Background: The purpose of this study was to develop a sustained drug-release model for water-soluble drugs using silica nanoparticles.

Methods: Hollow-type mesoporous silica nanoparticles (HMSNs) were prepared using Na_2CO_3 solution as the dissolution medium for the first time. The water-soluble compound, silybin meglumine, was used as the model drug. The Wagner–Nelson method was used to calculate the in vivo absorption fraction.

Results: The results of transmission electron microscopy and nitrogen adsorption revealed that the empty HMSNs had uniformly distributed particles of size 50–100 nm, a spherical appearance, a large specific surface area ($385.89 \pm 1.12 \text{ m}^2/\text{g}$), and ultralow mean pore size (2.74 nm). The highly porous structure allowed a large drug-loading rate ($58.91\% \pm 0.39\%$). In 0.08 M Na_2CO_3 solution, silybin meglumine-loaded HMSNs could achieve highly efficacious and long-term sustained release for 72 hours in vitro. The results of in vitro–in vivo correlation revealed that HMSNs in 0.08 M Na_2CO_3 solution had a correlation coefficient R^2 value of 0.9931, while those of artificial gastric juice and artificial intestinal juice were only 0.9287 and 0.7689, respectively.

Conclusion: The findings of in vitro–in vivo correlation indicate that HMSNs together with Na_2CO_3 solution could achieve an excellent linear relationship between in vitro dissolution and in vivo absorption for 72 hours, leading to a promising model for sustained release of water-soluble drugs.

Keywords: hollow-type mesoporous silica nanoparticle, silybin meglumine, in vitro dissolution, in vivo absorption, in vitro–in vivo correlation

Introduction

Over the past few decades, mesoporous silica nanoparticles have played an important role in the development of drug delivery systems. They have made a significant impact on medical technology by minimizing the size of drug delivery devices from the macro to the nano scale and significantly enhancing the performance of existing lifesaving drugs.^{1,2} Mesoporous silica nanoparticles have attracted considerable attention due to their ability to enhance solubility of poorly water-soluble drugs, as well as to achieve sustained drug release, leading to improved bioavailability.^{3,4} Advantages of mesoporous silica nanoparticles, such as large surface area, high pore volume, tunable pore size, and well defined pore structure, as well as mechanical and chemical stability and protection of the integrity of the molecular structure of the drug,^{5–7} make them ideal for controlled drug delivery systems. Most recently, mesoporous silica nanoparticles were developed for intracellular controlled drug/gene delivery^{8,9} and targeted drug delivery to cancer cells.^{10,11} Furthermore, the safety of silica materials

used as drug delivery systems has been well defined in several reports,^{12,13} which makes them desirable as perfect delivery systems. Chervenkov et al¹² found that oral (2 g/kg bodyweight) administration of silica dioxide xerogels did not result in significant changes in the biochemical parameters characterizing liver function and gastric mucosal damage.

So far, many attempts have been made to develop sustained-release preparations to improve the release behavior of orally delivered water-soluble drugs, such as sustained-release matrix tablets,^{14,15} nanostructured liquid crystalline matrix,¹⁶ surfactant-polymer nanoparticles,¹⁷ double-walled microspheres,¹⁸ and mesoporous silica nanoparticles.^{3,5} However, the in vitro sustained-release duration of these formulations lasted no longer than 24 hours. Therefore, it is desirable to develop a drug-release model that can achieve in vitro sustained release for a long period of time. In the present study, hollow-type mesoporous silica nanoparticles (HMSNs) were prepared and used as an in vitro sustained drug-release model for water-soluble drugs. Due to the highly porous structure of HMSNs, drugs can be loaded within the pores or canals, achieving in vitro sustained release for 72 hours. HMSNs have most of the advantages of mesoporous silica nanoparticles, but unlike mesoporous silica nanoparticles published earlier on, HMSNs possess a spherical shape with inner pores and channels and longer-lasting drug release in vitro. The possible reason is that, unlike the regularly and orderly distributed canals in mesoporous silica nanoparticles, the HMSNs prepared in this study possessed irregular and disordered canals which may result in prolonged drug release because it is harder for the drug to escape from disordered canals than from ordered ones.

Silybin meglumine, a commercially used compound of silybin and meglumine, was used as the model drug in this work. It has been widely used for the treatment of acute hepatitis, chronic hepatitis, initial-stage hepatocirrhosis, and liver damage due to intoxication because of the excellent hepatoprotective effect of silybin. Silybin is a naturally occurring polyphenolic flavonoid extracted from the seed of the milk thistle (*Silybum marianum*),^{19,20} and has been widely used to treat certain liver disorders, such as chronic active hepatitis, hepatic cirrhosis, as well as alcohol-induced and various types of drug-induced and toxin-induced liver damage.^{21,22} It is known that silybin is a poorly water-soluble drug; however, once silybin is combined with meglumine, its ionization ability increases and silybin meglumine is endowed with high water solubility. The present commercial formulation of silybin meglumine is in the form of a tablet and patients have to take the medicine three times a day in order to maintain an effective

plasma concentration. Obviously, it is inconvenient for most patients to take medicine so frequently. Therefore, it is important to develop a universally applicable technology for processing silybin meglumine in order to achieve high-efficacy, a long-term drug-release pattern, and reduce the frequency of drug administration. Furthermore, such a delivery system must be safe after oral or intravenous administration.

Until now, most investigations of silica nanoparticles have focused on porous silica nanoparticles and mesoporous silica nanoparticles, including preparation methods, drug-loading capacity, and in vitro release performance.^{23–25} Few attempts have been made to evaluate their in vivo absorption characteristics, and no research has been carried out to study in vitro–in vivo correlations (IVIVCs). Further, the present scientific literature shows that no report has been published about HMSNs for sustained drug delivery. In a report by Li et al,²⁶ the in vitro controlled release of loaded drugs from porous hollow silica nanoparticles could last for up to 30 days, but no in vivo investigation was carried out. Based on common knowledge, loaded drugs cannot survive up to 30 days after release in vivo. Previous studies have confirmed that the in vitro accumulated release of drug-loaded HMSNs in traditional dissolution media was less than 20%, but the drug could be eliminated within 72 hours following single-dose administration in Beagle dogs (data not shown). This inconsistency between in vitro dissolution and in vivo absorption has prompted researchers to seek out improved dissolution methods or better dissolution media in order to obtain better IVIVCs.

The in vitro dissolution medium is an important factor in constructing a good in vitro drug-release model. So far, many media, such as phosphate buffer solution,²⁷ HCl solution (pH 1–2),⁴ and water/ethanol mixture (70:30, v/v),²⁶ have been used to dissolve formulations prepared on the basis of porous silica nanoparticles, but none of these studies has evaluated IVIVCs. A possible reason is that there still remain many difficulties in developing appropriate dissolution test methods due to fast dissolution of submicron drug substances and in separating undissolved particles from dissolution medium.²⁸ What is more important is to find a proper dissolution medium that can achieve a good IVIVC.

In an effort to address the problems mentioned above, our research group attempted to develop a high-efficacy, long-acting in vitro drug-release model based on HMSNs for the delivery of water-soluble drugs. Water-soluble silybin meglumine was directly loaded into HMSNs in this study. The in vitro release profiles of silybin meglumine-loaded HMSNs were studied for the first time using Na₂CO₃ solutions with different concentrations (0.01 M, 0.06 M, 0.08 M, and 0.1 M). The treatment was repeated for other dissolution media such as traditional

artificial gastric juice (pH 1.2) and artificial intestinal juice (pH 6.8). Beagle dogs were used as an *in vivo* model to study pharmacokinetic characteristics after oral administration, and the IVIVC was then established. The use of HMSNs together with a Na_2CO_3 solution at a certain concentration is expected to be developed into an effective approach to obtain an *in vitro* drug-release model with a sustained-release pattern lasting for 72 hours, as well as a good IVIVC.

Methods and materials

Materials

Tetraethyl orthosilicate, absolute ethyl alcohol, ammonia water, cyclohexane, n-hexanol, and Na_2CO_3 were purchased from Chemical Reagent Co, Ltd, of the China National Pharmaceutical Group (Shanghai, China). NP-10 was obtained from Shanghai Jiafang Trade Co, Ltd (Shanghai, China). The animal experiments were performed strictly according to the experimental protocols approved by the university ethics committee for the use of experimental animals, and also conformed to the Guide for Care and Use of Laboratory Animals.

Preparation of empty HMSNs

A 6 mL quantity of nonylphenol 10 (NP-10) was added to 50 mL of cyclohexane, and shaken together. After adding 2.2 mL of n-hexanol and 1.8 mL of 25.6% ammonia water, the resulting mixture was again agitated for one hour at room temperature. Tetraethyl orthosilicate 4.2 mL was slowly added to the mixture and agitation was conducted for another 24 hours at room temperature. A 60 mL quantity of absolute ethyl alcohol was then added prior to ultrasound treatment for one hour (Wuxi Ultrasonic Devices Factory, Jiangsu, China). Centrifugal separation was performed at 15,000 per second for 15 minutes and the precipitate was washed three times with double-distilled water. After addition of water, freezing, and drying of the substance in succession, a powder of solid silica nanoparticles was obtained.

After addition of 1 g of the silica nanoparticles to 1000 mL of 0.6 mol/L Na_2CO_3 solution, ultrasound was administered for 5 minutes at 65°C and 200 W. The mixture was then centrifugally separated at 15,000 per second for 15 minutes and the precipitate was washed three times with double-distilled water. The resulting precipitate was then added to 10 mL of double-distilled water, followed by freezing and drying the substance in succession, and empty HMSNs were thus obtained. Fourier transform infrared analysis was carried out to examine the residual surfactant (NP-10). No absorption band characterizing NP-10 was observed, indicating that the surfactant had been completely washed away.

Preparation of silybin meglumine-loaded HMSNs

In this study, silybin meglumine was directly loaded into the HMSNs. Two grams of silybin meglumine was dissolved in 20 mL of double-distilled water, in which 1 g of empty HMSNs were soaked for 24 hours and then centrifugally separated at 15,000 per second for 15 minutes. The precipitate was washed three times with double-distilled water. It was then added to 10 mL of double-distilled water, then frozen and dried in succession. Drug-loaded nanoparticles were obtained.

Physicochemical characterization of HMSNs

The physicochemical features of HMSNs were characterized using transmission electron microscopy and the nitrogen adsorption method. The morphology and internal porous structure of the samples were observed using a transmission electron microscope (JEM-2100, JEOL, Tokyo, Japan). The specific surface area, pore volume, and pore diameter of the samples were measured by the nitrogen adsorption method using a high-speed automated surface area and pore size analyzer (Nova 2000, Quantachrome Instruments, Boynton Beach, FL) according to the Brunauer-Emmett-Teller and Barrett-Joyner-Halenda procedures.

The drug-loading rates of both silybin meglumine-loaded HMSNs and silybin meglumine-loaded solid silica nanoparticles were also determined. A 10 mg quantity of silybin meglumine-loaded HMSNs and the same amount of silybin meglumine-loaded solid silica nanoparticles were added to a certain amount of Na_2CO_3 solution and then water-bathed at a certain temperature for 30 minutes. The treatment was repeated for the same amount of HMSNs without a loading drug which resulted in a blank control solution.

The drug-loading rate was determined via ultraviolet spectroscopy (UV-2401PC, Shimadzu, Tokyo, Japan) at a wavelength of 288 nm. The blank control solution was used as reference. The drug-loading rate was calculated according to the following formula:

$$\text{Drug loading rate} = \frac{\text{Weight of drug in HSNs or SSNS}}{\text{Weight of drug loaded HSNs or SSNs}} \times 100\% \quad (1)$$

In vitro sustained-release studies

The *in vitro* release profiles of silybin meglumine from the sample were determined by a dialysis tubing method using dissolution testing apparatus (Tianjin University Radio Factory, Tianjin, China) according to the paddle method recorded by the Chinese Pharmacopoeia (2005). Artificial

gastric juice (pH 1.2), artificial intestinal juice (pH 6.8), Na_2CO_3 solutions with different concentrations (0.01 M pH 11.1, 0.06 M pH 11.5, 0.08 M pH 11.6, 0.1 M pH 11.7), and 0.01 M NaOH (pH 12) were used as dissolution media in this study. The paddles were rotated at 100 rpm for 72 hours. The samples were accurately weighed and added to the dialysis bags, which were then fixed on the paddles. The samples were then put into 900 mL of artificial gastric juice (pH 1.2) or intestinal juice (pH 6.8) as the dissolution medium with the temperature adjusted to $37^\circ\text{C} \pm 0.1^\circ\text{C}$.

Test fluids were withdrawn at predetermined time intervals from each vessel and then filtered through a $0.45\ \mu\text{m}$ membrane filter. The same volume of test fluid removed was then replaced by fresh medium. The quantity of silybin in the filtrate ($20\ \mu\text{L}$) was analyzed using a high-pressure liquid chromatography (HPLC) system (model 510; Waters Corporation, Milford, MA) equipped with an ultraviolet detector (model 486; Waters Corporation). The HPLC conditions were as follows: reverse-phase column, Nova-pack C18 column ($3.9 \times 150\ \text{mm}$, $5\ \mu\text{m}$) at 37°C ; mobile phase, dipotassium hydrogen phosphate (0.05 M): methanol 9.9:11 (v/v) mixture; flow rate, 1.0 mL/minute; and detection wavelength, 288 nm. All analyses were performed at 37°C and experiments were performed at least three times. The standard curve range was 1.68–31.8 $\mu\text{g/mL}$.

In vivo absorption study

Animal experiment

Healthy male Beagle dogs weighing $10 \pm 2\ \text{kg}$ were subjected to fasting overnight before the experiments, but allowed free access to water throughout the study. Silybin meglumine-loaded HMSNs were administered as an oral dose (21.2 mg/kg) to the test group of six dogs.

Serial blood samples of approximately 3 mL were collected at 0.25, 0.5, 1, 2, 4, 6, 8, 10, 12, 16, 20, 24, 36, 48, 60, and 72 hours after oral administration. Plasma obtained after centrifugation (10 minutes, 4000 per second) was immediately added to 20 μL of internal standard solution (α -naphthol, 10 $\mu\text{g/mL}$ in methanol) followed by gentle vortex agitation for 5 minutes. The mixture was centrifuged for 10 minutes at 3000 per second, and the organic layer was then transferred to a clean vial and evaporated under nitrogen at 30°C . Finally, the residue was dissolved in 100 μL of the mobile phase and transferred to the HPLC system for analysis.

HPLC analysis

Plasma silybin was determined by HPLC. A Nova-pack C18 column ($150\ \text{mm} \times 3.9\ \text{mm}$, $5\ \mu\text{m}$) with a column

temperature of 37.5°C and a mobile phase consisting of methanol and KH_2PO_4 (0.05 mol/L) with the ratio of 9.9:11 at pH 3.8 were used. The eluent was monitored at 288 nm with a flow rate of 1 mL/minute. α -Naphthol was used as an internal standard.

Calculation of in vivo absorption percentage

There are various methods that can be used to calculate the in vivo absorption percentage, including Wagner–Nelson and Loo–Riegelman methods. The former is applicable to a one-compartment model, the later is suitable for a two-compartment model, whereas according to the result determined by Akaike's information criterion method, which was conducted by using software BAPP2.3 (supplied by the Center of Drug Metabolism of China Pharmaceutical University, China) in our previous studies, the plasma concentration-time data for free silybin released from HMSNs were fit to a one-compartment model (data not shown). Therefore, the Wagner–Nelson method was used in the present work to calculate the in vivo absorption fraction:

$$f = \frac{Ct + k \int_0^T Ctdt}{k \int_0^\infty Ctdt} \times 100\% \quad (2)$$

In the above formula, f represents the in vivo absorption fraction, Ct is the plasma concentration at time point t , and k is the elimination rate constant.

Statistical analysis

All values are represented as the mean $\pm$ standard deviation. Statistical differences between the different groups were determined using the Student's t -test and one-way analysis of variance, with a least significant difference post-hoc test by SPSS statistical software (SPSS version 15.0, SPSS Inc, Chicago, IL). Differences between the two groups were considered to be statistically significant at $P < 0.01$.

Results and discussion

Preparation and physicochemical characteristics of HMSNs

So far, a number of studies have been conducted on the preparation of porous silica spheres by the modified Stober methods, in which cationic surfactants were used as porogens.^{29–31} In the present study, a Na_2CO_3 solution and

ultrasound were used to make pores and canals within the silica spheres. After lyophilization, the hollow-type mesoporous silica nanoparticles were then obtained. In this work, Na_2CO_3 solution was used innovatively to dissolve the silica partially under certain conditions. The resulting HMSNs were highly porous with a uniform small size, and had disordered holes, as well as a large surface area.

Transmission electron microscopy was used to characterize the morphology and porous structure of the HMSNs. It was observed that the empty/drug-loaded HMSNs with/without phosphotungstic acid staining, showed images of empty/drug-loaded HMSNs (with phosphotungstic acid staining) being less desirable as compared with the other component without phosphotungstic acid staining (data not shown). Thus, the transmission electron microscopy without phosphotungstic acid staining was used in the present study. Figure 1 shows transmission electron microscopic images of solid silica nanoparticles and HMSNs before and after drug-loading, in which a spherical appearance and uniformly distributed particle size within the range of 50–100 nm were observed. In addition, the highly porous inner structure of the empty HMSNs (Figure 1B) was clearly visible in comparison with the solid silica nanoparticles (Figure 1A). When loaded with drugs, the holes and canals on the surface of the particles disappeared, as shown in Figure 1C (silybin meglumine-loaded HMSNs). The most probable reason to explain this observation is that most of the canals and holes within the empty HMSNs were filled with drug.

In this study, to identify the specific surface area, pore volume, and pore diameter of the samples, the nitrogen adsorption method was employed. The results are shown in Figure 2, in which the nitrogen adsorption–desorption isotherms of both solid silica nanoparticles and HMSNs before and after drug-loading are demonstrated. The nitrogen adsorption–desorption isotherms for solid silica nanoparticles

completely overlapped, indicating no presence of pores, while an adsorption isotherm of empty HMSNs similar to Type II Langmuir adsorption isotherms and a hysteresis loop in the range of relative pressure from 0.696 to 0.989 indicated the presence of pores or canals in HMSNs.³² The average pore diameter of the empty HMSNs was 2.74 nm and the pore size was uniformly distributed within a relatively narrow range, between 1 nm and 6 nm. The empty HMSNs with an ultranarrow pore size (2.74 nm on average) prepared in this work were obviously smaller than that of the porous silica nanoparticles reported by Zhang et al.³ When loaded with drug, HMSNs showed no hysteresis loop, suggesting that most pores within the HMSNs were completely filled with drug. These results are in agreement with the transmission electron microscopic image in Figure 1. Additionally, nitrogen adsorption results demonstrated that the HMSNs had a much larger specific surface area ($385.89 \pm 1.12 \text{ m}^2/\text{g}$) than the solid silica nanoparticles ($5.84 \pm 0.26 \text{ m}^2/\text{g}$), indicating the highly porous structure of HMSNs. After adsorption of silybin meglumine, a significant decrease was observed in the surface area of HMSNs ($6.42 \text{ m}^2/\text{g}$) and the pore diameter (1.68 nm), indicating successful loading of silybin meglumine.

The drug-loading rate of the silybin meglumine-loaded HMSNs was $58.91\% \pm 0.39\%$, while the drug-loading rate of silybin meglumine-loaded solid silica nanoparticles was only $5.78\% \pm 0.12\%$. The results fully demonstrate the advantages of empty HMSNs over solid silica nanoparticles in drug delivery.

In vitro release studies

The in vitro release profiles of silybin meglumine from HMSNs are illustrated in Figure 3, in which silybin meglumine-loaded solid silica nanoparticles were used as a comparison. In order to select a suitable dissolution medium, several kinds of solutions were tested, including artificial

gastric juice (pH 1.2) and artificial intestinal juice (pH 6.8), 0.01 M NaOH solution (pH 12), as well as Na_2CO_3 solutions with different concentrations (0.01 M pH 11.1, 0.06 M pH 11.5, 0.08 M pH 11.6, and 0.1 M pH 11.7). For the preliminary research, artificial gastric and intestinal juices were used to dissolve samples according to the paddle method recorded by

the Chinese Pharmacopoeia (2005). As shown in Figure 3A, the accumulated release percentages of silybin meglumine from silybin meglumine-loaded HMSNs in artificial gastric and intestinal juices were less than 20% within 72 hours. It is obvious that artificial gastric and intestinal juices were not suitable for in vitro dissolution of silybin meglumine-loaded HMSNs, and more investigations were needed in order to find a more appropriate dissolution media. Therefore, NaOH and Na_2CO_3 solutions were introduced and the in vitro release profiles of silybin meglumine-loaded HMSNs are presented in Figure 3B, which show the slowest release rate in a 0.01 M Na_2CO_3 solution and the fastest release rate in a 0.1 M Na_2CO_3 solution. It is known that silybin meglumine is an ammonium salt which is chemically stable in basic media. An accelerating dissolution rate was observed with increasing Na_2CO_3 concentration. Significant enhancement of dissolution was observed in 0.06 M, 0.08 M, and 0.1 M Na_2CO_3 solutions as compared with that in artificial gastric or intestinal juices. A similarly rapid release was also observed in 0.06 M and 0.08 M Na_2CO_3 solutions, with an accumulative release rate of approximately 59% and 63% at 12 hours, respectively, but a significantly faster release

Note: Each datum point represents the mean $\pm$ standard deviation of three administrations.

from 0.1 M Na_2CO_3 solution with an accumulative release rate of approximately 94% at 12 hours. After that silybin meglumine-loaded HMSNs in a 0.08 M Na_2CO_3 solution was faster than that of a 0.06 M Na_2CO_3 solution. For 0.08 M Na_2CO_3 solution, the accumulative release rate was 80.0% at 24 hours, followed by a slow increase up to 92.3% at 72 hours, while the accumulative release rate was only 62.8% at 24 hours and 77.4% at 72 hours for 0.06 M Na_2CO_3 solution. One of the possible mechanisms for this phenomenon is that silica exhibited weak acidity^{33,34} and Na_2CO_3 solution exhibited weak alkalinity, so that an acid-base chemical reaction took place between silica and Na_2CO_3 , resulting in the water-soluble salt Na_2SiO_3 that existed in ion form in water. It could be speculated that the HMSN matrix disintegrated into many microparticles in Na_2CO_3 solution, similar to the disintegration of common tablets but at a much slower rate. Furthermore, in Na_2CO_3 solutions with different concentrations, there were different degrees of silica dissolution, resulting in different drug-release rates. Therefore, the *in vitro* release rate of loaded drugs can be controlled by using Na_2CO_3 solutions with different concentrations as the dissolution media. In other words, drug release from HMSNs could be affected by the pH value of the media. It is well known that silica is an acidic oxide that usually reacts with a basic oxide. As a result, silica can dissolve in alkaline media ($\text{pH} > 7$) with stronger alkalinity (a higher pH value), resulting in a faster reaction. Thus, with the increase in Na_2CO_3 concentration, the pH value of the media increased as well, leading to faster dissolution of HMSNs and quicker release of loaded drugs. However, according to the results (Figure 3B), a slower release profile was seen from 0.01 M NaOH solution with a pH value of 12 than from 0.06 M Na_2CO_3 solution. Therefore, pH value was not the only factor that *in vitro* degradation of HMSNs but also the concentration. The exact reason for the observation is still unknown and further investigation of the dissolution mechanism will be carried out in future works.

Figure 3C shows the *in vitro* release profiles for silybin meglumine from silybin meglumine-loaded solid silica nanoparticles in artificial gastric and intestinal juices. The accumulated release achieved a constant level at 0.5 hours for solid silica nanoparticles in artificial intestinal juice (with an accumulated release rate of 100%) and at one hour for artificial gastric juice (with an accumulated release rate of 70%). These results confirm the advantages of HMSNs over solid silica nanoparticles in drug storage and sustained release.

In this study, Na_2CO_3 solutions were used as dissolution media for the first time by our research group. It is of great

Table 1 Mean plasma concentration-time data for silybin meglumine-loaded incorporated into hollow-type silica nanoparticles following a single dose

significance for discovering a desirable *in vitro* dissolution model for drug-loaded HMSNs with long-term release for 72 hours.

In vivo absorption study

The oral absorption of silybin meglumine from HMSNs was studied in fasting Beagle dogs. The fasting state was selected to exclude the effect of food lipids, which can be confused with the effect of internal lipids. Because silybin meglumine is a compound of silybin and meglumine, it was speculated that the compound could be easily degraded into silybin and meglumine in the *in vivo* environment. Thus, silybin blood concentration was used as an indicator of silybin meglumine absorption *in vivo*.

Figure 4 In vivo absorption fraction of silybin meglumine-loaded hollow-type mesoporous silica nanoparticles generated from the Wagner–Nelson method.

The mean plasma concentration-time data for silybin meglumine-loaded HMSNs following a single dose are presented in Table 1. Based on these data, the percentages of silybin absorbed at specific time points were calculated from the plasma concentration data by using the Wagner–Nelson method,³⁵ as shown in Figure 4.

In vitro-in vivo correlation

The correlations between in vitro and in vivo data for silybin meglumine-loaded HMSNs and silybin meglumine tablets were investigated. Three levels of IVIVC are classified according to the US Food and Drug Administration.³⁶ A level A correlation, ie, a point-to-point relationship between in

vitro dissolution and in vivo absorption, was used in this present work.

Figure 5 showed the correlations between the in vitro dissolved fractions and in vivo absorbed fractions for silybin meglumine-loaded HMSNs and silybin meglumine tablets in the individual beagle dogs. The fractions dissolved in artificial gastric juice (pH 1.2), artificial intestinal juice (pH 6.8), and 0.06 M, 0.08 M, and 0.1 M Na_2CO_3 solutions were plotted against the fractions absorbed in 72 hours in the fasting condition, in order to find out the appropriate in vitro dissolution medium leading to better IVIVC. According to the statistics, the linear relationships between the in vitro dissolved fractions and the in vivo absorbed fractions for the silybin meglumine-loaded HMSNs in artificial gastric juice ($R^2 = 0.9287$, as shown in Figure 5A) and artificial intestinal juice ($R^2 = 0.7689$, as shown in Figure 5B) were not significantly correlated. In the case of the 0.06 M Na_2CO_3 solution as the in vitro dissolution medium, the value of the correlation coefficient R^2 was 0.9741 (Figure 5C). This value was lower than that for the 0.08 M Na_2CO_3 solution, which exhibited a correlation coefficient R^2 value of 0.9931 (Figure 5D). Interestingly, when the concentration of Na_2CO_3 solution increased to 0.1 M, the correlation coefficient R^2 decreased dramatically ($R^2 = 0.5600$). This phenomenon indicated that the use of Na_2CO_3 solution with concentration lower than 0.08 M gave a better IVIVC with increasing Na_2CO_3 concentration, but when the concentration of Na_2CO_3 solution was beyond 0.08 M, the correlation coefficient reduced with increasing Na_2CO_3 concentration. The exact reasons for this will be addressed in future work. According to the results of IVIVC, the 0.08 M Na_2CO_3 solution was the most effective dissolution medium for silybin meglumine-loaded HMSNs. In the case of the 0.08 M Na_2CO_3 solution, the in vitro dissolution rate was not the same as the in vivo absorption rate in each subject (Figure 5D). This difference could be due to the differences between the simple in vitro environment and the complex in vivo environment for dissolution. In addition, gastric emptying and intestinal transit would regulate the absorption process,²⁴ and therefore result in the differences observed between in vitro dissolution rates and in vivo absorption rates.

In summary, Na_2CO_3 solutions had been reported in this study for the first time as an in vitro dissolution medium for drug-loaded HMSNs, which exhibited excellent level A IVIVC. The drug-release model developed in this study achieved in vivo sustained release lasting for 72 hours, with advantages such as fast action, high efficacy, and long-lasting action. The results of this work have therefore had a considerable impact on the construction of sustained-release systems.

Conclusion

In this study, silybin meglumine was used as the model drug, and was loaded into HMSNs. The silybin meglumine-loaded HMSNs were successfully developed to enhance in vitro dissolution and in vivo absorption, and demonstrated an excellent IVIVC. The results of transmission electron microscopy and nitrogen adsorption showed that the empty HMSNs had a large specific surface area ($385.89 \text{ m}^2/\text{g}$) and a small pore size (average pore diameter of 2.74 nm), which led to a relatively large drug-loading capacity ($58.91\% \pm 0.39\%$). The in vitro dissolution studies conducted in different media revealed that Na_2CO_3 solutions of particular concentrations could achieve highly effective, long-acting, sustained release lasting for 72 hours. The results of IVIVC showed that HMSNs in 0.08 M Na_2CO_3 solution had a correlation coefficient R^2 value of 0.9931, while the correlation coefficient R^2 values for the artificial gastric and intestinal juices were only 0.9287 and 0.7689, respectively. The IVIVC investigated in this work indicated that HMSNs, together with a Na_2CO_3 solution, could achieve an excellent linear relationship between the in vitro dissolution and in vivo absorption for up to 72 hours.
