization due to a patient's obesity, anatomical variation, and other factors when ultrasound guidance is used alone. In the future, more techniques need to be investigated and developed for ultrasound combinations, to exploit the advantages of ultrasound and remedy its disadvantages.

## Journal of Pain Research

### Publish your work in this journal

The Journal of Pain Research is an international, peer reviewed, open access, online journal that welcomes laboratory and clinical findings in the fields of pain research and the prevention and management of pain. Original research, reviews, symposium reports, hypothesis formation and commentaries are all considered for publication. The manuscript

Submit your manuscript here: <https://www.dovepress.com/journal-of-pain-research-journal>

management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
